Built with inkling

Elsevier | ExpertConsult.com

Enhanced eBooks for medical professionals

Compatible with PC, Mac®, most mobile devices, and eReaders, Expert Consult allows you to browse, search, and interact with this title – online *and* offline. Redeem your PIN at expertconsult.com today!

Start using these innovative features today:

- Seamless, real-time integration between devices
- Straightforward navigation and search
- Notes and highlights sharing with other users through social media
- Enhanced images with annotations, labels, and hot spots for zooming on specific details *
- Live streaming video and animations *
- Self-assessment tools such as questions embedded within the text and multiple-format quizzes *

** some features vary by title*

PIN REDEMPTION INSTRUCTIONS

1. Login or Sign Up at ExpertConsult.com
2. Scratch off your PIN code below
3. Enter PIN into the "Redeem a Book Code" box
4. Click "Redeem"
5. Go to "My Library"

Use of the current edition of the electronic version of this book (eBook) is subject to the terms of the nontransferable, limited license granted on ExpertConsult.com. Access to the eBook is limited to the first individual who redeems the PIN, located on the inside cover of this book, at ExpertConsult.com and may not be transferred to another party by resale, lending, or other means.

Comprehensive Clinical Nephrology

Fifth Edition

Richard J. Johnson, MD
Professor of Medicine
Division Chief
Tomas Berl Professor of Nephrology
University of Colorado–Denver
Denver, Colorado, USA

John Feehally, DM, FRCP
Professor of Renal Medicine
The John Walls Renal Unit
Leicester General Hospital
Leicester, United Kingdom

Jürgen Floege, MD, FERA
Professor of Medicine
Director
Division of Nephrology and Clinical Immunology
RWTH University of Aachen
Aachen, Germany

Notices

Knowledge and best practice in this field are constantly changing. As new research and experience broaden our understanding, changes in research methods, professional practices, or medical treatment may become necessary.

Practitioners and researchers must always rely on their own experience and knowledge in evaluating and using any information, methods, compounds, or experiments described herein. In using such information or methods they should be mindful of their own safety and the safety of others, including parties for whom they have a professional responsibility.

With respect to any drug or pharmaceutical products identified, readers are advised to check the most current information provided (i) on procedures featured or (ii) by the manufacturer of each product to be administered, to verify the recommended dose or formula, the method and duration of administration, and contraindications. It is the responsibility of practitioners, relying on their own experience and knowledge of their patients, to make diagnoses, to determine dosages and the best treatment for each individual patient, and to take all appropriate safety precautions.

To the fullest extent of the law, neither the Publisher nor the authors, contributors, or editors, assume any liability for any injury and/or damage to persons or property as a matter of products liability, negligence or otherwise, or from any use or operation of any methods, products, instructions, or ideas contained in the material herein.

To our mentors in nephrology—especially Bill Couser, Stewart Cameron, and Karl M. Koch

To our colleagues and collaborators, as well as others, whose research continues to light the way

To our wives and families, who have once again endured the preparation of this fifth edition with unfailing patience and support

To our patients with renal disease, for whom it is a privilege to care

A special thanks to Bart Smeets, PhD, Division of Nephrology, University Hospital Aachen, Germany, for providing the cover image. Image caption: A glomerulus of a rat kidney immunostained for heparan sulfates in the tubular basement membranes and Bowman's capsule (green) and for synaptopodin expressed in podocytes (purple). The nuclei are stained with Hoechst 33342

CONTRIBUTORS

Ahmad Abou-Saleh, MBBS, BSc, MRCP(UK)
Specialist Registrar in Diabetes and Endocrinology, Guy's and St. Thomas' National Health Service Foundation Trust, London, England
32: Management of the Diabetic Patient with Chronic Kidney Disease

Ala Abudayyeh, MD
Assistant Professor, Division of Medicine, Section of Nephrology, University of Texas, MD Anderson Cancer Center, Houston, Texas, USA
68: Onconephrology: Renal Disease in Cancer Patients

Sharon Adler, MD
Professor of Medicine, Chief and Program Director, Division of Nephrology and Hypertension, Los Angeles Biomedical Research Institute at Harbor University of California–Los Angeles, David Geffen School of Medicine, Torrance, California, USA
31: Prevention and Treatment of Diabetic Nephropathy

Horacio J. Adrogué, MD
Professor of Medicine, Baylor College of Medicine; Chief, Nephrology and Hypertension, Houston Methodist Hospital, Houston, Texas, USA
14: Respiratory Acidosis, Respiratory Alkalosis, and Mixed Disorders

Anupam Agarwal, MD
Marie S. Ingalls Endowed Chair in Nephrology Leadership, Director, Division of Nephrology, Department of Medicine, University of Alabama–Birmingham, Birmingham, Alabama, USA
71: Diagnosis and Clinical Evaluation of Acute Kidney Injury

Venkatesh Aiyagari, MBBS, DM
Professor, Departments of Neurological Surgery and Neurology and Neurotherapeutics, University of Texas Southwestern School of Medicine, Dallas, Texas, USA
42: Neurogenic Hypertension, Including Hypertension Associated with Stroke or Spinal Cord Injury

Charles E. Alpers, MD
Professor and Vice Chair, Department of Pathology, University of Washington Medical Center, Seattle, Washington, USA
21: Membranoproliferative Glomerulonephritis and Cryoglobulinemic Glomerulonephritis

Gerald B. Appel, MD
Professor of Medicine, Department of Medicine, Columbia University Medical Center, New York, New York, USA
18: Primary and Secondary (Non-Genetic) Causes of Focal and Segmental Glomerulosclerosis
26. Lupus Nephritis

Fatiu A. Arogundade, MBBS, FMCP, FWACP
Associate Professor and Consultant Nephrologist, Department of Medicine, Obafemi Awolowo University and Teaching Hospitals Complex, Ile-Ife, Osun State, Nigeria
51: Sickle Cell Disease

Vicente Arroyo, MD, PhD
Full Professor of Medicine, Head, Center Esther Koplowitz, Senior Consultant Hepatologist, Liver Unit, Hospital Clinic Barcelona, August Pi i Sunyer Biomedical Research Institute, and CIBERehd (Network of Biomedical Research Center on Digestive and Liver Diseases), University of Barcelona, Barcelona, Spain
76: Hepatorenal Syndrome

Stephen R. Ash, MD, FACP
Director of Dialysis, Department of Nephrology, Indiana University Health Arnett; Chairman and Director, Research and Development, HemoCleanse, Inc. and Ash Access Technology, Inc., Lafayette, Indiana, USA
92: Diagnostic and Interventional Nephrology

Arif Asif, MD, FASN, FNKF
Thomas Ordway Professor and Chief, Department of Nephrology and Hypertension, Albany Medical College, Albany, New York, USA
92: Diagnostic and Interventional Nephrology

Pierre Aucouturier, PhD
Professor of Immunology at Pierre et Marie Curie University, Department of Biologic Immunology, Pôle de Biologie Médicale et Pathologie Hôpitaux Universitaires de l'Est Parisien, Paris, France
27: Renal Amyloidosis and Glomerular Diseases with Monoclonal Immunoglobulin Deposition

Matthew A. Bailey, PhD, BSc (Hons)
Senior Lecturer in Cardiovascular Biology, The British Heart Foundation Centre for Cardiovascular Science, The University of Edinburgh, Edinburgh, Scotland
2: Renal Physiology

Stephen C. Bain, MD, MA, FRCP
Professor of Medicine (Diabetes), Department of Diabetes, Institute of Life Sciences, Swansea University; Consultant Physician, Department of Diabetes and Endocrinology, Singleton Hospital, Abertawe Bro Morgannwg University Health Board, Swansea, Wales
32: Management of the Diabetic Patient with Chronic Kidney Disease

George L. Bakris, MD
Professor and Director, American Society of Hypertension Comprehensive Hypertension Center, Department of Medicine, The University of Chicago, Chicago, Illinois, USA
34: Primary Hypertension
37: Evaluation and Treatment of Hypertensive Urgencies and Emergencies

Adam D. Barlow, MD, MB, ChB, FRCS
Clinical Lecturer in Surgery, University of Cambridge, Cambridge, England
103: Kidney Transplantation Surgery

Rashad S. Barsoum, MD, FRCP, FRCPE
Professor, Internal Medicine, Kasr-El-Aini Medical School, Cairo, Egypt
56: The Kidney in Schistosomiasis
57: Glomerular Diseases Associated with Infection

Chris Baylis, PhD
Professor of Physiology and Medicine, Department of Physiology and Functional Genomics, University of Florida School of Medicine, Gainesville, Florida, USA
43: Renal Physiology in Normal Pregnancy

Tomas Berl, MD
Professor of Medicine, Renal, Division of Renal Diseases and Hypertension, University of Colorado School of Medicine, Aurora, Colorado, USA
8: Disorders of Water Metabolism

Suresh Bhat, MCh, DNB, PGDMLE
Professor and Head, Department of Urology, Government Medical College, Kottayam, Kerala, India
54: Tuberculosis of the Urinary Tract

Gemma Bircher, MSc, BSc (hons), RD
Dietetic Manager, Renal Dietitians, Leicester General Hospital, Leicester, England
87: Gastroenterology and Nutrition in Chronic Kidney Disease

Mabel A. Bodell, MD
Nephrologist, Confluence Health, Wenatchee, Washington, USA
101: Immunosuppressive Medications in Kidney Transplantation

Josée Bouchard, MD, FRCPC
Assistant Professor of Medicine, Department of Nephrology, Hôpital du Sacré-Coeur de Montréal, Université de Montréal, Montreal, Quebec, Canada
73: Prevention and Nondialytic Management of Acute Kidney Injury

Mark A. Brown, MD, MB, BS
Professor of Renal Medicine, St. George Hospital and University of New South Wales, Sydney, Australia
44: Renal Complications in Normal Pregnancy
45: Pregnancy with Preexisting Kidney Disease

Emmanuel A. Burdmann, MD, PhD
Associate Professor, Division of Nephrology, University of São Paulo Medical School, São Paulo, Brazil
57: Glomerular Diseases Associated with Infection
70: Acute Kidney Injury in the Tropics

David A. Bushinsky, MD
John J. Kuiper Distinguished Professor of Medicine and of Pharmacology and Physiology, University of Rochester School of Medicine; Chief, Nephrology Division, University of Rochester Medical Center, Rochester, New York, USA
59: Nephrolithiasis and Nephrocalcinosis

Daniel C. Cattran, MD, FRCPC
Professor of Medicine, University of Toronto; Senior Scientist, Toronto General Research Institute, University Health Network, Toronto General Hospital, Toronto, Ontario, Canada
20: Membranous Nephropathy

Matthew J. Cervelli, BPharm
Clinical Pharmacist Specialist, Royal Adelaide Hospital, Adelaide, Australia
77: Principles of Drug Therapy, Dosing, and Prescribing in Chronic Kidney Disease and Renal Replacement Therapy

Steven J. Chadban, PhD, Bmed(Hons), FRACP
Clinical Professor, Nephrologist, and Transplant Physician, Royal Prince Alfred Hospital and University of Sydney, Sydney, Australia
108: Recurrent Disease in Kidney Transplantation

Jeremy R. Chapman, MD, FRACP, FRCP
Director of Renal Medicine, Centre for Transplant and Renal Research, Sydney University Westmead Hospital, Westmead, Australia
109: Outcomes of Renal Transplantation

Karen E. Charlton, PhD, PG Dip. Diet, MSc, Mphil (Epi), APD, RPHNutr
Associate Professor, School of Medicine; Faculty of Science, Medicine and Health, University of Wollongong, Wollongong, Australia
35: Nonpharmacologic Prevention and Treatment of Hypertension

Yipu Chen, MD
Professor of Medicine, Division of Nephrology, Beijing Anzhen Hospital, Capital Medical University, Beijing, People's Republic of China
6: Renal Biopsy

John O. Connolly, PhD, FRCP
Consultant Nephrologist, University College London Centre for Nephrology, Royal Free London National Health Service Foundation Trust, London, England
52: Congenital Anomalies of the Kidney and Urinary Tract

H. Terence Cook, MB, BS, FRCPath
Professor of Renal Pathology, Centre for Complement and Inflammation Research, Imperial College, London, England
22: Glomerulonephritis Associated with Complement Disorders

James E. Cooper, MD
Assistant Professor, Department of Medicine, Renal Division, University of Colorado, Aurora, Colorado, USA
104: Prophylaxis and Treatment of Kidney Transplant Rejection

Vivette D. D'Agati, MD
Professor of Pathology, Department of Pathology, Columbia University College of Physicians and Surgeons; Director, Renal Pathology Laboratory, Department of Pathology, Columbia University Medical Center, New York, New York, USA
18: Primary and Secondary (Non-Genetic) Causes of Focal and Segmental Glomerulosclerosis

Kevin Damman, MD, PhD
Physician, Department of Cardiology, University Medical Center Groningen, Groningen, The Netherlands
75: Management of Refractory Heart Failure

Gabriel M. Danovitch, MD
Distinguished Professor of Medicine, David Geffen School of Medicine at University of California–Los Angeles; Medical Director, Kidney and Pancreas Transplant Program, Ronald Reagan Medical Center at University of California–Los Angeles, Los Angeles, California, USA
105. Medical Management of the Kidney Transplant Recipient: Infections, Malignant Neoplasms, and Gastrointestinal Disorders
106: Medical Management of the Kidney Transplant Recipient: Cardiovascular Disease and Other Issues

Simon J. Davies, MD, BSc, FRCP
Professor of Nephrology and Dialysis Medicine, Institute for Science and Technology in Medicine, Keele University; Consultant Nephrologist, Department of Nephrology, University Hospital of North Staffordshire, Staffordshire, England
97: Complications of Peritoneal Dialysis

John M. Davison, MD, MSc, FRCPE, FRCOG
Emeritus Professor of Obstetric Medicine and Consultant Obstetrician, Institute of Cellular Medicine, Medical School and Royal Victoria Infirmary, Newcastle University, Newcastle upon Tyne, England
43: Renal Physiology in Normal Pregnancy

Gerald F. DiBona, MD
Professor Emeritus, Departments of Internal Medicine and Molecular Physiology and Biophysics, University of Iowa Carver College of Medicine, Iowa City, Iowa, USA; Guest Professor in Renal Physiology, Gothenburg University, Gothenburg, Sweden
33: Normal Blood Pressure Control and the Evaluation of Hypertension

Tilman B. Drüeke, MD
Inserm Director Emeritus, Inserm Unit 1088, UFR Médecine/Pharmacie, Université de Picardie Jules Verne, Amiens, France
10: Disorders of Calcium, Phosphate, and Magnesium Metabolism

Jamie P. Dwyer, MD
Associate Professor of Medicine, Co-Director, Nephrology Clinical Trials Center, Vanderbilt Center for Kidney Disease, Nephrology and Hypertension, Vanderbilt University Medical Center, Nashville, Tennessee, USA
66: Thromboembolic Renovascular Disease

James E. Dyer, MBChB, BSc Hons
Clinical Research Fellow, Department of Urology, Leicester General Hospital, Leicester, England
61: Urologic Issues for the Nephrologist

Kai-Uwe Eckardt, MD
Professor of Medicine, Department of Nephrology and Hypertension, University of Erlangen–Nürnberg, Erlangen, Germany
83: Anemia in Chronic Kidney Disease

Frank Eitner, MD
Head, Kidney Diseases Research, Global Drug Discovery, Bayer Pharma AG, Wuppertal, Germany
89: Acquired Cystic Kidney Disease and Malignant Neoplasms

Meguid El Nahas, MD, PhD
Professor of Nephrology, Sheffield Kidney Institute; Chairman, Global Kidney Academy, Sheffield, England
79: Epidemiology, Natural History, and Pathophysiology of Chronic Kidney Disease

Marlies Elger, PhD
Anatomy and Developmental Biology, Medical Faculty Mannheim, University of Heidelberg, Mannheim, Germany
1: Renal Anatomy

Elwaleed A. Elhassan, MD, FACP, FASN
Assistant Professor, Division of Nephrology, Wayne State University, Detroit, Michigan, USA
7: Disorders of Extracellular Volume

Pieter Evenepoel, MD, PhD
Professor, Nephrology and Renal Transplantation, University Hospital Leuven, Leuven, Belgium
88: Dermatologic Manifestations of Chronic Kidney Disease

Ronald J. Falk, MD
Allan Brewster Distinguished Professor, Director, University of North Carolina Kidney Center; Chief, Division of Nephrology and Hypertension, University of North Carolina, Chapel Hill, North Carolina, USA
25: Renal and Systemic Vasculitis

Li Fan, PhD
Department of Nephrology, Tufts Medical Center, Boston, Massachusetts, USA
3: Assessment of Renal Function

John Feehally, DM, FRCP
Professor of Renal Medicine, The John Walls Renal Unit, Leicester General Hospital, Leicester, United Kingdom
15: Introduction to Glomerular Disease: Clinical Presentations
16: Introduction to Glomerular Disease: Histologic Classification and Pathogenesis
23: IgA Nephropathy and Henoch-Schönlein Nephritis

Javier Fernández, MD, PhD
Consultant Hepatologist, Head, Liver Intensive Care Unit, Liver Unit, Hospital Clinic Barcelona, August Pi i Sunyer Biomedical Research Institute, and CIBERehd (Network of Biomedical Research Center on Digestive and Liver Diseases), University of Barcelona, Barcelona, Spain
76: Hepatorenal Syndrome

Evelyne A. Fischer, MD, PhD
Senior Researcher, EGDM Team, Cochin Institute, Paris, France
62: Acute Interstitial Nephritis

Jonathan S. Fisher, MD, FACS
Transplant Surgeon, Scripps Center for Organ Transplantation, Scripps Clinic and Green Hospital, La Jolla, California, USA
110: Pancreas and Islet Transplantation

Jürgen Floege, MD, FERA
Professor of Medicine, Director, Division of Nephrology and Clinical Immunology, RWTH University of Aachen, Aachen, Germany
15: Introduction to Glomerular Disease: Clinical Presentations
16: Introduction to Glomerular Disease: Histologic Classification and Pathogenesis
23: IgA Nephropathy and Henoch-Schönlein Nephritis
85: Bone and Mineral Metabolism in Chronic Kidney Disease

Giovanni B. Fogazzi, MD
Director, Clinical and Research Laboratory on Urinary Sediment, Unità Operativa di Nefrologia e Dialisi, Fondazione IRCCS Ca' Granda Ospedale Maggiore Policlinico, Milano, Italy
4: Urinalysis

John W. Foreman, MD
Professor and Chief, Division of Pediatric Nephrology, Department of Pediatrics, Duke University Medical Center, Durham, North Carolina, USA
50: Fanconi Syndrome and Other Proximal Tubule Disorders

Giuseppe Garigali, ScD
Clinical and Research Laboratory on Urinary Sediment, Unità Operativa di Nefrologia e Dialisi, Fondazione IRCCS Ca' Granda Ospedale Maggiore Policlinico, Milano, Italy
4: Urinalysis

F. John Gennari, MD
Professor Emeritus, Department of Medicine, University of Vermont College of Medicine; Attending Physician, Department of Medicine, Fletcher Allen Health Care, Burlington, Vermont, USA
13: Metabolic Alkalosis

Evangelos G. Gkougkousis, MD
Department of Urology, Leicester General Hospital, Leicester, England
61: Urologic Issues for the Nephrologist

Richard J. Glassock, MD
Emeritus Professor of Medicine, Department of Medicine, David Geffen School of Medicine at University of California–Los Angeles, Los Angeles, California, USA
28: Other Glomerular Disorders and the Antiphospholipid Syndrome

David J. A. Goldsmith, MA, MB Bchir, FRCP (Lond), FRCP (Ed), FASN, FERA
Consultant Nephrologist, Professor of Cardio-Renal Medicine, Member of the Faculty of Translational Medicine, King's Health Partners Academic Health Sciences Centre, London, England
32: Management of the Diabetic Patient with Chronic Kidney Disease

Philip B. Gorelick, MD, MPH
Professor, Department of Translational Science and Molecular Medicine, Michigan State University College of Human Medicine; Medical Director, Mercy Health Hauenstein Neurosciences, Grand Rapids, Michigan, USA
42: Neurogenic Hypertension, Including Hypertension Associated with Stroke or Spinal Cord Injury

Barbara A. Greco, MD
Associate Clinical Professor of Medicine, Department of Nephrology, Baystate Medical Center, Tufts; Western New England Renal and Transplant Associates, Springfield, Massachusetts, USA
39: Renovascular Hypertension and Ischemic Nephropathy
66: Thromboembolic Renovascular Disease

Peter Gross, MD
Professor of Medicine Emeritus, Department of Medicine III, Universitätskilinikum C.G. Carus, Dresden, Germany
49: Inherited Disorders of Sodium and Water Handling

Lisa M. Guay-Woodford, MD
Professor and Director, Center for Translational Science, Children's National Health System, Washington, District of Columbia, USA
47: Other Cystic Kidney Diseases

Nabil J. Haddad, MD
Associate Professor of Clinical Medicine, Division of Nephrology, Department of Internal Medicine, The Ohio State University Medical Center, Columbus, Ohio, USA
80: Retarding Progression of Kidney Disease

Gentzon Hall, MD, PhD
Nephrology Fellow, Duke University Medical Center, Durham, North Carolina, USA
19: Inherited Causes of Nephrotic Syndrome

Peter C. Harris, PhD
Professor of Biochemistry/Molecular Biology and Medicine, Division of Nephrology and Hypertension, Mayo Clinic, Rochester, Minnesota, USA
46: Autosomal Dominant Polycystic Kidney Disease

Lee A. Hebert, MD
Professor of Medicine, Department of Internal Medicine, Division of Nephrology, The Ohio State University Medical Center, Columbus, Ohio, USA
80: Retarding Progression of Kidney Disease

Peter Heduschka, MD
Nephrologist, PHV-Dialysezentrum Dresden Friedrichstadt, Dresden, Germany
49: Inherited Disorders of Sodium and Water Handling

Charles A. Herzog, MD
Professor of Medicine, Division of Cardiology, Department of Medicine, Hennepin County Medical Center and University of Minnesota; Chronic Disease Research Group, Minneapolis Medical Research Foundation, Minneapolis, Minnesota, USA
82: Cardiovascular Disease in Chronic Kidney Disease

Thomas Hooton, MD
Professor of Clinical Medicine, Division of Infectious Diseases, Department of Medicine, University of Miami Miller School of Medicine; Chief of Medicine, Miami Veterans Administration Healthcare System, Miami, Florida, USA
53: Bacterial Urinary Tract Infections

†Walter H. Hörl, MD, PhD, FRCP
Professor of Medicine, University of Vienna, Vienna, Austria
84: Other Blood and Immune Disorders in Chronic Kidney Disease

Peter F. Hoyer, MD
Director, University Children's Hospital Essen; Director and Chair, Pediatrics II, Pediatric Nephrology, Endocrinology, Gastroenterology, and Transplant Medicine, University Duisburg–Essen, Essen, Germany
17: Minimal Change Nephrotic Syndrome

Jeremy Hughes, MA, MB, BS, PhD, FRCPE
Professor of Experimental Nephrology, Medical Research Council Centre for Inflammation Research, University of Edinburgh; Honorary Consultant Physician, Edinburgh Royal Infirmary, Edinburgh, Scotland
60: Urinary Tract Obstruction

Enyu Imai, MD, PhD
Lecturer, Department of Nephrology, Nagoya University Graduate School of Medicine, Nagoya, Aichi, Japan; Director, Department of Internal Medicine, Nakayamedera Imai Clinic, Takarazuka, Hyogo, Japan
90: Approach to Renal Replacement Therapy

Lesley A. Inker, MD, MS
Department of Medicine, Tufts University School of Medicine; William B. Schwartz Division of Nephrology, Tufts Medical Center, Boston, Massachusetts, USA
3: Assessment of Renal Function

Ashley B. Irish, MBBS, FRACP
Consultant Nephrologist, Department of Nephrology and Renal Transplantation, Royal Perth Hospital, Perth, Australia
65: Myeloma and the Kidney

Sunjay Jain, MD
Department of Urology, St. James University Hospital, Leeds, England
61: Urologic Issues for the Nephrologist

†Deceased.

David Jayne, MD, FRCP, FMedSci
Consultant in Nephrology and Vasculitis, Addenbrookes Hospital, Cambridge, England
26: Lupus Nephritis

J. Ashley Jefferson, MD, FRCP
Associate Professor of Medicine, Division of Nephrology, University of Washington, Seattle, Washington, USA
69: Pathophysiology and Etiology of Acute Kidney Injury

J. Charles Jennette, MD
Brinkhous Distinguished Professor and Chair, Pathology and Laboratory Medicine, University of North Carolina, Chapel Hill, North Carolina, USA
25: Renal and Systemic Vasculitis

Vivekanand Jha, MD, DM, FRCP
Professor, Department of Nephrology, Postgraduate Institute of Medical Education and Research, Chandigarh, India; Executive Director, George Institute for Global Health, New Delhi, India
70: Acute Kidney Injury in the Tropics

Richard J. Johnson, MD
Professor of Medicine, Division Chief, Tomas Berl Professor of Nephrology, University of Colorado–Denver, Denver, Colorado, USA
16: Introduction to Glomerular Disease: Histologic Classification and Pathogenesis
34: Primary Hypertension

Eric Judd, MD
Postdoctoral Clinical Research Fellow, Department of Medicine, University of Alabama–Birmingham, Birmingham, Alabama, USA
71: Diagnosis and Clinical Evaluation of Acute Kidney Injury

Luis A. Juncos, MD
Professor of Medicine, Physiology and Biophysics, John D. Bower Chief of Nephrology, Department of Internal Medicine, University of Mississippi Medical Center, Jackson, Mississippi, USA
74: Dialytic Management of Acute Kidney Injury and Intensive Care Unit Nephrology

Nigel S. Kanagasundaram, MD, MB ChB, FRCP
Honorary Clinical Senior Lecturer, Institute of Cellular Medicine, Newcastle University; Consultant Nephrologist, Renal Services, Newcastle upon Tyne Hospitals National Health Service Foundation Trust, Newcastle upon Tyne, England
98: Dialytic Therapies for Drug Overdose and Poisoning

John Kanellis, PhD, MBBS(Hons), FRACP
Nephrologist, Department of Nephrology, Monash Medical Centre; Department of Medicine, Monash University, Clayton, Australia
102: Evaluation and Preoperative Management of Kidney Transplant Recipient and Donor

Clifford E. Kashtan, MD
Professor of Pediatrics, Department of Pediatrics, Division of Pediatric Nephrology, University of Minnesota Medical School, Minneapolis, Minnesota, USA
48: Alport and Other Familial Glomerular Syndromes

Carol A. Kauffman, MD
Professor of Internal Medicine, University of Michigan Medical School; Chief, Infectious Diseases, Veteran Affairs Ann Arbor Healthcare System, Ann Arbor, Michigan, USA
55: Fungal Infections of the Urinary Tract

Peter G. Kerr, PhD, MB, BS, FRACP
Professor and Director, Department of Nephrology, Monash Medical Centre; Professor, Department of Medicine, Monash University, Clayton, Australia
95: Acute Complications During Hemodialysis

Bryan Kestenbaum, MD, MS
Associate Professor, Division of Nephrology, Department of Medicine, University of Washington, Seattle, Washington, USA
10: Disorders of Calcium, Phosphate, and Magnesium Metabolism

Markus Ketteler, MD, FERA
Division of Nephrology, Klinikum Coburg GmbH, Coburg, Germany
85: Bone and Mineral Metabolism in Chronic Kidney Disease

Arif Khwaja, MD, PhD, FRCP
Consultant Nephrologist, Sheffield Kidney Institute, Sheffield Teaching Hospitals Foundation Trust; Honorary Senior Lecturer, University of Sheffield, Sheffield, England
79: Epidemiology, Natural History, and Pathophysiology of Chronic Kidney Disease

Jeffrey B. Kopp, MD
Senior Investigator, Kidney Disease Section, Kidney Diseases Branch, National Institute of Diabetes and Digestive and Kidney Diseases, National Institutes of Health, Bethesda, Maryland, USA
58: Human Immunodeficiency Virus Infection and the Kidney

Ulla C. Kopp, PhD
Professor Emeritus, Department of Internal Medicine and Pharmacology, University of Iowa Carver College of Medicine, Iowa City, Iowa, USA
33: Normal Blood Pressure Control and the Evaluation of Hypertension

Peter Kotanko, MD
Research Director, Renal Research Institute, New York, New York, USA
93: Hemodialysis: Principles and Techniques
94: Hemodialysis: Outcomes and Adequacy

Wilhelm Kriz, MD
Anatomy and Developmental Biology, Medical Faculty Mannheim, University of Heidelberg, Mannheim, Germany
1: Renal Anatomy

Henry Krum, PhD, MBBS, FRACP, FCSANZ, FESC
Centre of Cardiovascular Research and Education in Therapeutics, Department of Epidemiology and Preventive Medicine, Monash University/Alfred Hospital, Melbourne, Australia
38: Interventional Treatments for Resistant Hypertension

Martin K. Kuhlmann, MD
Director, Department of Internal Medicine, Nephrology, Vivantes Klinikum im Friedrichshain, Berlin, Germany
93: Hemodialysis: Principles and Techniques
94: Hemodialysis: Outcomes and Adequacy

Dirk R. Kuypers, MD, PhD
Professor, Department of Nephrology and Renal Transplantation, University Hospitals Leuven, Leuven, Belgium
88: Dermatologic Manifestations of Chronic Kidney Disease

Tony Kwan, BSc(Med) Hons, MBBS, FRACP
PhD Fellow, Renal Medicine, Royal Prince Alfred Hospital; PhD Candidate, Collaborative Transplantation Group, University of Sydney, Sydney, Australia
108: Recurrent Disease in Kidney Transplantation

Jonathan R. T. Lakey, PhD, MSM
Director of Research and Associate Professor of Surgery and Biomedical Engineering, University of California–Irvine, Orange, California, USA
110: Pancreas and Islet Transplantation

Estelle V. Lambert, PhD, MS, BS
Professor, University of Cape Town/Medical Research Council Research Unit for Exercise Science and Sports Medicine, Department of Human Biology, Faculty of Health Sciences, University of Cape Town, Cape Town, South Africa
35: Nonpharmacologic Prevention and Treatment of Hypertension

William J. Lawton, MD, FACP
Associate Professor Emeritus, Department of Internal Medicine, Nephrology-Hypertension Division, University of Iowa Carver College of Medicine, Iowa City, Iowa, USA
33: Normal Blood Pressure Control and the Evaluation of Hypertension

Edgar V. Lerma, MD, FACP, FASN
Clinical Professor of Medicine, Section of Nephrology, University of Illinois at Chicago College of Medicine, Chicago, Illinois, USA; Educational Coordinator, Section of Nephrology, Advocate Christ Medical Center–University of Illinois at Chicago, Oak Lawn, Illinois, USA
67: Geriatric Nephrology

Andrew S. Levey, MD
Dr. Gerald J. and Dorothy R. Friedman Professor of Medicine, Tufts University School of Medicine; Chief, William B. Schwartz Division of Nephrology, Tufts Medical Center, Boston, Massachusetts, USA
3: Assessment of Renal Function

Nathan W. Levin, MD
Chairman, Research Board, Renal Research Institute; Professor of Clinical Medicine, Albert Einstein College of Medicine, New York, New York, USA
93: Hemodialysis: Principles and Techniques
94: Hemodialysis: Outcomes and Adequacy

Jeremy Levy, MD, PhD, FRCP
Consultant Nephrologist, Renal and Transplant Centre, Imperial College Healthcare National Health Service Trust, London, England
99: Plasma Exchange

Andrew Lewington, MD, BSc Med, FRCP, FRCPE
Honorary Clinical Associate Professor, Department of Medicine, University of Leeds; Consultant, Renal Physician, Department of Renal Medicine, St. James's University Hospital, Leeds, England
98: Dialytic Therapies for Drug Overdose and Poisoning

Julia B. Lewis, MD
Professor of Medicine, Nephrology, and Hypertension, Vanderbilt University Medical School, Nashville, Tennessee, USA
66: Thromboembolic Renovascular Disease

Stuart L. Linas, MD
Professor of Medicine, Division of Renal Diseases and Hypertension, University of Colorado School of Medicine and Chief of Nephrology, Denver Health Medical Center, Denver, Colorado, USA
9: Disorders of Potassium Metabolism

Friedrich C. Luft, MD, FACP
Professor of Medicine, Charité Medical Faculty; Director of the Experimental and Clinical Research Center, Berlin, Germany
33: Normal Blood Pressure Control and the Evaluation of Hypertension

Iain C. Macdougall, BSc, MD, FRCP
Consultant Nephrologist and Professor of Clinical Nephrology, Department of Renal Medicine, King's College Hospital, London, England
83: Anemia in Chronic Kidney Disease

Etienne Macedo, MD, PhD
Assistant Professor of Nephrology, University of São Paulo, São Paulo, Brazil
73: Prevention and Nondialytic Management of Acute Kidney Injury

Nicolaos E. Madias, MD, FASN
Chairman, Department of Medicine, St. Elizabeth's Medical Center; Maurice S. Segal, MD, Professor of Medicine, Tufts University School of Medicine, Boston, Massachusetts, USA
14: Respiratory Acidosis, Respiratory Alkalosis, and Mixed Disorders

Colm C. Magee, MD, MPH
Consultant Nephrologist, Beaumont Hospital; Lecturer in Medicine, Royal College of Surgeons in Ireland, Dublin, Ireland
111: Kidney Disease in Liver, Cardiac, Lung, and Hematopoietic Cell Transplantation

Christopher L. Marsh, MD, FACS
Division Chief, Scripps Center for Organ Transplantation, Scripps Clinic and Green Hospital, La Jolla, California, USA
110: Pancreas and Islet Transplantation

Mark R. Marshall, MBChB, MPH(Hons), FRACP
Honorary Associate Professor, Faculty of Medical and Health Sciences, South Auckland Clinical School; Clinical Director, Department of Renal Medicine, Counties Manukau District Health Board, Auckland, New Zealand
74: Dialytic Management of Acute Kidney Injury and Intensive Care Unit Nephrology

Annabel C. Martin, MBBS BmedSci, B Surg, FRACP
Consultant Nephrologist, Albury Wodonga Health, Victoria, Australia
44: Renal Complications in Normal Pregnancy

Kevin J. Martin, MB, BCH, FASN
Professor of Internal Medicine, Director, Division of Nephrology, Saint Louis University, Saint Louis, Missouri, USA
85: Bone and Mineral Metabolism in Chronic Kidney Disease

Philip D. Mason, PhD, MB BS, BSc, FRCP
Consultant Nephrologist, Oxford Kidney Unit, The Churchill Hospital; Honorary Senior Lecturer, Oxford University, Oxford, England
17: Minimal Change Nephrotic Syndrome

Ranjiv Mathews, MD
Clinical Adjunct Associate Professor, The Brady Urological Institute, Johns Hopkins School of Medicine, Baltimore, Maryland, USA; Clinical Associate Professor, Department of Pediatrics, University of Nevada, Las Vegas, Nevada, USA
63: Primary Vesicoureteral Reflux and Reflux Nephropathy

Tej K. Mattoo, MD, DCH, FRCP(UK)
Professor, Department of Pediatrics, Wayne State University School of Medicine; Chief, Pediatric Nephrology, Children's Hospital of Michigan, Detroit, Michigan, USA
63: Primary Vesicoureteral Reflux and Reflux Nephropathy

JulieAnne G. McGregor, MD
Assistant Professor, Department of Medicine, University of North Carolina, Chapel Hill, North Carolina, USA
25: Renal and Systemic Vasculitis

Ravindra L. Mehta, MBBS, MD, DM
Professor of Clinical Medicine, Department of Medicine, University of California–San Diego, San Diego, California, USA
73: Prevention and Nondialytic Management of Acute Kidney Injury

J. Kilian Mellon, MD, FRCS (Urol)
Professor of Urology, Department of Urology, Leicester General Hospital, Leicester, England
61: Urologic Issues for the Nephrologist

Rebeca D. Monk, MD
Professor of Medicine, University of Rochester School of Medicine; Program Director, Nephrology Fellowship, University of Rochester Medical Center, Rochester, New York, USA
59: Nephrolithiasis and Nephrocalcinosis

Christian Morath, MD
Division of Nephrology, Heidelberg University Hospital, Heidelberg, Germany
107: Chronic Allograft Injury

Bruno Moulin, MD, PhD
Professor of Nephrology and Transplantation, Hôpitaux Universitaires de Strasbourg, Strasbourg, France
27: Renal Amyloidosis and Glomerular Diseases with Monoclonal Immunoglobulin Deposition

Anja S. Mühlfeld, MD
Consultant, Division of Nephrology and Immunology, Uniklinikum RWTH Aachen University, Aachen, Germany
89: Acquired Cystic Kidney Disease and Malignant Neoplasms

William R. Mulley, PhD, B.Med(Hons), FRACP
Nephrologist, Department of Nephrology, Monash Medical Centre; Senior Lecturer, Department of Medicine, Monash University, Clayton, Australia
102: Evaluation and Preoperative Management of Kidney Transplant Recipient and Donor

Saraladevi Naicker, MD, PhD
Professor of Nephrology, Division of Nephrology, Department of Internal Medicine, University of the Witwatersrand, Faculty of Health Sciences, Johannesburg, South Africa
58: Human Immunodeficiency Virus Infection and the Kidney

Masaomi Nangaku, MD, PhD
Professor and Head, Division of Nephrology and Endocrinology, The University of Tokyo School of Medicine, Tokyo, Japan
64: Chronic Interstitial Nephritis

Guy H. Neild, MD, FRCP, FRCPath
University College London Centre for Nephrology, Royal Free London National Health Service Foundation Trust, London, England
52: Congenital Anomalies of the Kidney and Urinary Tract

M. Gary Nicholls, MD
Christchurch School of Medicine and Health Sciences, Christchurch, New Zealand
41: Endocrine Causes of Hypertension

Michael L. Nicholson, MD DSc, MBBS, BMedSci, FRCS
Professor of Surgery, Leicester General Hospital, Leicester, England
103: Kidney Transplantation Surgery

Marina Noris, PhD
Head, Laboratory of Immunology and Genetics of Transplantation and Rare Diseases, Department of Molecular Medicine, IRCSS–Istituto di Ricerche Farmacologiche "Mario Negri," Bergamo, Italy
29: Thrombotic Microangiopathies, Including Hemolytic Uremic Syndrome

W. Charles O'Neill, MD
Professor of Medicine, Director of Ultrasonography, Renal Division, Department of Medicine, Emory University, Atlanta, Georgia, USA
92: Diagnostic and Interventional Nephrology

Biff F. Palmer, MD
Professor of Internal Medicine, Distinguished Teaching Professor, Department of Medicine, University of Texas Southwestern Medical Center, Dallas, Texas, USA
11: Normal Acid-Base Balance
12: Metabolic Acidosis

Neesh Pannu, MD, SM
Associate Professor, Department of Medicine, University of Alberta, Edmonton, Alberta, Canada
72: Epidemiology and Prognostic Impact of Acute Kidney Injury

Chirag Parikh, MD, PhD
Associate Professor of Medicine, Division of Renal Diseases, Yale University School of Medicine, New Haven, Connecticut, USA
8: Disorders of Water Metabolism

Samir V. Parikh, MD
Assistant Professor of Medicine, Department of Internal Medicine, Division of Nephrology, The Ohio State University Wexner Medical Center, Columbus, Ohio, USA
80: Retarding Progression of Kidney Disease

Phuong-Anh Pham, MD, FACC
Interventional Cardiologist, Department of Cardiology, Southern Arizona Veterans Affairs Health Care System, Tucson, Arizona, USA
106: Medical Management of the Kidney Transplant Recipient: Cardiovascular Disease and Other Issues

Phuong-Chi T. Pham, MD
Clinical Professor of Medicine, David Geffen School of Medicine at University of California–Los Angeles, Los Angeles, California, USA; Chief, Division of Nephrology and Hypertension, Olive View–UCLA Medical Center, Sylmar, California, USA
105: Medical Management of the Kidney Transplant Recipient: Infections, Malignant Neoplasms, and Gastrointestinal Disorders

Phuong-Thu Pham, MD
Clinical Professor of Medicine, David Geffen School of Medicine at University of California–Los Angeles, Division of Nephrology; Director, Outpatient Services, Kidney and Pancreas Transplant Program, Ronald Reagan Medical Center at University of California–Los Angeles, Los Angeles, California, USA
105: Medical Management of the Kidney Transplant Recipient: Infections, Malignant Neoplasms, and Gastrointestinal Disorders
106: Medical Management of the Kidney Transplant Recipient: Cardiovascular Disease and Other Issues

Son Pham, MD
Assistant Professor of Medicine, Department of Medicine/Cardiology, University of Texas Health Science Center; Chief, Cardiology, Audie L. Murphy Memorial Veterans Hospital, San Antonio, Texas, USA
106: Medical Management of the Kidney Transplant Recipient: Cardiovascular Disease and Other Issues

Richard G. Phelps, PhD, FRCP
Senior Lecturer in Nephrology, MRC Centre for Inflammation Research, University of Edinburgh; Honorary Consultant, Renal Medicine, Royal Infirmary of Edinburgh, Edinburgh, Scotland
24: Anti–Glomerular Basement Membrane Disease and Goodpasture Disease

Matthew C. Pickering, PhD, MB, BS
Professor of Rheumatology, Centre for Complement and Inflammation Research, Imperial College, London, England
22: Glomerulonephritis Associated with Complement Disorders

Kevan R. Polkinghorne, PhD, MBChB, M Clin Epi, BHB, FRACP
Associate Professor, Department of Nephrology, Monash Medical Centre; Associate Professor, Department of Medicine, Epidemiology and Preventative Medicine, Monash University, Melbourne, Australia
95: Acute Complications During Hemodialysis

Hamid Rabb, MD
Professor, Department of Medicine, Johns Hopkins University, Baltimore, Maryland, USA
101: Immunosuppressive Medications in Kidney Transplantation

Brian Rayner, MMed, MBChB, FCP(SA)
Head and Associate Professor, University Department of Nephrology and Hypertension, University of Cape Town, Cape Town, South Africa
35: Nonpharmacologic Prevention and Treatment of Hypertension

Hugh C. Rayner, MD, MA, DipMedEd, FRCP
Consultant Nephrologist, Department of Renal Medicine, Heart of England National Health Service Foundation Trust, Birmingham, England
90: Approach to Renal Replacement Therapy

Giuseppe Remuzzi, MD, FRCP
Director, Department of Medicine, Azienda Ospedaliera Papa Giovanni XXIII; Director, IRCCS–Istituto di Ricerche Farmacologiche "Mario Negri," Bergamo, Italy
29: Thrombotic Microangiopathies, Including Hemolytic Uremic Syndrome

A. Mark Richards, MD, PhD, DSc, MB, ChB
Professor, Department of Medicine, University of Otago Christchurch, Christchurch, New Zealand; Director, Cardiovascular Research Institute, National University of Singapore, Singapore
41: Endocrine Causes of Hypertension

Bengt Rippe, MD, PhD
Professor, Department of Nephrology, University Hospital of Lund, Lund, Sweden
96: Peritoneal Dialysis: Principles, Techniques, and Adequacy

Bernardo Rodriguez-Iturbe, MD
Professor of Medicine, Department of Nephrology, Hospital Universitario and Universidad del Zulia, Maracaibo, Zulia, Venezuela
34: Primary Hypertension
57: Glomerular Diseases Associated with Infection

Pierre M. Ronco, MD, PhD
Professor of Nephrology, Pierre et Marie Curie University; Department of Nephrology and Dialysis, Hôpital Tenon, Paris, France
27: Renal Amyloidosis and Glomerular Diseases with Monoclonal Immunoglobulin Deposition

Mitchell H. Rosner, MD
Professor of Medicine, Division of Nephrology, University of Virginia Health System, Charlottesville, Virginia, USA
67: Geriatric Nephrology

Edward A. Ross, MD
Chairman, Department of Medicine, University of Central Florida, Orlando, Florida, USA
75: Management of Refractory Heart Failure

Jerome A. Rossert, MD, PhD
Chief Medical and Scientific Officer, Thrasos Therapeutics, Montreal, Quebec, Canada
62: Acute Interstitial Nephritis

Brad H. Rovin, MD
Professor and Director, Division of Nephrology, Department of Internal Medicine, The Wexner Medical Center at The Ohio State University, Columbus, Ohio, USA
26: Lupus Nephritis

Piero L. Ruggenenti, MD
Assistant Professor, Unit of Nephrology, Azienda Ospedaliera Papa Giovanni; Head, Department of Renal Medicine, IRCSS–Instituto di Ricerche Farmacologiche "Mario Negri," Bergamo, Italy
29: Thrombotic Microangiopathies, Including Hemolytic Uremic Syndrome

Sean Ruland, DO
Associate Professor, Department of Neurology, Stritch School of Medicine, Loyola University Health System, Maywood, Illinois, USA
42: Neurogenic Hypertension, Including Hypertension Associated with Stroke or Spinal Cord Injury

Graeme R. Russ, PhD, MBBS, FRACP
Royal Adelaide Hospital, Adelaide, Australia
77: Principles of Drug Therapy, Dosing, and Prescribing in Chronic Kidney Disease and Renal Replacement Therapy

Abdulla Salahudeen, MD
Professor, Division of Medicine, Section of Nephrology, University of Texas MD Anderson Cancer Center, Houston, Texas, USA
68: Onconephrology: Renal Disease in Cancer Patients

David J. Salant, MD, BCh
Professor of Medicine, Renal Section, Department of Medicine, Boston University School of Medicine, Boston, Massachusetts, USA
20: Membranous Nephropathy

Martin A. Samuels, MD, DSc(hon), FAAN, MACP, FRCP
Miriam Sydney Joseph Professor of Neurology, Harvard Medical School; Chair, Department of Neurology, Brigham and Women's Hospital; Senior Consultant, Neurology, Massachusetts General Hospital, Boston, Massachusetts
86: Neurologic Complications of Chronic Kidney Disease

Paul W. Sanders, MD
Thomas E. Andreoli Professor in Nephrology; Director, Nephrology Research and Training Center; Chief of the Section of Nephrology at Birmingham Veterans Affairs Medical Center; Department of Medicine, University of Alabama–Birmingham, Birmingham, Alabama, USA
71: Diagnosis and Clinical Evaluation of Acute Kidney Injury

Pantelis A. Sarafidis, MD, MSc, PhD
Senior Lecturer in Nephrology, Department of Nephrology, Hippokration Hospital, Aristotle University of Thessaloniki, Thessaloniki, Greece
37: Evaluation and Treatment of Hypertensive Urgencies and Emergencies

Francesco P. Schena, MD
Professor of Nephrology, Department of Organ Transplantation, University of Bari, Bari, Italy
21: Membranoproliferative Glomerulonephritis and Cryoglobulinemic Glomerulonephritis

Markus P. Schlaich, MD, PhD, FAHA
Professor, Neurovascular Hypertension and Kidney Disease Laboratory, Baker IDI Heart and Diabetes Institute; Cardiovascular Medicine, Alfred Hospital; Central Clinical School, Faculty of Medicine, Nursing and Health Sciences, Monash University, Melbourne, Australia
38: Interventional Treatments for Resistant Hypertension

Robert W. Schrier, MD, MACP
Professor Emeritus, Division of Renal Diseases and Hypertension, University of Colorado, Denver, Colorado, USA
7: Disorders of Extracellular Volume
69: Pathophysiology and Etiology of Acute Kidney Injury

Mark S. Segal, MD, PhD
Associate Professor and Chief, Division of Nephrology, Hypertension, and Renal Transplantation, Department of Medicine, University of Florida; Staff Physician, Renal Service, Department of Veterans Affairs Medical Center, North Florida/South Georgia Veterans Health System, Gainesville, Florida, USA
78: Herbal and Over-the-Counter Medicines and the Kidney

Julian L. Seifter, MD
Brigham and Women's Hospital, Boston, Massachusetts, USA
86: Neurologic Complications of Chronic Kidney Disease

Kumar Sharma, MD, FAHA
Professor of Medicine; Director, Center for Renal Translational Medicine; Director, Institute of Metabolomic Medicine, University of California–San Diego, La Jolla, California, USA
30: Pathogenesis, Clinical Manifestations, and Natural History of Diabetic Nephropathy

David G. Shirley, BSc, PhD
Reader in Renal Physiology, University College London Medical School, Royal Free Hospital, London, England
2: Renal Physiology

Visith Sitprija, MD, PhD, FACP, FRCP, FRACP, FRCPE
Director, Queen Saovabha Memorial Institute, Bangkok, Thailand
70: Acute Kidney Injury in the Tropics

Paul A. Sobotka, MD, FACC, FACP
Professor of Medicine, Affiliate, Department of Medicine, Division of Cardiology, The Ohio State University, Columbus, Ohio, USA; Staff Cardiologist, Division of Cardiology, Hennepin County Medical Center, Minneapolis, Minnesota, USA; Chief Medical Officer, Cibiem, Inc., New York, New York, USA
38: Interventional Treatments for Resistant Hypertension

Peter Stenvinkel, MD, PhD
Professor, Senior Lecturer, Department of Nephrology, Karolinska Institute, Karolinska University Hospital at Huddinge, Stockholm, Sweden
82: Cardiovascular Disease in Chronic Kidney Disease

Sundararaman Swaminathan, MD
Associate Professor of Medicine, Division of Nephrology, University of Virginia Health System, Charlottesville, Virginia, USA
67: Geriatric Nephrology

Jan C. ter Maaten, MD, PhD
Consultant, Acute Internal Medicine, Department of Internal Medicine, University Medical Center Groningen, Groningen, The Netherlands
51: Sickle Cell Disease

Stephen C. Textor, MD
Professor of Medicine, Division of Nephrology and Hypertension, Mayo Clinic, Rochester, Minnesota, USA
39: Renovascular Hypertension and Ischemic Nephropathy

Joshua M. Thurman, MD
Associate Professor of Medicine, Department of Medicine, Division of Nephrology and Hypertension, University of Colorado–Denver School of Medicine, Aurora, Colorado, USA
69: Pathophysiology and Etiology of Acute Kidney Injury

Laurie A. Tomlinson, PhD, MBBS, MRCP
Department of Epidemiology and Population Health, London School of Hygiene and Tropical Medicine, London, England
81: Clinical Evaluation and Management of Chronic Kidney Disease

Marcello Tonelli, MD, SM
Professor, Department of Medicine, University of Alberta, Edmonton, Alberta, Canada
72: Epidemiology and Prognostic Impact of Acute Kidney Injury

Li-Li Tong, MD
Assistant Professor of Medicine, Division of Nephrology and Hypertension, Los Angeles Biomedical Research Institute at Harbor University of California–Los Angeles, David Geffen School of Medicine, Torrance, California, USA
31: Prevention and Treatment of Diabetic Nephropathy

Peter S. Topham, MD, MB, ChB
Consultant Nephrologist, The John Walls Renal Unit, University Hospitals of Leicester; Honorary Senior Lecturer, Department of Infection, Immunity and Inflammation, University of Leicester, Leicester, England
6: Renal Biopsy

Jan H. M. Tordoir, PhD
Vascular Surgeon, Director of the Vascular Laboratory, Department of Surgery, Maastricht University Medical Center, Maastricht, The Netherlands
91: Vascular Access for Dialytic Therapies

Vicente E. Torres, MD, PhD
Professor of Medicine, Division of Nephroogy and Hypertension, Mayo Clinic, Rochester, Minnesota, USA
46: Autosomal Dominant Polycystic Kidney Disease

A. Neil Turner, PhD, FRCP
Professor of Nephrology, Department of Renal Medicine, Royal Infirmary; Centre for Inflammation, University of Edinburgh, Edinburgh, Scotland
24: Anti–Glomerular Basement Membrane Disease and Goodpasture Disease

Robert J. Unwin, PhD, BM, FRCP, FSB
Professor of Nephrology and Physiology, Centre for Nephrology, University College London, London, England
2: Renal Physiology

Deepa Usulumarty, MD
Visiting Fellow, Centre for Transplantation and Renal Research, Sydney University, Westmead Hospital, Westmead, Australia
109: Outcomes of Renal Transplantation

R. Kasi Visweswaran, MD, DM, FRCP (Edin)
Visiting Professor, Department of Nephrology, Pushpagiri Institute of Medical Sciences, Tiruvalla, Kerala, India; Senior Consultant in Nephrology, Ananthapuri Hospitals and Research Institute, Trivandrum, Kerala, India
54: Tuberculosis of the Urinary Tract

Haimanot Wasse, MD, MPH
Associate Professor and Director of Interventional Nephrology, Emory University School of Medicine, Atlanta, Georgia, USA
92: Diagnostic and Interventional Nephrology

I. David Weiner, MD
Professor of Medicine, Physiology, and Functional Genomics, Division of Nephrology, Hypertension, and Transplantation, University of Florida College of Medicine; Nephrology and Hypertension Section, North Florida/South Georgia Veterans Health System; Gainesville, Florida, USA
9: Disorders of Potassium Metabolism
40: Endocrine Causes of Hypertension: Aldosterone

David C. Wheeler, MD, FRCP
Professor of Kidney Medicine, Centre for Nephrology, University College London Medical School, London, England
81: Clinical Evaluation and Management of Chronic Kidney Disease

Martin E. Wilkie, MD, FRCP
Consultant Renal Physician and Honorary Reader, Editor in Chief, Peritoneal Dialysis International, Sheffield Kidney Institute, Northern General Hospital, Sheffield, England
97: Complications of Peritoneal Dialysis

Bryan Williams, MD
Professor of Medicine, Institute of Cardiovascular Science, University College London, London, England
36: Pharmacologic Treatment of Hypertension

Charles S. Wingo, MD
Professor of Medicine and Physiology and Functional Genomics, Craig and Audrae Tisher Endowed Chair in Nephrology, Department of Medicine and Physiology and Functional Genomics, University of Florida Health System; Research Investigator, Nephrology Section, North Florida/South Georgia Veterans Health System, Gainesville, Florida, USA
9: Disorders of Potassium Metabolism
40: Endocrine Causes of Hypertension: Aldosterone

Michelle P. Winn, MD
Associate Professor of Medicine, Duke University Medical Center, Durham, North Carolina, USA
19: Inherited Causes of Nephrotic Syndrome

Alexander C. Wiseman, MD
Associate Professor, Division of Renal Diseases and Hypertension, University of Colorado; Medical Director, Kidney and Pancreas Transplant Programs, University of Colorado Hospital, Aurora, Colorado, USA
104: Prophylaxis and Treatment of Kidney Transplant Rejection

Gunter Wolf, MD, MHBA
Professor and Department Head, Internal Medicine III, University of Jena, University Hospital, Jena, Germany
30: Pathogenesis, Clinical Manifestations, and Natural History of Diabetic Nephropathy

Karl L. Womer, MD
Professor of Medicine, University of Florida, Gainesville, Florida, USA
100: Immunologic Principles in Kidney Transplantation
101: Immunosuppressive Medications in Kidney Transplantation

Graham Woodrow, MBChB, MD, FRCP
Consultant Nephrologist, Renal Unit, St. James's University Hospital, Leeds, England
87: Gastroenterology and Nutrition in Chronic Kidney Disease

David C. Wymer, MD, FACR, FACNM
Associate Chair, Department of Radiology, University of Florida; Chief of Service, Imaging Department of Radiology, Malcom Randall Veterans Affairs Medical Center, Gainesville, Florida, USA
5: Imaging

Xueqing Yu, MD, PhD
First Affiliated Hospital, Sun Yat-Sen University, Guangzhou, Guangdong, China
78: Herbal and Over-the-Counter Medicines and the Kidney

Martin Zeier, MD
Division of Nephrology, Heidelberg University Hospital, Heidelberg, Germany
107: Chronic Allograft Injury

PREFACE

In the fifth edition of *Comprehensive Clinical Nephrology,* we continue to offer a text for fellows, practicing nephrologists, and internists that covers all aspects of the clinical work of the nephrologist, including fluids and electrolytes, hypertension, diabetes, dialysis, and transplantation. We continue to recognize that this single volume does not compete with multivolume, highly referenced texts, and it remains our goal to provide "comprehensive" coverage of clinical nephrology yet also ensure that inquiring nephrologists can find the scientific issues and pathophysiology that underlie their clinical work.

For this edition all chapters have been extensively revised and updated in response to the advice and comments that we have received from many readers and colleagues. These revisions include latest developments, such as the discovery of the major autoantigen in membranous nephropathy, and the latest data on important issues in therapeutics such as blood pressure targets and use of RAS blockade. New diseases (for example, C3 glomerulopathy) and new interventions (including renal denervation) have entered the scene since the fourth edition came out, and these are now covered. Another new feature of the fifth edition is coverage of the rapidly expanding field of renal disease in cancer patients.

For this edition, we have also refined the algorithms, which are a popular feature of the book, by using color more consistently to emphasize different aspects of the information being provided. Thus yellow boxes are used for general information, green boxes indicate therapeutic intervention, and blue boxes indicate necessary investigations.

By popular demand we continue to offer readers access to the images from the book that we are pleased to see used in lectures and seminars in many parts of the world.

This is the second edition that features access to a companion Expert Consult website, with fully searchable text, a downloadable image library, and links to PubMed. New to this edition is an online question bank with more than 400 multiple-choice questions.

Jürgen Floege
Richard J. Johnson
John Feehally

CONTENTS

Section I Essential Renal Anatomy and Physiology

1 Renal Anatomy 2
Wilhelm Kriz and Marlies Elger

2 Renal Physiology 14
Matthew A. Bailey, David G. Shirley, and Robert J. Unwin

Section II Investigation of Renal Disease

3 Assessment of Renal Function 30
Lesley A. Inker, Li Fan, and Andrew S. Levey

4 Urinalysis 39
Giovanni B. Fogazzi and Giuseppe Garigali

5 Imaging 53
David C. Wymer

6 Renal Biopsy 71
Peter S. Topham and Yipu Chen

Section III Fluid and Electrolyte Disorders

7 Disorders of Extracellular Volume 80
Elwaleed A. Elhassan and Robert W. Schrier

8 Disorders of Water Metabolism 94
Tomas Berl and Chirag Parikh

9 Disorders of Potassium Metabolism 111
I. David Weiner, Stuart L. Linas, and Charles S. Wingo

10 Disorders of Calcium, Phosphate, and Magnesium Metabolism 124
Bryan Kestenbaum and Tilman B. Drüeke

11 Normal Acid-Base Balance 142
Biff F. Palmer

12 Metabolic Acidosis 149
Biff F. Palmer

13 Metabolic Alkalosis 160
F. John Gennari

14 Respiratory Acidosis, Respiratory Alkalosis, and Mixed Disorders 169
Horacio J. Adrogué and Nicolaos E. Madias

Section IV Glomerular Disease

15 Introduction to Glomerular Disease: Clinical Presentations 184
Jürgen Floege and John Feehally

16 Introduction to Glomerular Disease: Histologic Classification and Pathogenesis 198
Richard J. Johnson, Jürgen Floege, and John Feehally

17 Minimal Change Nephrotic Syndrome 208
Philip D. Mason and Peter F. Hoyer

18 Primary and Secondary (Non-Genetic) Causes of Focal and Segmental Glomerulosclerosis 218
Gerald B. Appel and Vivette D. D'Agati

19 Inherited Causes of Nephrotic Syndrome 231
Gentzon Hall and Michelle P. Winn

20 Membranous Nephropathy 239
David J. Salant and Daniel C. Cattran

21 Membranoproliferative Glomerulonephritis and Cryoglobulinemic Glomerulonephritis 253
Francesco P. Schena and Charles E. Alpers

22 Glomerulonephritis Associated with Complement Disorders 261
H. Terence Cook and Matthew C. Pickering

23 IgA Nephropathy and Henoch-Schönlein Nephritis 266
John Feehally and Jürgen Floege

24 Anti–Glomerular Basement Membrane Disease and Goodpasture Disease 278
Richard G. Phelps and A. Neil Turner

25 Renal and Systemic Vasculitis 287
J. Charles Jennette, Ronald J. Falk, and JulieAnne G. McGregor

26 Lupus Nephritis 303
Gerald B. Appel, David Jayne, and Brad H. Rovin

27 Renal Amyloidosis and Glomerular Diseases with Monoclonal Immunoglobulin Deposition 317
Pierre M. Ronco, Pierre Aucouturier, and Bruno Moulin

28 Other Glomerular Disorders and the Antiphospholipid Syndrome 330
Richard J. Glassock

29 Thrombotic Microangiopathies, Including Hemolytic Uremic Syndrome 339
Marina Noris, Piero L. Ruggenenti, and Giuseppe Remuzzi

Section V Diabetic Nephropathy

30 Pathogenesis, Clinical Manifestations, and Natural History of Diabetic Nephropathy 354
Gunter Wolf and Kumar Sharma

31 Prevention and Treatment of Diabetic Nephropathy 372
Li-Li Tong and Sharon Adler

32 Management of the Diabetic Patient with Chronic Kidney Disease 381
Ahmad Abou-Saleh, Stephen C. Bain, and David J. A. Goldsmith

Section VI Hypertension

33 **Normal Blood Pressure Control and the Evaluation of Hypertension** 392
William J. Lawton, Gerald F. DiBona, Ulla C. Kopp, and Friedrich C. Luft

34 **Primary Hypertension** 407
Richard J. Johnson, George L. Bakris, and Bernardo Rodriguez-Iturbe

35 **Nonpharmacologic Prevention and Treatment of Hypertension** 417
Brian Rayner, Karen E. Charlton, and Estelle V. Lambert

36 **Pharmacologic Treatment of Hypertension** 425
Bryan Williams

37 **Evaluation and Treatment of Hypertensive Urgencies and Emergencies** 439
Pantelis A. Sarafidis and George L. Bakris

38 **Interventional Treatments for Resistant Hypertension** 447
Henry Krum, Markus P. Schlaich, and Paul A. Sobotka

39 **Renovascular Hypertension and Ischemic Nephropathy** 453
Stephen C. Textor and Barbara A. Greco

40 **Endocrine Causes of Hypertension: Aldosterone** 470
I. David Weiner and Charles S. Wingo

41 **Endocrine Causes of Hypertension** 478
A. Mark Richards and M. Gary Nicholls

42 **Neurogenic Hypertension, Including Hypertension Associated with Stroke or Spinal Cord Injury** 488
Venkatesh Aiyagari, Sean Ruland, and Philip B. Gorelick

Section VII Pregnancy and Renal Disease

43 **Renal Physiology in Normal Pregnancy** 498
Chris Baylis and John M. Davison

44 **Renal Complications in Normal Pregnancy** 506
Annabel C. Martin and Mark A. Brown

45 **Pregnancy with Preexisting Kidney Disease** 523
Mark A. Brown

Section VIII Hereditary and Congenital Diseases of the Kidney

46 **Autosomal Dominant Polycystic Kidney Disease** 536
Vicente E. Torres and Peter C. Harris

47 **Other Cystic Kidney Diseases** 549
Lisa M. Guay-Woodford

48 **Alport and Other Familial Glomerular Syndromes** 565
Clifford E. Kashtan

49 **Inherited Disorders of Sodium and Water Handling** 579
Peter Gross and Peter Heduschka

50 **Fanconi Syndrome and Other Proximal Tubule Disorders** 590
John W. Foreman

51 **Sickle Cell Disease** 601
Jan C. ter Maaten and Fatiu A. Arogundade

52 **Congenital Anomalies of the Kidney and Urinary Tract** 613
John O. Connolly and Guy H. Neild

Section IX Infectious Diseases and the Kidney

53 **Bacterial Urinary Tract Infections** 632
Thomas Hooton

54 **Tuberculosis of the Urinary Tract** 644
R. Kasi Visweswaran and Suresh Bhat

55 **Fungal Infections of the Urinary Tract** 652
Carol A. Kauffman

56 **The Kidney in Schistosomiasis** 657
Rashad S. Barsoum

57 **Glomerular Diseases Associated with Infection** 665
Bernardo Rodriguez-Iturbe, Emmanuel A. Burdmann, and Rashad S. Barsoum

58 **Human Immunodeficiency Virus Infection and the Kidney** 678
Jeffrey B. Kopp and Saraladevi Naicker

Section X Urologic Disorders

59 **Nephrolithiasis and Nephrocalcinosis** 688
David A. Bushinsky and Rebeca D. Monk

60 **Urinary Tract Obstruction** 703
Jeremy Hughes

61 **Urologic Issues for the Nephrologist** 716
Sunjay Jain, James E. Dyer, Evangelos G. Gkougkousis, and J. Kilian Mellon

Section XI Tubulointerstitial and Vascular Diseases

62 **Acute Interstitial Nephritis** 728
Jerome A. Rossert and Evelyne A. Fischer

63 **Primary Vesicoureteral Reflux and Reflux Nephropathy** 737
Ranjiv Mathews and Tej K. Mattoo

64 **Chronic Interstitial Nephritis** 746
Masaomi Nangaku

65 **Myeloma and the Kidney** 759
Ashley B. Irish

66 **Thromboembolic Renovascular Disease** 767
Barbara A. Greco, Jamie P. Dwyer, and Julia B. Lewis

Section XII Geriatric Nephrology

67 **Geriatric Nephrology** 780
Mitchell H. Rosner, Edgar V. Lerma, and Sundararaman Swaminathan

Section XIII Renal Disease and Cancer

68 **Onconephrology: Renal Disease in Cancer Patients** 792
Ala Abudayyeh and Abdulla Salahudeen

Section XIV Acute Kidney Injury

69 **Pathophysiology and Etiology of Acute Kidney Injury** 802
J. Ashley Jefferson, Joshua M. Thurman, and Robert W. Schrier

70 **Acute Kidney Injury in the Tropics** 818
Emmanuel A. Burdmann, Vivekanand Jha, and Visith Sitprija

71 **Diagnosis and Clinical Evaluation of Acute Kidney Injury** 827
Eric Judd, Paul W. Sanders, and Anupam Agarwal

72 **Epidemiology and Prognostic Impact of Acute Kidney Injury** 836
Neesh Pannu and Marcello Tonelli

73 **Prevention and Nondialytic Management of Acute Kidney Injury** 842
Etienne Macedo, Josée Bouchard, and Ravindra L. Mehta

74 **Dialytic Management of Acute Kidney Injury and Intensive Care Unit Nephrology** 855
Mark R. Marshall and Luis A. Juncos

75 **Management of Refractory Heart Failure** 867
Edward A. Ross and Kevin Damman

76 **Hepatorenal Syndrome** 873
Javier Fernández and Vicente Arroyo

Section XV Drug Therapy in Kidney Disease

77 **Principles of Drug Therapy, Dosing, and Prescribing in Chronic Kidney Disease and Renal Replacement Therapy** 884
Matthew J. Cervelli and Graeme R. Russ

SECTION I

Essential Renal Anatomy and Physiology

CHAPTER 1

Renal Anatomy

Wilhelm Kriz and Marlies Elger

The complex structure of the mammalian kidney is best understood in the unipapillary form that is common to all small species. Figure 1-1 is a schematic coronal section through a unipapillary kidney, with a cortex enclosing a pyramid-shaped medulla, the tip of which protrudes into the renal pelvis. The medulla is divided into an outer and an inner medulla; the outer medulla is further subdivided into an outer and an inner stripe.

STRUCTURE OF THE KIDNEY

The specific components of the kidney are the nephrons, the collecting ducts, and a unique microvasculature.[1] The multipapillary kidney of humans contains about 1 million nephrons, although this number varies considerably. The number of nephrons is already established during prenatal development; after birth, new nephrons cannot be developed, and a lost nephron cannot be replaced.

Nephrons

A nephron consists of a renal corpuscle *(glomerulus)* connected to a complicated and twisted tubule that finally drains into a collecting duct (Fig. 1-2 and Table 1-1). Three types of nephron can be distinguished by the location of renal corpuscles within the cortex: superficial, midcortical, and juxtamedullary nephrons. The tubular part of the nephron consists of a proximal tubule and a distal tubule connected by a loop of Henle[2] (see later discussion). There are two types of nephron, those with long loops of Henle and those with short loops. Short loops turn back in the outer medulla or even in the cortex (cortical loops). Long loops turn back at successive levels of the inner medulla.

Collecting Ducts

A collecting duct is formed in the renal cortex when several nephrons join. A connecting tubule is interposed between a nephron and a cortical collecting duct. Cortical collecting ducts descend within the medullary rays of the cortex. These ducts traverse the outer medulla as unbranched tubes. On entering the inner medulla, the cortical collecting ducts fuse successively and open finally as papillary ducts into the renal pelvis (see Fig. 1-2 and Table 1-1).

Microvasculature

The microvascular pattern of the kidney is similarly organized in mammalian species[1,3] (Fig. 1-3; see also Fig. 1-1). The renal artery, after entering the renal sinus, finally divides into the interlobar arteries, which extend toward the cortex in the space between the wall of the pelvis (or calyx) and the adjacent cortical tissue. At the junction between cortex and medulla, the interlobar arteries divide and pass over into the arcuate arteries, which also branch. The arcuate arteries give rise to the cortical radial arteries (interlobular arteries), which ascend radially through the cortex. No arteries penetrate the medulla.

Afferent arterioles supply the glomerular tufts and generally arise from cortical radial arteries. *Aglomerular* tributaries to the capillary plexus are rarely found. As a result, the blood supply of the peritubular capillaries of the cortex and the medulla is exclusively *postglomerular.*

Glomeruli are drained by efferent arterioles. Two basic types of efferent arterioles can be distinguished, cortical and juxtamedullary. *Cortical* efferent arterioles, which derive from superficial and midcortical glomeruli, supply the capillary plexus of the cortex. The efferent arterioles of *juxtamedullary* glomeruli represent the supplying vessels of the renal medulla. Within the outer stripe of the medulla, these vessels divide into the *descending* vasa recta and then penetrate the inner stripe in cone-shaped vascular bundles. At intervals, individual vessels leave the bundles to supply the capillary plexus at the adjacent medullary level.

Ascending vasa recta drain the renal medulla. In the inner medulla, the vasa recta arise at every level, ascending as unbranched vessels, and traverse the inner stripe within the vascular bundles. The ascending vasa recta that drain the inner stripe may join the vascular bundles or may ascend directly to the outer stripe between the bundles. All the ascending vasa recta traverse the outer stripe as individual wavy vessels with wide lumina interspersed among the tubules. Because true capillaries derived from direct branches of efferent arterioles are relatively scarce, the ascending vasa recta form the capillary plexus of the outer stripe. The ascending vasa recta empty into arcuate veins.

The vascular bundles represent a countercurrent exchanger between the blood entering and that leaving the medulla. In addition, the organization of the vascular bundles results in a separation of the blood flow to the inner stripe from that to the inner medulla. Descending vasa recta supplying the inner medulla traverse the inner stripe within the vascular bundles. Therefore blood flowing to the inner medulla has not been exposed previously to tubules of the inner or outer stripe. All ascending vasa recta originating from the inner medulla traverse the inner stripe within the vascular bundles. Thus blood that has perfused tubules of the inner medulla does not subsequently perfuse tubules of the inner stripe. However, the blood returning from either the inner medulla or the inner stripe afterward does perfuse the tubules of the outer stripe. This arrangement in the outer stripe may function as the ultimate trap to prevent solute loss from the medulla.

The intrarenal veins accompany the arteries. Central to the renal drainage of the kidney are the arcuate veins, which, in contrast to arcuate arteries, do form real anastomosing arches at the corticomedullary border. The arcuate veins accept the veins from the cortex and the renal medulla. The arcuate veins join to form interlobar veins, which run alongside the corresponding arteries.

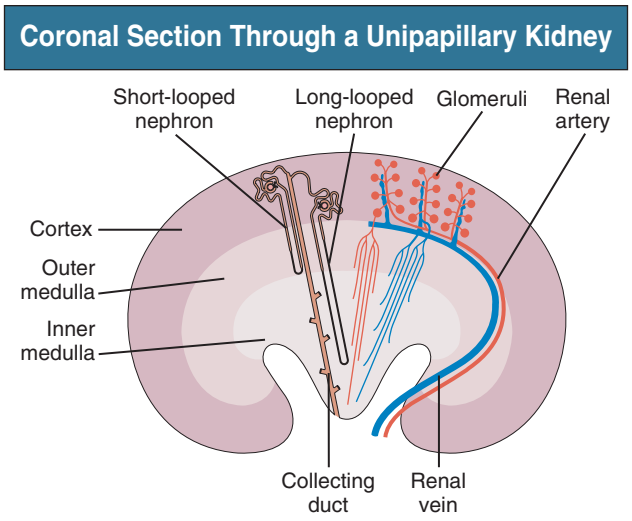

Figure 1-1 **Coronal section through a unipapillary kidney.**

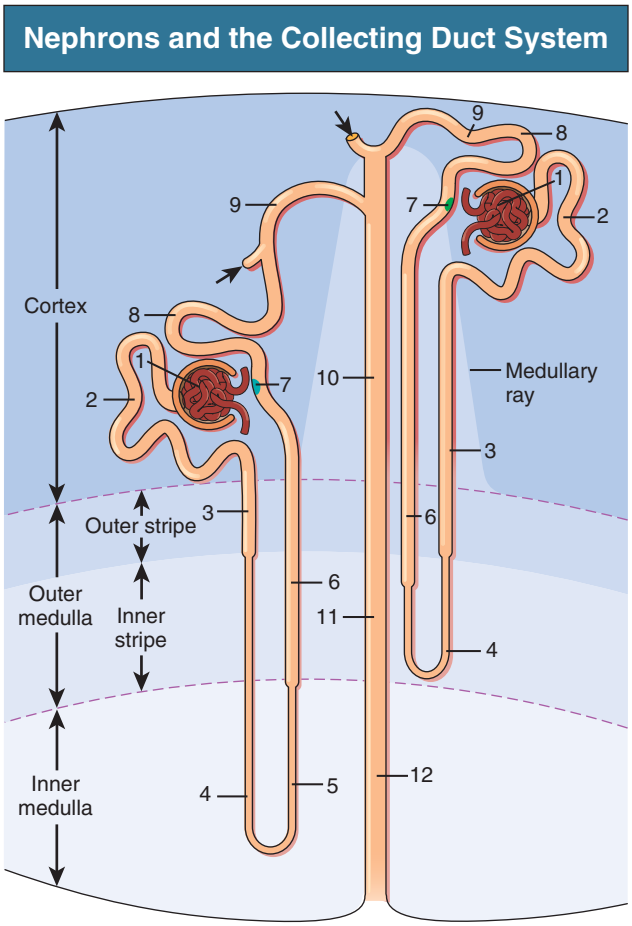

Figure 1-2 **Nephrons and the collecting duct system.** Shown are short-looped and long-looped nephrons, together with a collecting duct (not drawn to scale). *Arrows* denote confluence of further nephrons.

Subdivisions of the Nephron and Collecting Duct System

Section	Subsections
Nephron	
Renal corpuscle	*Glomerulus:* term used most frequently to refer to entire renal corpuscle Bowman capsule
Proximal tubule	Convoluted part Straight part (pars recta), or thick descending limb of Henle loop
Intermediate tubule	Descending part, or thin descending limb of Henle loop Ascending part, or thin ascending limb of Henle loop
Distal tubule	Straight part, or thick ascending limb of Henle loop: subdivided into medullary and cortical parts; the cortical part contains the macula densa in its terminal portion Convoluted part
Collecting Duct System	
Connecting tubule	Includes the arcades in most species
Collecting duct	Cortical collecting duct Outer medullary collecting duct: subdivided into an outer stripe and an inner stripe portion Inner medullary collecting duct: subdivided into basal, middle, and papillary portions

Table 1-1 **Subdivisions of the nephron and collecting duct system.**

The intrarenal arteries and the afferent and efferent glomerular arterioles are accompanied by sympathetic nerve fibers and terminal axons representing the efferent nerves of the kidney.[1] Tubules have direct contact to terminal axons only when the tubules are located around the arteries or the arterioles. Tubular innervation consists of "occasional fibers adjacent to perivascular tubules."[4] The density of nerve contacts to convoluted proximal tubules is low; contacts to straight proximal tubules, thick ascending limbs of Henle loops, and collecting ducts (located in medullary rays and outer medulla) have never been encountered. The vast majority of tubular portions have no direct relationships to nerve terminals. Afferent nerves of the kidney are believed to be sparse.[5]

NEPHRON

Renal Glomerulus (Renal Corpuscle)

The glomerulus comprises a tuft of specialized capillaries attached to the mesangium, both of which are enclosed in a pouch-like extension of the tubule, the glomerular capsule, or Bowman capsule (Figs. 1-4 and 1-5). The capillaries and mesangium are covered by epithelial cells (podocytes), forming the visceral epithelium of Bowman capsule. At the vascular pole, this structure is reflected to become the parietal epithelium of Bowman capsule. At the interface between the glomerular capillaries and the mesangium on one side and the podocyte layer on the other side, the glomerular basement membrane (GBM) develops. The space between both layers of Bowman capsule represents the urinary space, which at the urinary pole continues as the tubule lumen.

On entering the tuft, the afferent glomerular arteriole immediately divides into up to five primary capillary branches, each of which gives rise to an anastomosing capillary network representing a

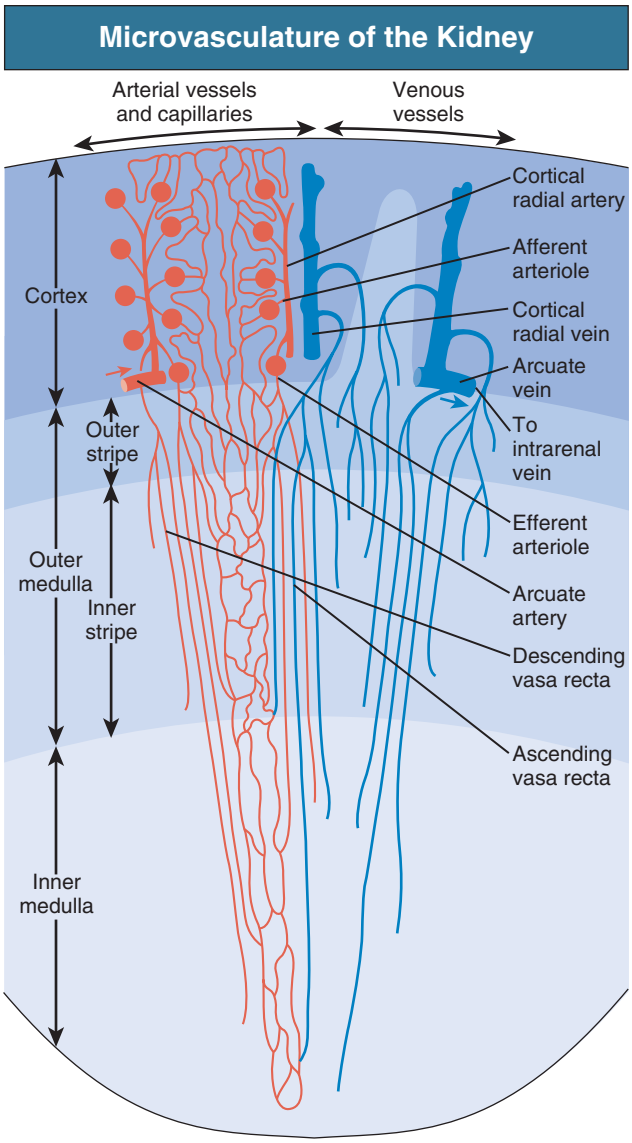

Figure 1-3 Microvasculature of the kidney. Afferent arterioles supply the glomeruli and efferent arterioles leave the glomeruli and divide into the descending vasa recta, which together with the ascending vasa recta form the vascular bundles of the renal medulla. The vasa recta ascending from the inner medulla all traverse the inner stripe within the vascular bundles, whereas most of the vasa recta from the inner stripe of the outer medulla ascend outside the bundles. Both types traverse the outer stripe as wide, tortuous channels.

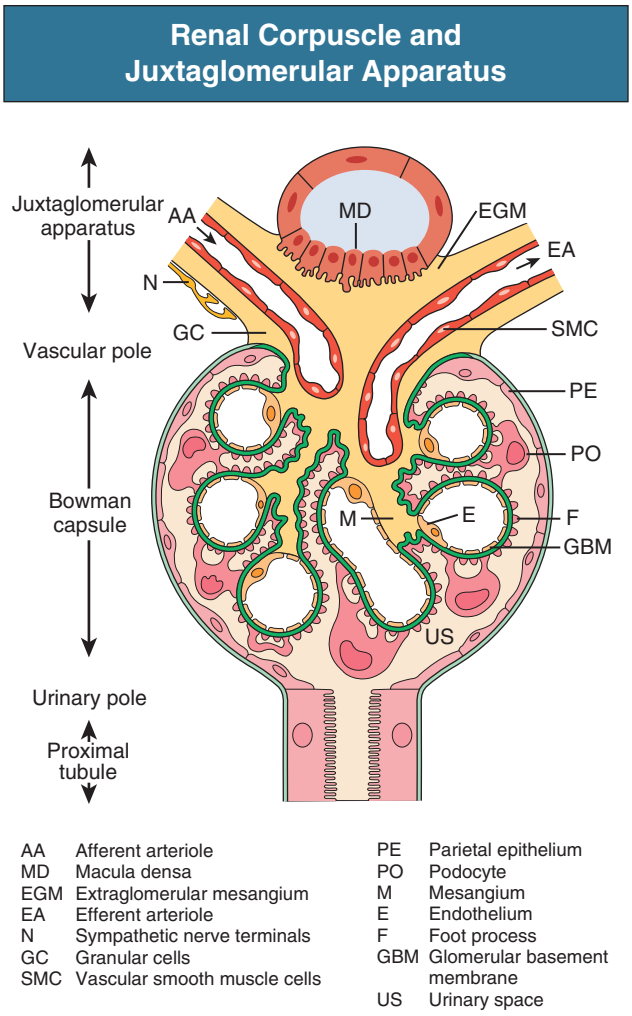

Figure 1-4 Renal corpuscle and juxtaglomerular apparatus. *(Modified with permission from reference 1.)*

glomerular lobule. In contrast to the afferent arteriole, the efferent glomerular arteriole is already established inside the tuft by confluence of capillaries from each lobule.[6] Thus the efferent arteriole has a significant intraglomerular segment located within the glomerular stalk.

Glomerular capillaries are a unique type of blood vessel consisting of only an endothelial tube (Figs. 1-6 and 1-7). A small stripe of the outer aspect of this tube directly abuts the mesangium; a major part bulges toward the urinary space and is covered by the GBM and the podocyte layer. This peripheral portion of the capillary wall is the filtration area. The glomerular mesangium represents the axis of a glomerular lobule to which the glomerular capillaries are attached.

Glomerular Basement Membrane

The GBM serves as the skeleton of the glomerular tuft. This membrane is a complexly folded sack with an opening at the glomerular hilum (see Fig. 1-4). The outer aspect of this GBM sack is completely covered with podocytes. The interior of the sack is filled with the capillaries and the mesangium. As a result, on its inner aspect, the GBM is in contact with either capillaries or the mesangium. At any transition between these two locations, the GBM changes from a convex pericapillary to a concave perimesangial course; the turning points are called *mesangial angles.*

In electron micrographs of traditionally fixed tissue, the GBM appears as a trilaminar structure, with a lamina densa bounded by two less dense layers, the lamina rara interna and lamina rara externa (see Fig. 1-7). Studies with freeze techniques reveal only one thick dense layer directly attached to the bases of the epithelium and endothelium.[7]

The major components of the GBM include type IV collagen, laminin, and heparan sulfate proteoglycans, as in basement membranes at other sites. Types V and VI collagen and nidogen (entactin) have also been demonstrated. However, the GBM has several unique properties, notably a distinct spectrum of type IV collagen and laminin isoforms. The mature GBM consists of type IV collagen made of α3, α4, and α5 chains (instead of α1 and α2 chains of most other basement membranes) and laminin 11, made of α5, β2, and γ1 chains.[8] Type IV collagen is the antigenic target in Goodpasture disease (see Chapter 24), and mutations in the genes of the α3, α4, and α5 chains of type IV collagen are responsible for Alport syndrome (see Chapter 48).

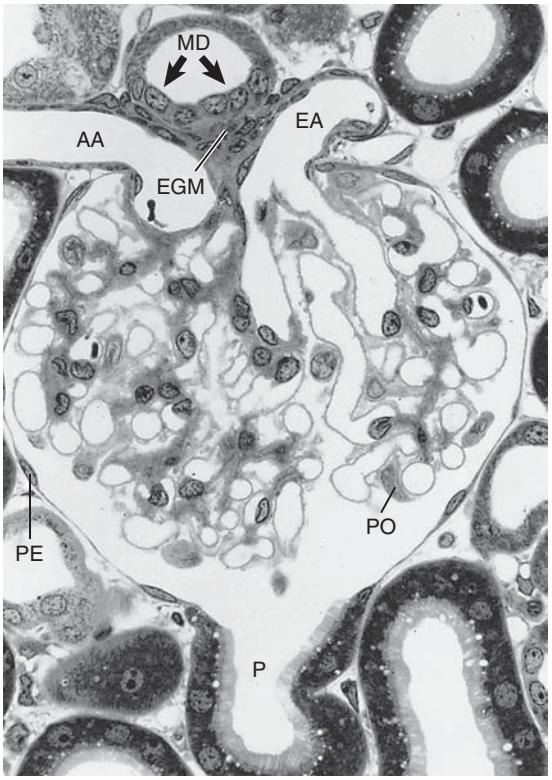

Figure 1-5 Longitudinal section through a glomerulus (rat). At the vascular pole, the afferent arteriole *(AA),* the efferent arteriole *(EA),* the extraglomerular mesangium *(EGM),* and the macula densa *(MD)* are seen; *PO,* podocyte. At the urinary pole, the parietal epithelium *(PE)* transforms into the proximal tubule *(P)*. (Light microscopy; magnification ×390.)

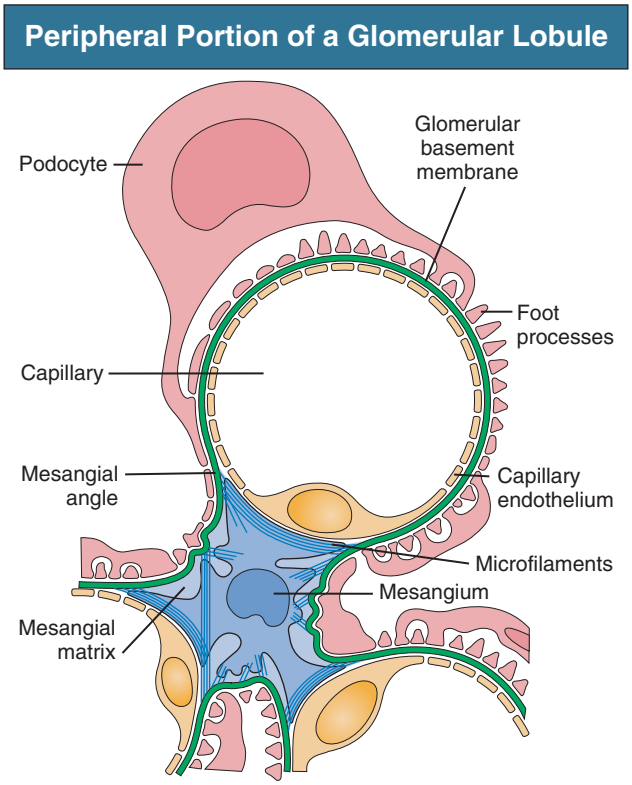

Figure 1-6 Peripheral portion of a glomerular lobule. This part shows a capillary, the axial position of the mesangium, and the visceral epithelium (podocytes). At the capillary-mesangial interface, the capillary endothelium directly abuts the mesangium.

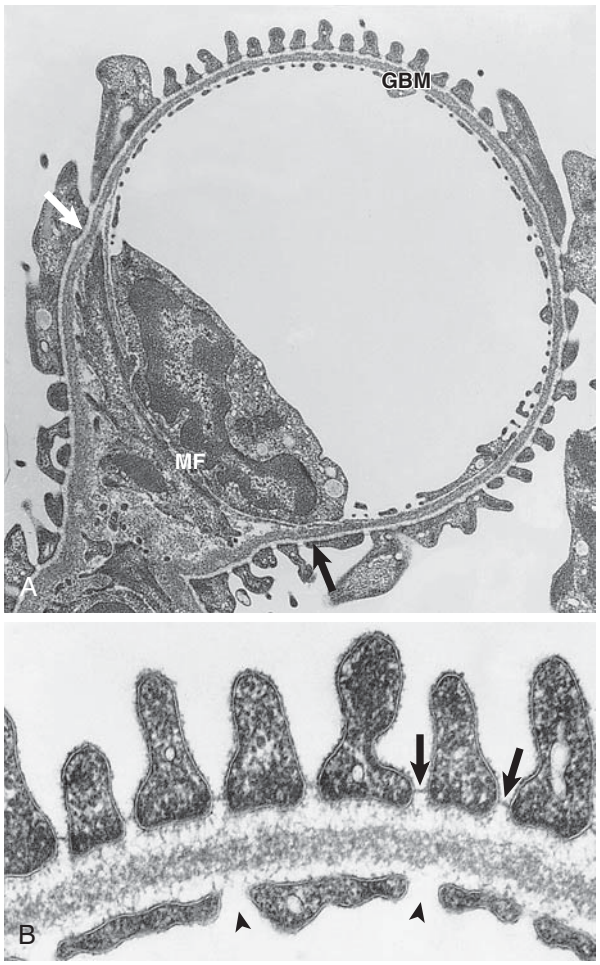

Figure 1-7 Glomerular capillary. A, The layer of interdigitating podocyte processes and the glomerular basement membrane *(GBM)* do not completely encircle the capillary. At the mesangial angles *(arrows),* both deviate from a pericapillary course and cover the mesangium. Mesangial cell processes containing dense bundles of microfilaments *(MF)* interconnect the GBM and bridge the distance between the two mesangial angles. **B,** Filtration barrier. The peripheral part of the glomerular capillary wall comprises the endothelium with open pores *(arrowheads),* the GBM, and the interdigitating foot processes. The GBM shows a lamina densa bounded by the lamina rara interna and externa. The foot processes are separated by filtration slits bridged by thin diaphragms *(arrows)*. (Transmission electron microscopy [TEM]; magnification: **A,** ×8770; **B,** ×50,440.)

Current models depict the basic structure of the GBM as a three-dimensional network of type IV collagen.[7] The type IV collagen monomer consists of a triple helix that is 400 nm in length, with a large, noncollagenous globular domain at its C-terminal end called NC1. At the N terminus, the helix possesses a triple helical rod 60 nm long: the 7S domain. Interactions between the 7S domains of two triple helices or the NC1 domains of four triple helices allow type IV collagen monomers to form dimers and tetramers. In addition, triple helical strands interconnect by lateral associations through binding of NC1 domains to sites along the collagenous region. This network is complemented by an interconnected network of laminin 11, resulting in a flexible, nonfibrillar polygonal assembly that provides mechanical strength to the basement membrane and serves as a scaffold for alignment of other matrix components.

The electronegative charge of the GBM mainly results from the presence of polyanionic proteoglycans. The major proteoglycans of the GBM are heparan sulfate proteoglycans, including perlecan and

agrin. Proteoglycan molecules aggregate to form a meshwork that is kept well hydrated by water molecules trapped in the interstices of the matrix. Abrahamson[9] provides an up-to-date summary of the molecular organization of the GBM.

Mesangium

Three major cell types occur within the glomerular tuft, all of which are in close contact with the GBM: mesangial cells, endothelial cells, and podocytes. The mesangial/endothelial/podocyte cell ratio is 2:3:1 in the rat. The mesangial cells and mesangial matrix establish the glomerular mesangium. In addition, some studies suggest that macrophages bearing HLA-DR/Ia-like antigens may also rarely be found in the normal mesangium.

Mesangial Cells Mesangial cells are irregular in shape, with many processes extending from the cell body toward the GBM (see Figs. 1-6 and 1-7). In these processes, dense assemblies of microfilaments are found, containing actin, myosin, and α-actinin.[10] The processes are attached to the GBM directly or through the interposition of microfibrils (see later discussion). The GBM represents the effector structure of mesangial contractility. Mesangial cell–GBM connections are especially prominent alongside the capillaries, interconnecting the two opposing mesangial angles of the GBM.

Mesangial cells possess a great variety of receptors, including those for angiotensin II (Ang II), vasopressin, atrial natriuretic factor, prostaglandins, transforming growth factor β (TGF-β), and other growth factors (PDGFs, EGF, CTGF)[11].

Mesangial Matrix The mesangial matrix fills the highly irregular spaces between the mesangial cells and the perimesangial GBM, anchoring the mesangial cells to the GBM.[6] The ultrastructural organization of this matrix is incompletely understood. In specimens prepared by a technique that avoids osmium tetroxide and uses tannic acid for staining, a dense network of elastic microfibrils is seen. Many common extracellular matrix proteins have been demonstrated within the mesangial matrix, including collagen types IV, V, and VI and microfibrillar protein components such as fibrillin and the 31-kilodalton microfibril-associated glycoprotein. The matrix also contains several glycoproteins, most abundantly fibronectin, as well as several types of proteoglycans.

Endothelium

Glomerular endothelial cells consist of cell bodies and peripherally located, attenuated, and highly fenestrated cytoplasmic sheets (see Figs. 1-6 and 1-7). Glomerular endothelial pores lack diaphragms, which are encountered only in the endothelium of the final tributaries to the efferent arteriole.[6] The round to oval pores have a diameter of 50 to 100 nm. The luminal membrane of endothelial cells is negatively charged because of the cell coat of several polyanionic glycoproteins, including podocalyxin. In addition, the endothelial pores are filled with sieve plugs mainly made of sialoglycoproteins.[12]

Visceral Epithelium (Podocytes)

The visceral epithelium of Bowman capsule comprises highly differentiated cells, the podocytes (Fig. 1-8; see also Fig. 1-6). In the developing glomerulus, podocytes have a simple polygonal shape. In rats, mitotic activity of these cells is completed soon after birth together with the cessation of forming new nephron anlagen (primordia). In humans, this point is already reached during prenatal life. Differentiated podocytes are unable to replicate; therefore degenerated podocytes cannot be replaced in the adult. All efforts of the last decade to find progenitor cells that might migrate into the tuft and replace lost podocytes have failed. In response to an extreme growth stimulus, as by basic fibroblast growth factor 2 (FGF-2), podocytes may undergo mitotic nuclear division. However, the cells are unable to complete cell division by cytokinesis, resulting in binucleated or multinucleated cells.[13]

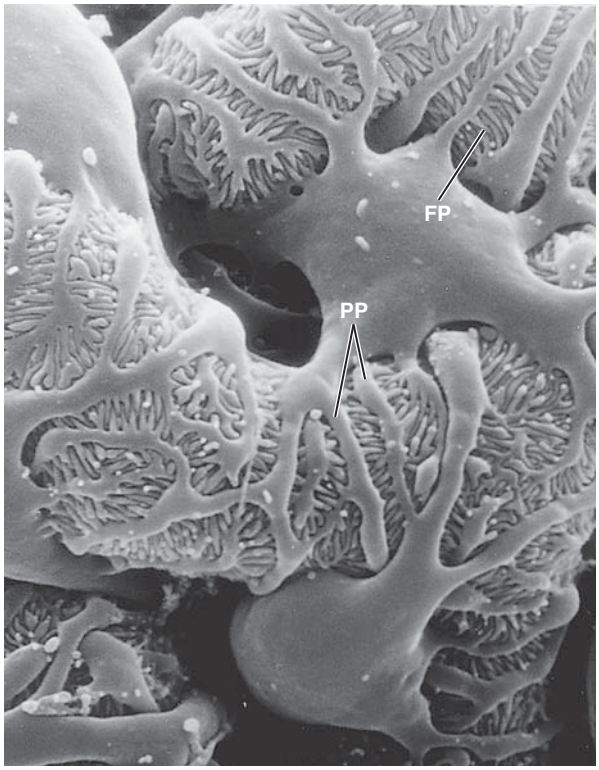

Figure 1-8 Glomerular capillaries in the rat. Urinary side of the capillary is covered by the highly branched podocytes. The interdigitating system of primary processes *(PP)* and foot processes *(FP)* lines the entire surface of the tuft, also extending beneath the cell bodies. The foot processes of neighboring cells interdigitate but spare the filtration slits in between. (Scanning electron microscopy; magnification ×2200.)

Podocytes have a voluminous cell body that floats within the urinary space, separated from the GBM by a subpodocyte space.[14] The cell bodies give rise to long primary processes that extend toward and affix to the capillaries by the most distal portions and by an extensive array of foot processes. This precarious situation of being fixed to the GBM only by the processes results in a unique vulnerability of podocytes: being lost as viable cells into the urine.[15] This is apparently the major mechanism for how podocytes are lost during life, with apoptosis (cell death) playing no relevant role.[16]

The most specific structural feature of podocytes is the pattern of foot processes covering the outer aspect of glomerular capillaries. The foot processes of neighboring podocytes regularly interdigitate with each other, leaving meandering slits (filtration slits) between the cells that are bridged by an extracellular structure, the *slit diaphragm* (Fig. 1-9; see also Figs. 1-6 to 1-8). Podocytes are polarized epithelial cells with a luminal and a basal cell membrane domain; the basal cell membrane domain corresponds to the sole plates of the foot processes that are embedded into the GBM. The border between basal and luminal membrane is the slit diaphragm.[17]

The luminal membrane and the slit diaphragm are covered by a thick surface coat that is rich in sialoglycoproteins, including podocalyxin and podoendin, and is responsible for the high negative surface charge of the podocytes. By comparison, the abluminal membrane (i.e., soles of podocyte processes) contains specific transmembrane proteins that connect the cytoskeleton to the GBM. Two systems are known: (1) $\alpha_3\beta_1$ integrin dimers interconnect the cytoplasmic focal adhesion proteins vinculin, paxillin, and talin with the α3, α4, and α5 chains of type IV collagen and laminin 521; and (2)

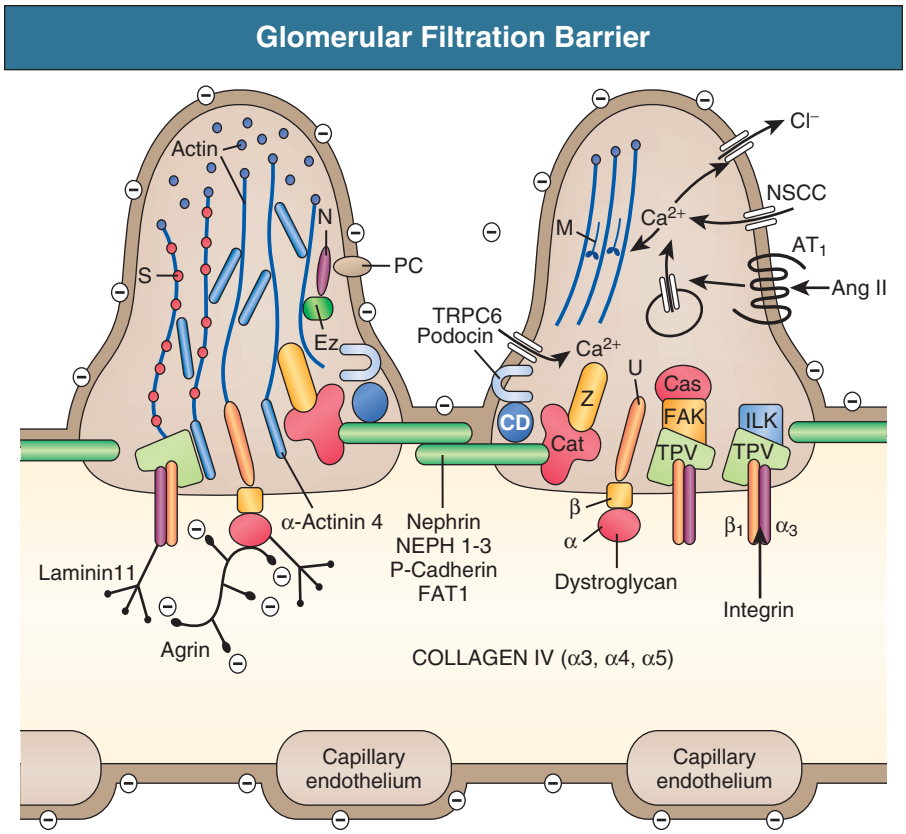

Figure 1-9 Glomerular filtration barrier. Two podocyte foot processes bridged by the slit membrane, the GBM, and the porous capillary endothelium are shown. The surfaces of podocytes and of the endothelium are covered by a negatively charged glycocalyx containing the sialoprotein podocalyxin *(PC).* The GBM is mainly composed of type IV collagen (α3, α4, and α5), laminin 11 (α5, β2, and γ1 chains), and the heparan sulfate proteoglycan agrin. The slit membrane represents a porous proteinaceous membrane composed of (as far as known) nephrin, NEPH 1-3, P-cadherin, and FAT1. The actin-based cytoskeleton of the foot processes connects to both the GBM and the slit membrane. Regarding the connections to the GBM, $\beta_1\alpha_3$ integrin dimers specifically interconnect the TPV complex (talin, paxillin, vinculin) to laminin 11; the β- and α-dystroglycans interconnect utrophin to agrin. The slit membrane proteins are joined to the cytoskeleton by various adapter proteins, including podocin, zonula occludens protein 1 (ZO-1; *Z*), CD2-associated protein *(CD),* and catenins *(Cat).* Among the nonselective cation channels *(NSCC),* TRPC6 associates with podocin (and nephrin, not shown) at the slit membrane. Only the angiotensin II *(Ang II)* type 1 receptor (AT_1) is shown as an example of the many surface receptors. *Cas,* p130Cas; *Ez,* ezrin; *FAK,* focal adhesion kinase; *ILK,* integrin-linked kinase; *M,* myosin; *N,* Na^+-H^+ exchanger regulatory factor (NHERF2); *S,* synaptopodin. *(Modified from reference 41.)*

β-α-dystroglycans interconnect the cytoplasmic adapter protein utrophin with agrin and laminin α5 chains in the GBM.[9]

In contrast to the cell body, which harbors a prominent endoplasmic reticulum and Golgi system and has well-developed autophagic machinery, the cell processes contain only a few organelles. A sophisticated cytoskeleton accounts for the complex shape of the cells. In the cell body and the primary processes, microtubules and intermediate filaments (vimentin, desmin) dominate. Within the foot processes, microfilaments form prominent U-shaped bundles arranged in the longitudinal axis of two successive foot processes in an overlapping pattern. Centrally, the bends of these bundles are linked to the microtubules of the primary processes; peripherally, the bends are linked to the GBM by integrins and dystroglycans. α-Actinin-4 and synaptopodin establish the podocyte-specific bundling of the microfilament.

Podocytes contain a great variety of surface receptors, including those for cyclic guanosine monophosphate (cGMP) signaling, stimulated by natriuretic peptides (ANP, BNP, and CNP) as well as by nitric oxide (NO); cyclic adenosine monophosphate (cAMP) signaling stimulated by prostaglandin E_2 (PGE_2), dopamine, isoproterenol, parathyroid hormone (PTH) and PTH-related peptide; and calcium ion (Ca^{2+}) signaling stimulated by numerous ligands, including Ang II, acetylcholine, PGF_2, arginine vasopressin (AVP), adenosine triphosphate (ATP), endothelin, and histamine).[17] Among the transient receptor potential (TRP) cation channels, TRPC5 and TRPC6 have recently received much attention.[18-20] The major target of this signaling orchestra is the cytoskeleton, although the concrete effects are poorly understood. Other receptors, such as for C3b, TGF-β, FGF-2, and other cytokines/chemokines, have been shown to be involved in the development of podocyte diseases.[17] Megalin is a multiligand endocytotic receptor and the major antigen of Heymann nephritis in the rat,[21] but is not present in humans.

The filtration slits are the sites of convective fluid flow through the visceral epithelium (see Figs. 1-7 and 1-9). Filtration slits have a constant width of about 30 to 40 nm and are bridged by the slit diaphragm, a proteinaceous membrane with an incompletely defined molecular composition. Chemically fixed and tannic acid–treated tissue reveals a zipper-like structure with a row of pores approximately 14 nm^2 on either side of a central bar. Currently, the proteins known to establish the slit membrane or mediate its connection to the actin cytoskeleton of the foot processes include nephrin, P-cadherin, FAT1, NEPH 1-3, and podocin.[17] However, how these molecules interact with each other to establish a size-selective porous membrane is not yet known. In addition to its barrier function, the slit membrane is a platform for signaling to the cytoskeleton.[22]

Parietal Epithelium

The parietal epithelium of Bowman capsule consists of squamous epithelial cells resting on a basement membrane (see Figs. 1-4 and 1-5). The flat cells are filled with bundles of actin filaments running in all directions. In contrast to the GBM, the parietal basement membrane comprises several proteoglycan-dense layers that, in addition to type IV, contain type XIV collagen. The predominant proteoglycan of the parietal basement membrane is a chondroitin sulfate proteoglycan.[23] Recent observations suggest that a niche of glomerular epithelial stem cells resides within the parietal epithelium at the transition to the proximal tubule,[24] but unequivocal evidence is lacking.

Filtration Barrier

Filtration through the glomerular capillary wall occurs along an extracellular pathway, including the endothelial pores, GBM, and slit diaphragm (see Figs. 1-7 and 1-9). All these components are quite permeable for water; the high permeability for water, small solutes,

and ions results because no cell membranes are interposed. The hydraulic conductance of the individual layers of the filtration barrier is difficult to study. In a mathematical model of glomerular filtration, the hydraulic resistance of the endothelium was predicted to be small, whereas the GBM and the filtration slits each contribute about one half to the total hydraulic resistance of the capillary wall.[25]

The barrier function of the glomerular capillary wall for macromolecules is selective for size, shape, and charge.[17] The charge selectivity of the barrier results from the dense accumulation of negatively charged molecules throughout the entire depth of the filtration barrier, including the surface coat of endothelial cells, and from the high content of negatively charged heparan sulfate proteoglycans in the GBM. Polyanionic macromolecules, such as plasma proteins, are repelled by the electronegative shield originating from these dense assemblies of negative charges.

The crucial structure accounting for the size selectivity of the filtration barrier appears to be the slit diaphragm.[25] Uncharged macromolecules up to an effective radius of 1.8 nm pass freely through the filter. Larger components are increasingly restricted (indicated by their fractional clearances, which progressively decrease) and are totally restricted at effective radii of more than 4 nm. Plasma albumin has an effective radius of 3.6 nm; without the repulsion from the negative charge, plasma albumin would pass through the filter in considerable amounts. As recently proposed, an electric field (streaming potential) may be generated by filtration across the glomerular capillary wall, which in turn may prevent the passage of the negatively charged plasma proteins across the barrier by electrophoresis.[26]

Stability of Glomerular Tuft

The main challenge for the glomerular capillaries is to combine selective leakiness with stability. The capillary walls are constantly exposed to high transmural pressure gradients from the high perfusion pressure of glomerular capillaries.

The major system for the maintenance of the complex structure of the tuft consists of the GBM and the mesangium. In fact, cylinders of the GBM largely define the shape of glomerular capillaries. These cylinders do not completely encircle the capillary tube, however, and are open toward the mesangium. Mechanically, the cylinders are completed by contractile mesangial cell processes that bridge the gaps of the GBM between two opposing mesangial angles, permitting these two structures together to develop wall tension.[27]

Traditionally, podocytes have been interpreted as a type of pericyte contributing to the development of wall tension by varying the tonus of its contractile system. In a recent challenge to this view,[16] however, the only remaining system capable of creating wall tension consists of the open cylinders of the GBM bridged by mesangial cells.

In addition to the need to develop wall tension to prevent dilation of glomerular capillaries, the folding pattern of the GBM (i.e., arrangement of glomerular capillaries) must be stabilized against the centrifugal pressure gradients as well. This occurs by interconnecting the turning points of the GBM by mesangial cells from inside and by podoytes from outside.[10]

Renal Tubule

The renal tubule is subdivided into several distinct segments: a proximal tubule, an intermediate tubule, a distal tubule, a connecting tubule (CNT), and the collecting duct (see Fig. 1-1 and Table 1-1).[1,2] The loop of Henle comprises the straight part of the proximal tubule (representing thick descending limb), the thin descending and thin ascending limbs (representing intermediate tubule), and the thick ascending limb (representing straight portion of distal tubule),

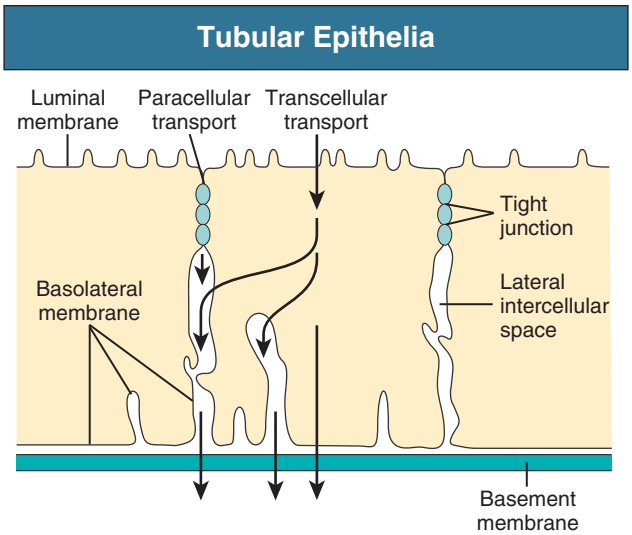

Figure 1-10 Tubular epithelia. Transport across the epithelium may follow two routes: transcellular, across luminal and basolateral membranes, and paracellular, through the tight junction and intercellular spaces.

which includes the macula densa. The CNT and various collecting duct segments form the collecting duct system.

The renal tubules are outlined by a single-layer epithelium anchored to a basement membrane. The epithelium is a transporting epithelium consisting of flat or cuboidal epithelial cells connected apically by a junctional complex consisting of a tight junction (zonula occludens), an adherens junction, and rarely a desmosome. As a result of this organization, two different pathways through the epithelium exist (Fig. 1-10): a *transcellular* pathway, including transport across the luminal and basolateral cell membranes and through the cytoplasm, and a *paracellular* pathway through the junctional complex and lateral intercellular spaces. The functional characteristics of paracellular transport are determined by the tight junction, which differs greatly in its elaboration in the various tubular segments. Transcellular transport is determined by the specific channels, carriers, and transporters included in the apical and basolateral cell membranes. The various nephron segments differ in function, distribution of transport proteins, and responsiveness to hormones and drugs such as diuretics.

Proximal Tubule

The proximal tubule reabsorbs the bulk of filtered water and solutes (Fig. 1-11, *A*). The epithelium shows numerous structural adaptations to this role. The proximal tubule has a prominent brush border (increasing the luminal cell surface area) and extensive interdigitation by basolateral cell processes (increasing the basolateral cell surface area). This lateral cell interdigitation extends up to the leaky tight junction, thus increasing the tight junctional belt in length and providing a greatly increased passage for the passive transport of ions. Proximal tubules have large, prominent mitochondria intimately associated with the basolateral cell membranes, where the sodium-potassium (Na^+,K^+)–adenosine triphosphatase (ATPase) is located; this machinery dominates the transcellular transport. The luminal transporter for Na^+ entry specific for the proximal tubule is the sodium-hydrogen ion (Na^+-H^+) exchanger. The high hydraulic permeability for water is rooted in abundant occurrence of the water channel protein aquaporin 1 (AQP1). A prominent lysosomal system is known as the "apical vacuolar endocytotic apparatus" and is responsible for the reabsorption of macromolecules (polypeptides

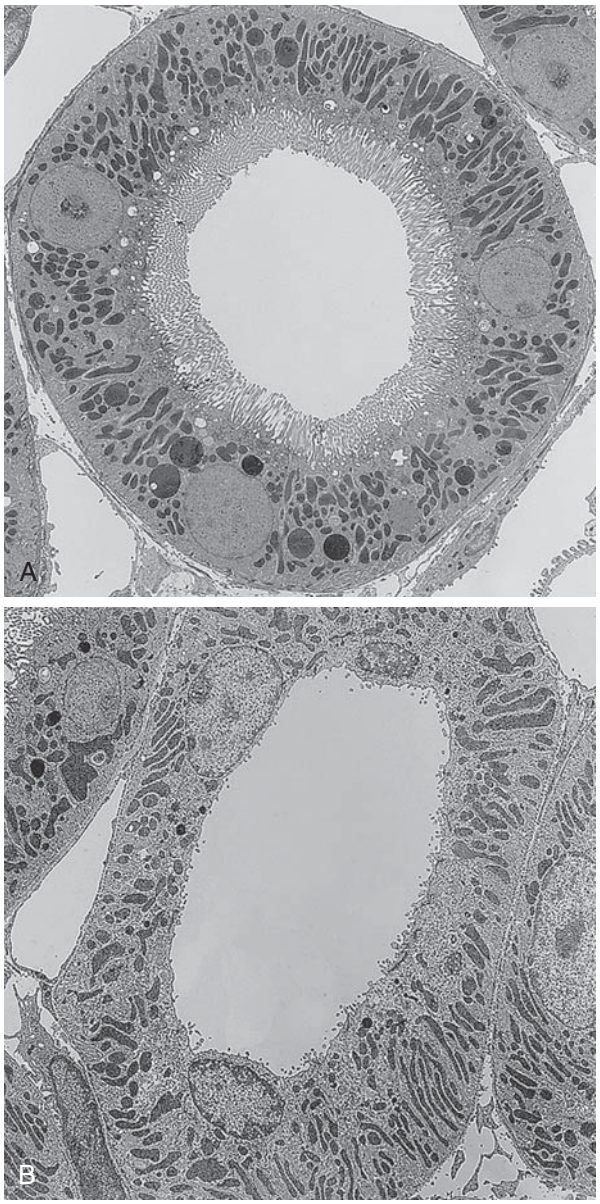

Figure 1-11 Tubules of the renal cortex. A, Proximal convoluted tubule is equipped with a brush border and a prominent vacuolar apparatus in the apical cytoplasm. The rest of the cytoplasm is occupied by a basal labyrinth consisting of large mitochondria associated with basolateral cell membranes. **B,** Distal convoluted tubule also has interdigitated basolateral cell membranes intimately associated with large mitochondria. In contrast to the proximal tubule, however, the apical surface is amplified only by some stubby microvilli. (TEM; **A,** ×1530; **B,** ×1830.)

and proteins such as albumin) that have passed through the glomerular filter. The proximal tubule is generally subdivided into three segments (known as S_1, S_2, S_3, or P_1, P_2, P_3) that differ considerably in cellular organization and therefore also in function.[28]

Loop of Henle

The loop of Henle consists of the straight portion of the proximal tubule, thin descending limb and (in long loops) thin ascending limb, and thick ascending limb (Fig. 1-12; see also Fig. 1-2). The thin descending limb, as with the proximal tubule, is highly permeable for water (channels are of AQP1), whereas beginning exactly at the turning point, the thin ascending limb is impermeable for water. The specific transport functions of the thin limbs of Henle contributing

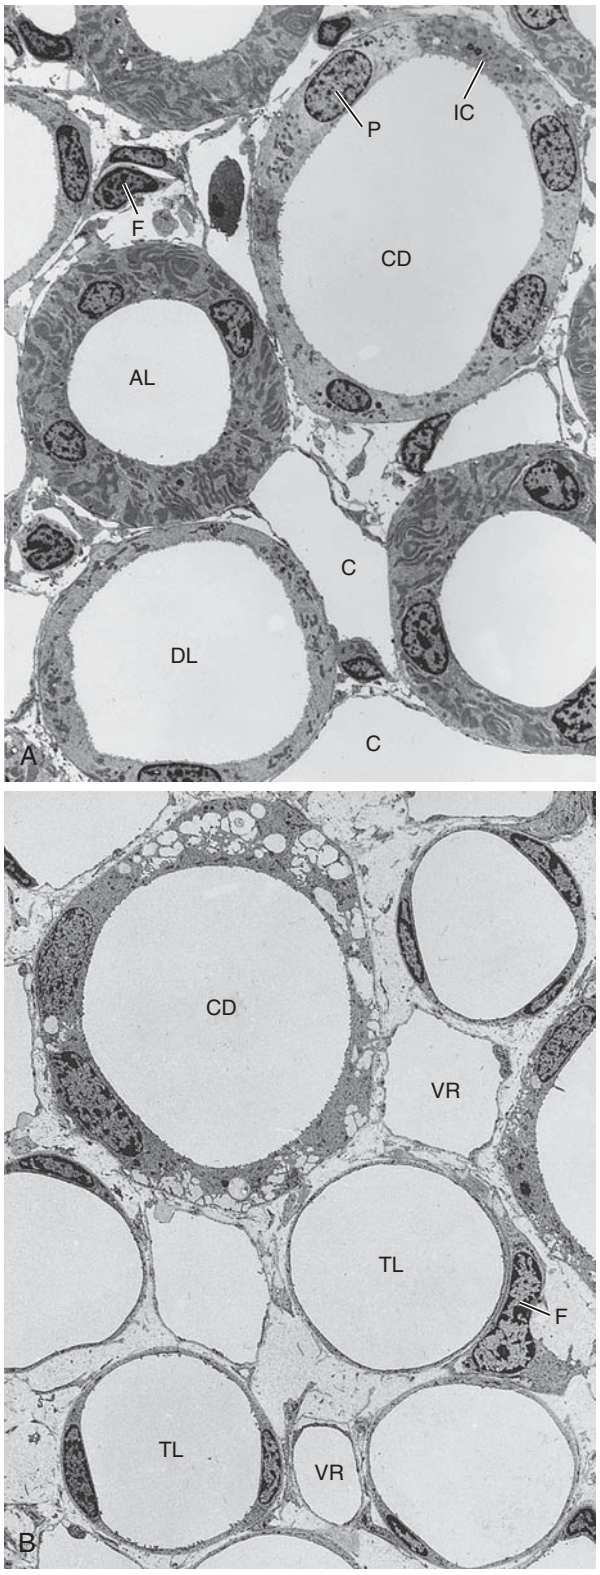

Figure 1-12 Tubules in the medulla. A, Cross section through the inner stripe of the outer medulla shows a descending thin limb of a long Henle loop *(DL),* the medullary thick ascending limbs of Henle *(AL),* and a collecting duct *(CD)* with principal cells *(P)* and intercalated cells *(IC); C,* peritubular capillaries; *F,* fibroblast. **B,** In the inner medulla cross section, thin descending and ascending limbs *(TL),* a collecting duct *(CD),* and vasa recta *(VR)* are seen. (TEM; **A,** ×990; **B,** ×1120.)

to the generation of the osmotic medullary gradient are under debate.

The thick ascending limb of Henle is often called the "diluting segment." It is water impermeable but reabsorbs considerable sodium chloride (NaCl, salt), resulting in the separation of salt from water. The salt is trapped in the medulla, whereas the water is carried to the cortex, where it may return into the systemic circulation. The specific transporter for Na^+ entry in this segment is the luminal Na^+-K^+-$2Cl^-$ cotransporter, which is the target of diuretics such as furosemide. The tight junctions of the thick ascending limb have a comparatively low permeability. The cells heavily interdigitate by basolateral cell processes, associated with large mitochondria supplying the energy for the transepithelial transport. The cells synthesize a specific protein, the Tamm-Horsfall protein, and release it into the tubular lumen. Tamm-Horsfall protein is thought to be important later for preventing the formation of kidney stones. In contrast to the proximal tubule, the luminal membrane is only sparsely amplified by microvilli. Just before the transition to the distal convoluted tubule, the thick ascending limb of Henle contains the macula densa, which adheres to the parent glomerulus (see Juxtaglomerular Apparatus).

Distal Convoluted Tubule

The epithelium is quite highly differentiated, exhibiting the most extensive basolateral interdigitation of the cells and the greatest density of mitochondria in all nephron portions (see Fig. 1-11, *B*). Apically, the cells are equipped with numerous microvilli. The specific Na^+ transporter of the distal convoluted tubule is the luminal Na^+-Cl^- cotransporter, which is the target of thiazide diuretics.

The apical cell membrane bears some stubby microvilli covered by a prominent glycocalyx; the basal cell membrane forms invaginations. Note the deep tight junction. **B,** Intercalated cells, type A. Note the dark cytoplasm (dark cells) with many mitochondria and apical microfolds; the basal membrane forms invaginations. (TEM; **A,** ×8720; **B,** ×6970.)

COLLECTING DUCT SYSTEM

The collecting duct system includes the CNT and the cortical and medullary collecting ducts (see Fig. 1-2). Two nephrons may join at the level of the CNT, forming an arcade that cytologically is a CNT. Two types of cell line the connecting tubule: the CNT cell, which is specific to CNTs, and the intercalated (IC) cell, which also occurs later in the collecting duct. The CNT cells are similar to the collecting duct (CD) cells in cellular organization. Both cell types share sensitivity to vasopressin (see next section); the CNT cell, however, lacks sensitivity to mineralocorticoids.

Collecting Ducts

The collecting ducts may be subdivided into cortical and medullary ducts, and the medullary ducts into outer and inner; the transitions are gradual (see Fig. 1-12). As with the CNT, the collecting ducts are lined by two types of cell: CD cells (principal cells) and IC cells. The IC cells decrease in number as the collecting duct descends into the medulla and are absent from the papillary collecting ducts.

The CD cells are simple, polygonal cells increasing in size toward the tip of the papilla (Fig. 1-13, *A*). The basal surface of these cells is characterized by invaginations of the basal cell membrane (basal infoldings). The tight junctions have great apicobasal depth, and the apical cell surface has a prominent glycocalyx. Along the entire collecting duct, these cells contain a luminal shuttle system for aquaporin 2 under the control of antidiuretic hormone (ADH, vasopressin), providing the potential to switch the water permeability of the collecting ducts from zero (or at least from low) to permeable.[29] A luminal amiloride-sensitive Na^+ channel is involved in the responsiveness of cortical collecting ducts to aldosterone. The terminal portions of the collecting duct in the inner medulla express the urea transporter UTB1, which in ADH-dependent manner accounts for the recycling of urea, a process that is crucial in the urine-concentrating mechanism.[30]

The second cell type, the IC cell, is present in both the CNT and the collecting duct (Fig. 1-13, *B*). There are at least two types, designated A and B intercalated cells, distinguished by structural, immunocytochemical, and functional characteristics. Type A cells have been defined as expressing H^+-ATPase at their luminal membrane; these IC cells secrete protons. Type B cells express the H^+-ATPase at their basolateral membrane; these IC cells secrete bicarbonate (HCO_3^-) ions and reabsorb protons.[31]

With these different cell types, the collecting ducts are the final regulators of fluid and electrolyte balance, playing important roles in the handling of Na^+, Cl^-, and K^+, as well as acid and base. The responsiveness of the collecting ducts to vasopressin enables an organism to live in arid conditions, allowing it to produce a concentrated urine and, if necessary, a dilute urine.

JUXTAGLOMERULAR APPARATUS

The juxtaglomerular apparatus comprises the macula densa, the extraglomerular mesangium, the terminal portion of the afferent arteriole with its renin-producing granular cells (also often termed *juxtaglomerular cells*), and the beginning portions of the efferent arteriole (see Fig. 1-4).

The macula densa is a plaque of specialized cells in the wall of the thick ascending limb of Henle at the site where the limb attaches to the extraglomerular mesangium of the parent glomerulus (Fig. 1-14, *A*; see also Fig. 1-5). The most obvious structural feature is the

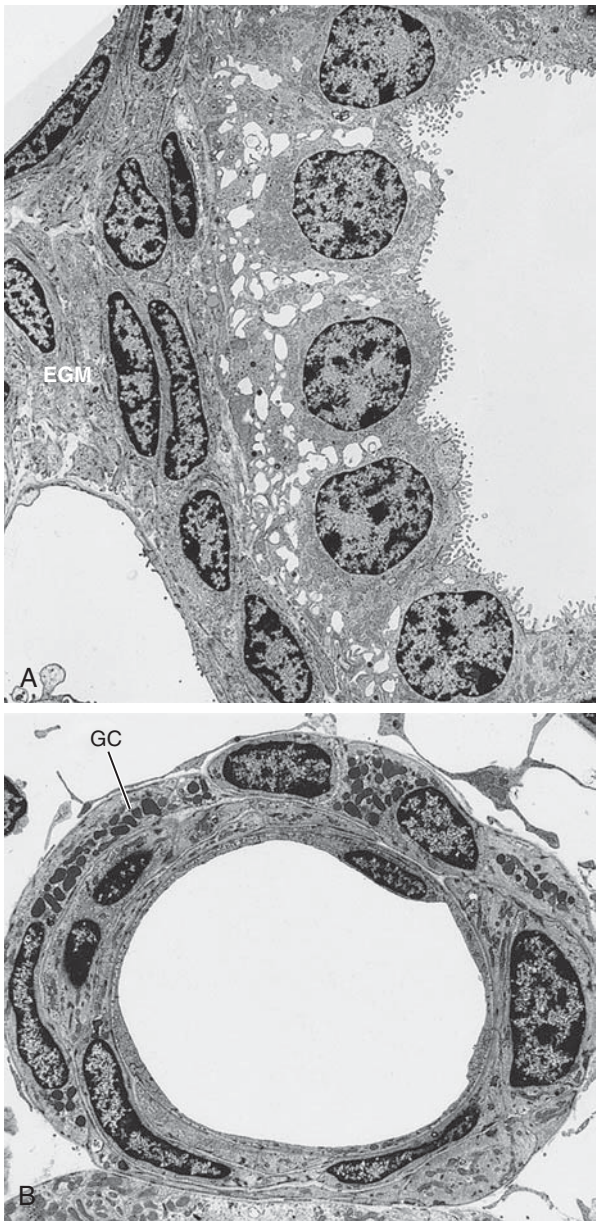

Figure 1-14 Juxtaglomerular apparatus. A, Macula densa of a thick ascending limb of Henle. The cells have prominent nuclei and lateral intercellular spaces. Basally, they attach to the extraglomerular mesangium *(EGM).* **B,** Afferent arteriole near the vascular pole. Several smooth muscle cells are replaced by granular cells *(GC)* containing accumulations of renin granules. (TEM; **A,** ×1730; **B,** ×1310.)

narrowly packed cells with large nuclei, which account for the name macula *densa.* The cells are anchored to a basement membrane, which blends with the matrix of the extraglomerular mesangium. The cells are joined by tight junctions with very low permeability and have prominent lateral intercellular spaces. The width of these spaces varies under different functional conditions.[1] The most conspicuous immunocytochemical difference between macula densa cells and other epithelial cells of the nephron is the high content of neuronal nitric oxide synthase and cyclooxygenase-2 in macula densa cells.[32,33]

The basal aspect of the macula densa is firmly attached to the extraglomerular mesangium, a solid complex of cells and matrix penetrated by neither blood vessels nor lymphatic capillaries. As with the mesangial cells proper, extraglomerular mesangial cells are heavily branched. Their processes are interconnected by gap junctions, contain prominent bundles of microfilaments, and are connected to the basement membrane of Bowman capsule as well as to the walls of both glomerular arterioles. As a whole, the extraglomerular mesangium interconnects all structures of the glomerular entrance.[6]

The granular cells are assembled in clusters within the terminal portion of the afferent glomerular arteriole (Fig. 1-14, *B*), replacing ordinary smooth muscle cells. "Granular" refers to the specific cytoplasmic granules in which renin, the major secretion product of these cells, is stored. Granular cells are the main site of the body where renin is secreted. Renin release occurs by exocytosis into the surrounding interstitium. Granular cells are connected to extraglomerular mesangial cells, adjacent smooth muscle cells, and endothelial cells by gap junctions and are densely innervated by sympathetic nerve terminals. Granular cells are modified smooth muscle cells; under conditions requiring enhanced renin synthesis (e.g., volume depletion, renal artery stenosis), additional smooth muscle cells located upstream in the wall of the afferent arteriole may transform into granular cells.

The structural organization of the juxtaglomerular apparatus suggests a regulatory function. Some component of the distal urine, probably chloride, is sensed by the macula densa. This information is used first to adjust the tone of the glomerular arterioles, producing a change in glomerular blood flow and filtration rate. Even if many details of this mechanism are still subject to debate, studies have verified the essence of this system, known as the "tubular glomerular feedback mechanism."[34] Second, the juxtaglomerular system determines the amount of renin that is released, through the interstitium, into the circulation, thereby acquiring great systemic relevance.[35,36]

RENAL INTERSTITIUM

The interstitium of the kidney is comparatively sparse. Its fractional volume in the cortex ranges from 5% to 7%, with a tendency to increase with age. Renal interstitium increases across the medulla from cortex to papilla. In the outer stripe, it is 3% to 4%, the lowest value of all kidney zones; this is interpreted as forming a barrier to prevent loss of solutes from a hyperosmolar medulla into the cortex. Renal interstitium is 10% in the inner stripe and up to about 30% in the inner medulla. The cellular constituents of the interstitium include resident fibroblasts, which establish the scaffold frame for renal corpuscles, tubules, and blood vessels, as well as varying numbers of migrating cells of the immune system, especially dendritic cells. The space between the cells is filled with extracellular matrix, namely, ground substance (proteoglycans, glycoproteins), fibrils, and interstitial fluid.[37]

Morphologically, fibroblasts are the central cells in the renal interstitium. Fibroblasts are interconnected by specialized contacts and adhere by specific attachments to the basement membranes surrounding the tubules, renal corpuscles, capillaries, and lymphatics.

Renal fibroblasts are difficult to distinguish from interstitial dendritic cells on a morphologic basis because both may show a stellate cellular shape and both display substantial amounts of mitochondria and endoplasmic reticulum. However, renal fibroblasts may easily be distinguished by immunocytochemical techniques. Dendritic cells constitutively express the major histocompatibility complex class II antigen and may express antigens such as CD11c. Dendritic cells may have an important role in maintaining peripheral tolerance in the kidney (Fig. 1-15).[38] In contrast, fibroblasts in the renal cortex (not in the medulla) contain the enzyme ecto-5′-nucleotidase (5′-NT). A subset of 5′-NT–positive fibroblasts of the renal cortex

synthesizes epoetin.[39] Under normal conditions, these fibroblasts are exclusively found within the juxtamedullary portions of the cortical labyrinth. When there is an increasing demand for epoetin, the synthesizing cells extend to more superficial portions of the cortical labyrinth and, to a lesser degree, to the medullary rays.[40]

Fibroblasts within the medulla, especially within the inner medulla, have a particular phenotype known as *lipid-laden interstitial cells*. The cells are oriented strictly perpendicularly toward the longitudinal axis of the tubules and vessels (running all in parallel) and contain conspicuous lipid droplets. These fibroblasts of the inner medulla produce large amounts of glycosaminoglycans and, possibly related to the lipid droplets, vasoactive lipids, in particular PGE_2.[38]

The intrarenal arteries are accompanied by a prominent sheath of loose interstitial tissue (Fig. 1-16); the renal veins are in apposition to this sheath but not included in it. Intrarenal nerve fibers and lymphatics run within this periarterial tissue. Lymphatics start in the vicinity of the afferent arteriole and leave the kidney running within the periarterial tissue sheath toward the hilum. Together with the lymphatics, the periarterial tissue constitutes a pathway for interstitial fluid drainage of the renal cortex; the renal medulla has no lymphatic drainage.

CHAPTER 2

Renal Physiology

Matthew A. Bailey, David G. Shirley, and Robert J. Unwin

The prime function of the kidney is to maintain a stable *milieu intérieur* by the selective retention or elimination of water, electrolytes, and other solutes. This is achieved by three processes: (1) filtration of circulating blood from the glomerulus to form an ultrafiltrate of plasma in the urinary space (Bowman space), (2) selective reabsorption (from tubular fluid to blood) across the cells lining the renal tubule, and (3) selective secretion (from peritubular capillary blood to tubular fluid).

GLOMERULAR STRUCTURE AND ULTRASTRUCTURE

The process of urine formation begins by the production of an ultrafiltrate of plasma. Chapter 1 describes glomerular anatomy and ultrastructure, so this discussion provides only the essentials for understanding how the ultrafiltrate is formed. The pathway for ultrafiltration of plasma from the glomerulus to Bowman space consists of the fenestrated capillary endothelium, the capillary basement membrane, and the visceral epithelial cell layer (podocytes) of Bowman capsule; the podocytes have large cell bodies and make contact with the basement membrane only by cytoplasmic foot processes. Mesangial cells, which fill the spaces between capillaries, have contractile properties and are capable of altering the capillary surface area available for filtration.

Filtration is determined principally by the molecular size and shape of the solute and, to a much lesser extent, by its charge. The size cutoff is not absolute; resistance to filtration begins at an effective molecular radius of slightly less than 2 nm, whereas substances with an effective radius exceeding about 4 nm are not filtered at all. The fenestrations between capillary endothelial cells have a diameter of 50 to 100 nm. The podocyte foot processes have gaps with a diameter of 30 to 40 nm, although these filtration slits are bridged by the slit diaphragms, which are themselves penetrated by small pores. The slit diaphragms likely constitute the main filtration barrier, although both the endothelium (by preventing the passage of blood cells) and the basement membrane contribute.[1] The "subpodocyte space" also provides an additional and variable resistance to glomerular filtration.[2] Furthermore, the podocytes and the endothelial cells are covered by a glycocalyx composed of negatively charged glycoproteins, glycosaminoglycans, and proteoglycans, and the basement membrane is rich in heparan sulfate proteoglycans. This accumulation of fixed negative charges further restricts the filtration of large, negatively charged ions, mainly proteins (Fig. 2-1). Thus, with an effective radius (3.6 nm) permitting significant filtration, albumin is normally almost completely excluded. If these fixed negative charges are lost, as in some forms of early or mild glomerular disease (e.g., minimal change disease), albumin filterability increases and proteinuria results. Although it has been proposed that albumin is normally filtered and then almost completely reabsorbed along the proximal tubule, the evidence is controversial. The glomerular barrier is usually considered as a passive unidirectional filter. However, recent studies indicate that filtration pressure generates a potential difference between the glomerular capillaries and Bowman space. Although small in magnitude, this potential difference may help to clear the filter continuously, driving negatively charged proteins such as albumin out of the slit diaphragm and back into the blood.[3]

GLOMERULAR FILTRATION RATE

At the level of the single glomerulus, the driving force for glomerular filtration (the *net ultrafiltration pressure*) is determined by the net hydrostatic and oncotic (colloid osmotic) pressure gradients between glomerular plasma and the filtrate in Bowman space. The single-nephron glomerular filtration rate (SNGFR) is determined by the product of the net ultrafiltration pressure and the *ultrafiltration coefficient;* the latter being a composite of the surface area available for filtration and the hydraulic conductivity of the glomerular membranes. Therefore, the single-nephron glomerular filtration rate is as follows:

$$K_f[(P_{gc} - P_{bs}) - (\pi_{gc} - \pi_{bs})]$$

where K_f is the ultrafiltration coefficient, P_{gc} is glomerular capillary hydrostatic pressure (~45 mm Hg), P_{bs} is Bowman space hydrostatic pressure (~10 mm Hg), π_{gc} is glomerular capillary oncotic pressure (~25 mm Hg), and π_{bs} is Bowman space oncotic pressure (0 mm Hg).

Net ultrafiltration pressure is about 10 mm Hg at the afferent end of the capillary tuft. As filtration of plasma from blood proceeds along the glomerular capillaries, proteins are concentrated and the glomerular capillary oncotic pressure (π_{gc}) increases. Theoretically, toward the efferent end of a glomerular capillary, π_{gc} may equal the net hydrostatic pressure gradient, at which point ultrafiltration pressure would fall to zero: *filtration equilibrium* in the human kidney is approached, but rarely (if ever) achieved (Fig. 2-2).

The total glomerular filtration rate (GFR) is the sum of the SNGFRs of the functioning nephrons in each kidney. The normal range for GFR is wide but typically cited at about 120 ml/min per 1.73 m^2 surface area. GFR can be measured with renal clearance techniques. The renal clearance of any substance not metabolized by the kidneys is the volume of plasma required to provide that amount of the substance excreted in the urine per unit time. This is a virtual volume that can be expressed mathematically as follows:

$$C_y = U_y / P_y \times V$$

where C_y is the renal clearance of *y;* U_y and P_y is the concentration of *y* in the urine and plasma, respectively; and *V* is the urine flow rate. If a substance is freely filtered by the glomerulus and is not reabsorbed or secreted by the tubule, its renal clearance equals GFR; that is, renal clearance measures the volume of plasma filtered through the glomeruli per unit time. The various methods for measuring GFR and their pitfalls are discussed in Chapter 3.

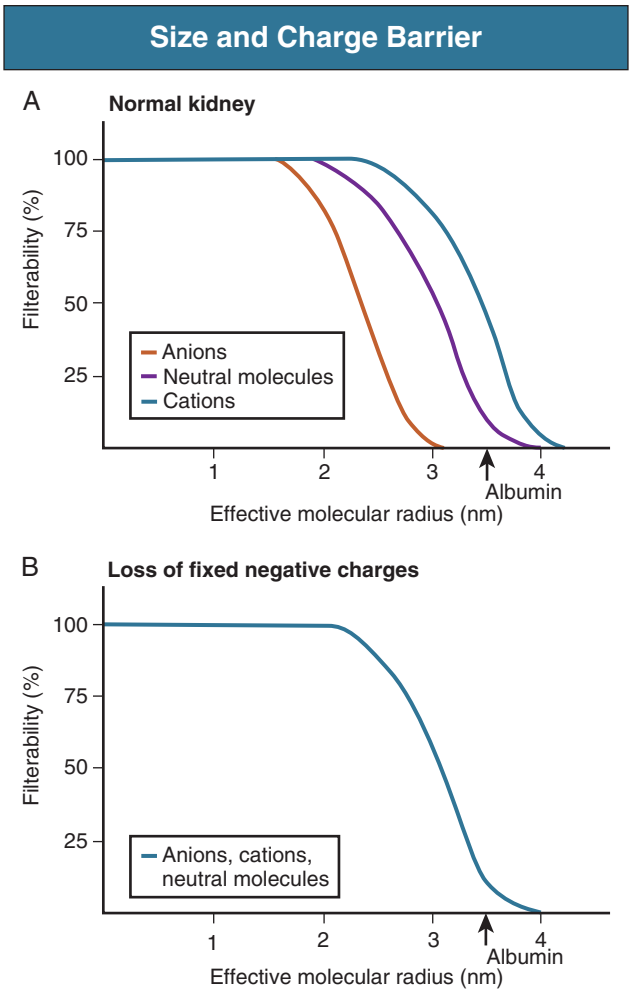

Figure 2-1 Effects of size and electrical charge on filterability. **A,** Normal kidney. **B,** Loss of fixed negative charges. Filterability of 100% indicates that the substance is freely filtered; that is, its concentration in Bowman space equals that in glomerular capillary plasma. For molecules and small ions (e.g., Na^+, Cl^-), charge has no effect on filterability; but for ions whose effective molecular radius exceeds 1.6 nm, anions are filtered less easily than neutral molecules or cations. Thus insignificant amounts of albumin (anion) are normally filtered. If the fixed negative charges of the glomerular basement membranes are lost, as in early minimal change nephropathy, charge no longer influences filterability; consequently, significant albumin filtration occurs.

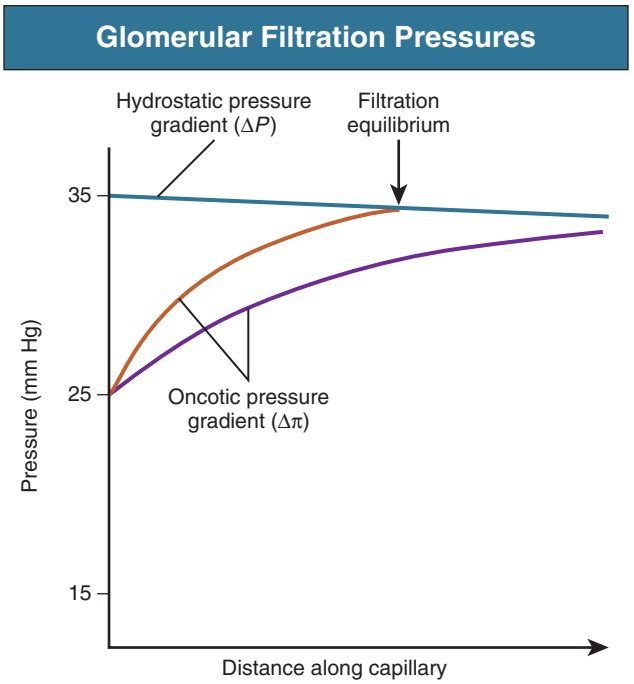

Figure 2-2 Glomerular filtration pressures along a glomerular capillary. The hydrostatic pressure gradient ($\Delta P = P_{gc} - P_{bs}$) is relatively constant along the length of a capillary, whereas the opposing oncotic pressure gradient ($\Delta\pi = \pi_{gc}$) increases as protein-free fluid is filtered, thereby reducing net ultrafiltration pressure. Two curves are shown, one where filtration equilibrium is reached and one where it is merely approached.

MEASUREMENT OF RENAL PLASMA FLOW

The use of the clearance technique and the availability of substances that undergo both glomerular filtration and virtually complete (or *effective*) tubular secretion have made it possible to measure renal plasma flow (RPF; typically ~650 ml/min). Para-aminohippuric acid (PAH, hippurate) is an organic acid that is filtered by the glomerulus and actively secreted by the proximal tubule through organic anion transporters in the cell membranes. The amount of PAH found in the urine is the sum of that filtered plus that secreted. PAH clearance is a robust marker of RPF when the plasma concentration is less than 10 mg/dl, because most of the PAH reaching the peritubular capillaries is cleared by tubular secretion. Under these circumstances, little PAH appears in renal venous plasma and the amount found in the final urine approximates that delivered to the kidneys in the plasma. Therefore:

$$RPF \times P_{PAH} = U_{PAH} \times V$$

$$or\ RPF = (U_{PAH} \times V)/P_{PAH} = PAH\ clearance$$

where U_{PAH} and P_{PAH} are the concentrations of PAH in the urine and plasma, respectively, and V is the urine flow rate. Renal blood flow (RBF) can be calculated as follows:

$$RBF = [RPF/(100 - Hematocrit)] \times 100$$

Typically, RBF is about 1200 ml/min.

The most important limitation of this method is the renal extraction of PAH, which is always less than 100%. At high plasma concentrations, greater than 10 to 15 mg/dl, the tubular transport proteins become saturated, the fractional tubular secretion of PAH declines, and considerable amounts of PAH appear in the renal veins. Under these circumstances, PAH clearance significantly underestimates RPF. In patients with liver or renal failure, the production of toxins and weak organic acids can interfere with PAH secretion or cause tubular damage, leading to inhibition of PAH transport. Certain drugs, such as probenecid, are organic acids and compete with PAH for tubular secretion, thereby reducing PAH clearance. Also, the expression of transport proteins that mediate PAH secretion is hormonally regulated, and the clearance of PAH can therefore change independent of true RPF.

AUTOREGULATION OF RENAL BLOOD FLOW AND GLOMERULAR FILTRATION RATE

Although acute physiologic variations in arterial blood pressure inevitably cause corresponding changes in RBF and GFR, these are short-lived because compensatory mechanisms return both RBF and GFR toward normal within a few seconds.[4] This is the phenomenon of *autoregulation* (Fig. 2-3). Autoregulation is achieved primarily at

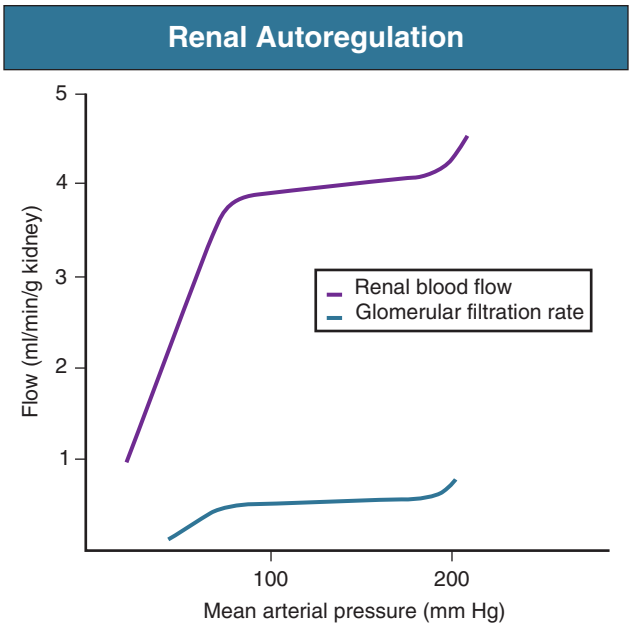

Figure 2-3 Renal autoregulation of renal blood flow and glomerular filtration rate. If mean arterial blood pressure is in the range of 80 to 180 mm Hg, fluctuations in blood pressure have only marginal effects on renal blood flow and glomerular filtration rate. This is an intrinsic mechanism and can be modulated or overridden by extrinsic factors.

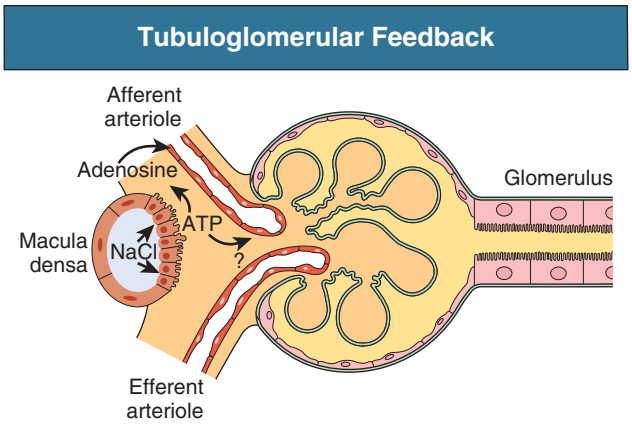

Figure 2-4 Tubuloglomerular feedback. Changes in the delivery of NaCl to the macula densa region of the thick ascending limb of Henle loop cause changes in the afferent arteriolar caliber. The response is mediated by adenosine triphosphate *(ATP),* either directly or after metabolism to adenosine, and modulated by other locally produced agents such as angiotensin II and nitric oxide. Increased macula densa NaCl delivery results in afferent arteriolar constriction, thereby reducing GFR.

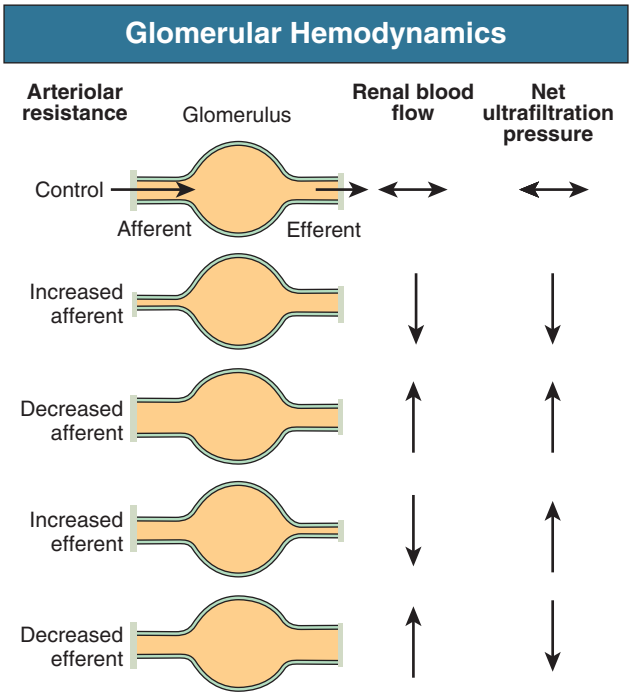

Figure 2-5 Glomerular hemodynamics. Changes in afferent or efferent arteriolar resistance will alter renal blood flow and (usually) net ultrafiltration pressure. However, the effect on ultrafiltration pressure depends on the relative changes in afferent and efferent arteriolar resistance. The overall effect on glomerular filtration rate will depend not only on renal blood flow and net ultrafiltration pressure, but also on the ultrafiltration coefficient (K_f; see Table 2-1).

the level of the afferent arterioles and believed to result from a combination of the following two mechanisms:

Myogenic reflex. Afferent arteriolar smooth muscle wall constricts automatically when renal perfusion pressure rises.

Tubuloglomerular feedback (TGF). Increased delivery of sodium chloride (NaCl) to the nephron's macula densa region (specialized plaque of cells at distal end of ascending limb of Henle) results from increases in renal perfusion pressure and causes vasoconstriction of the afferent arteriole supplying the same nephron's glomerulus.

Because these mechanisms restore both RBF and P_{gc} toward normal, the initial change in GFR is also reversed. The TGF system is possible because of the juxtaglomerular apparatus (see Chapter 1), which consists of the macula densa region of each nephron and the adjacent glomerulus and afferent and efferent arterioles (Fig. 2-4). The primary mediator of TGF is adenosine triphosphate (ATP). Increased NaCl delivery to the macula densa leads to increased NaCl uptake by these cells, which triggers ATP release into the surrounding extracellular space.[5] It is thought that ATP has a direct vasoconstrictor effect, acting on $P2X_1$ purinoceptors on afferent arteriolar cells; although evidence also indicates that nucleotidases present in this region degrade ATP to adenosine, which, acting on afferent arteriolar A_1 receptors, can also cause vasoconstriction.[6] The sensitivity of TGF is modulated by locally produced angiotensin II, nitric oxide, and certain eicosanoids (see later discussion).

The TGF regulation of filtration rate may be more complex than typically described, with evidence for regulatory crosstalk between the distal nephron and the vasculature at sites beyond the macula densa,[7] as well as for synchronization of blood flow across networks of nephrons in response to changes in sodium delivery.[8]

Despite renal autoregulation, a number of extrinsic factors (nervous and humoral) can alter renal hemodynamics. Independent or unequal changes in the resistance of afferent and efferent glomerular arterioles, together with alterations in K_f (thought to result largely from mesangial cell contraction/relaxation), can result in disproportionate, or even contrasting, changes in RBF and GFR. In addition, changes in regional vascular resistance can alter the distribution of blood flow within the kidney. For example, medullary vasoconstriction may affect whole-kidney blood flow because blood can be diverted through the cortex: nevertheless, this renders the medulla hypoxic and vulnerable to ischemic injury.[9] Figure 2-5 indicates how,

Physiologic and Pharmacologic Influences on Glomerular Hemodynamics

	Arteriolar Resistance

Table 2-1 Physiologic and pharmacologic influences on glomerular hemodynamics. The overall effect on glomerular filtration rate (GFR) will depend on renal blood flow, net ultrafiltration pressure, and the ultrafiltration coefficient (K_f), which is controlled by mesangial cell contraction and relaxation. The effects shown are those seen when the agents are applied (or inhibited) in isolation; the actual changes that occur are dose dependent and are modulated by other agents. *ACE,* Angiotensin-converting enzyme; *ARBs,* angiotensin receptor blockers; *ANP,* atrial natriuretic peptide; *NSAIDs,* nonsteroidal anti-inflammatory drugs: *PGE_2/PGI_2*, prostaglandins E_2 and I_2.
*In clinical practice, GFR is usually either decreased or unaffected.

in principle, changes in afferent and efferent arteriolar resistance can affect net ultrafiltration. Table 2-1 outlines vasoactive factors that alter renal hemodynamics (see Integrated Control of Renal Function). In addition, damage to the renal afferent arteriole, as in patients with hypertension and progressive kidney disease, may also interfere with renal autoregulatory mechanisms.

TUBULAR TRANSPORT

Vectorial transport is net movement of substances from tubular fluid to blood (reabsorption), or vice versa (secretion). The cell membrane facing the tubular fluid (*luminal* or *apical*) must have different properties than the membrane facing the blood (*peritubular* or *basolateral*). Such epithelia are said to be "polarized," thus allowing the net movement of substances across the cell (transcellular route). The *tight junction*, which is a contact point close to the apical side of adjacent cells, limits water and solute movement between cells (paracellular route).

Solute transport across cell membranes uses either passive or active mechanisms.

Passive Transport

Simple diffusion always occurs down an electrochemical gradient, which is a composite of the concentration gradient and the electrical gradient. With an undissociated molecule, only the concentration gradient is relevant, whereas for a charged ion, the electrical gradient must also be considered. Simple diffusion does not require a direct energy source, although an active transport process is usually necessary to establish the initial concentration and electrical gradients.

Facilitated diffusion (or carrier-mediated diffusion) depends on an interaction of the molecule or ion with a specific membrane carrier protein that facilitates its passage across the cell membrane's lipid bilayer. In almost all cases of carrier-mediated transport in the kidney, two or more ions or molecules share the carrier; one moiety moves down its electrochemical gradient, while the other(s) move against the gradient.

Diffusion through a membrane channel (or pore) formed by specific integral membrane proteins is also a form of facilitated diffusion, because it allows charged and lipophobic molecules to pass through the membrane at a high rate.

Active Transport

Ion movement directly against an electrochemical gradient ("uphill") requires a source of energy and is known as active transport. In cells, this energy is derived from ATP production and its hydrolysis. The most important active cell transport mechanism is the sodium pump, which extrudes sodium ions (Na^+) from inside the cell in exchange for potassium ions (K^+) from outside the cell.[10] In the kidney, this process is confined to the basolateral membrane. The Na pump derives energy from the enzymatic hydrolysis of ATP and thus is more precisely termed Na^+,K^+-ATPase. It exchanges $3Na^+$ for $2K^+$ and is electrogenic because it extrudes a net positive charge from the cell; Na^+,K^+-ATPase is an example of a *primary* active transport mechanism. Other well-defined primary active transport processes in the kidney are the proton-secreting H^+-ATPase, important in hydrogen ion secretion in the distal nephron, and the Ca^{2+}-ATPase, partly responsible for calcium reabsorption.

Activity of the basolateral Na^+,K^+-ATPase underpins the operation of all the passive transport processes outlined earlier. It ensures that the intracellular Na^+ concentration is kept low (10 to

20 mmol/l) and the K^+ concentration high (~150 mmol/l), compared with their extracellular concentrations (~140 and 4 mmol/l, respectively). The *pump-leak* model of sodium transport uses the electrochemical gradient established and maintained by the Na pump to allow "leak" of Na^+ into the cell through a variety of membrane transport proteins. These can be Na^+ channels (in the distal nephron) or specific membrane carrier proteins that couple Na^+ entry to the influx (*symport* or *cotransport*) or efflux (*antiport* or *countertransport*) of other molecules or ions. In various parts of the nephron, glucose, phosphate, amino acids, K^+, and chloride ions (Cl^-) can all be cotransported with Na^+; moreover, H^+ and Ca^{2+} can be countertransported against Na^+ entry. In each case, the non-Na molecule or ion is transported against its electrochemical gradient, using energy derived from the "downhill" movement of Na^+. Their ultimate dependence on the Na^+,K^+-ATPase makes them *secondary* active transport mechanisms.

TRANSPORT IN SPECIFIC NEPHRON SEGMENTS

Given a typical GFR, approximately 180 liters of plasma (largely protein-free) is filtered each day, necessitating massive reabsorption by the whole nephron. Figure 2-6 shows the major transport mechanisms operating along the nephron (except the loop of Henle, dealt with separately).

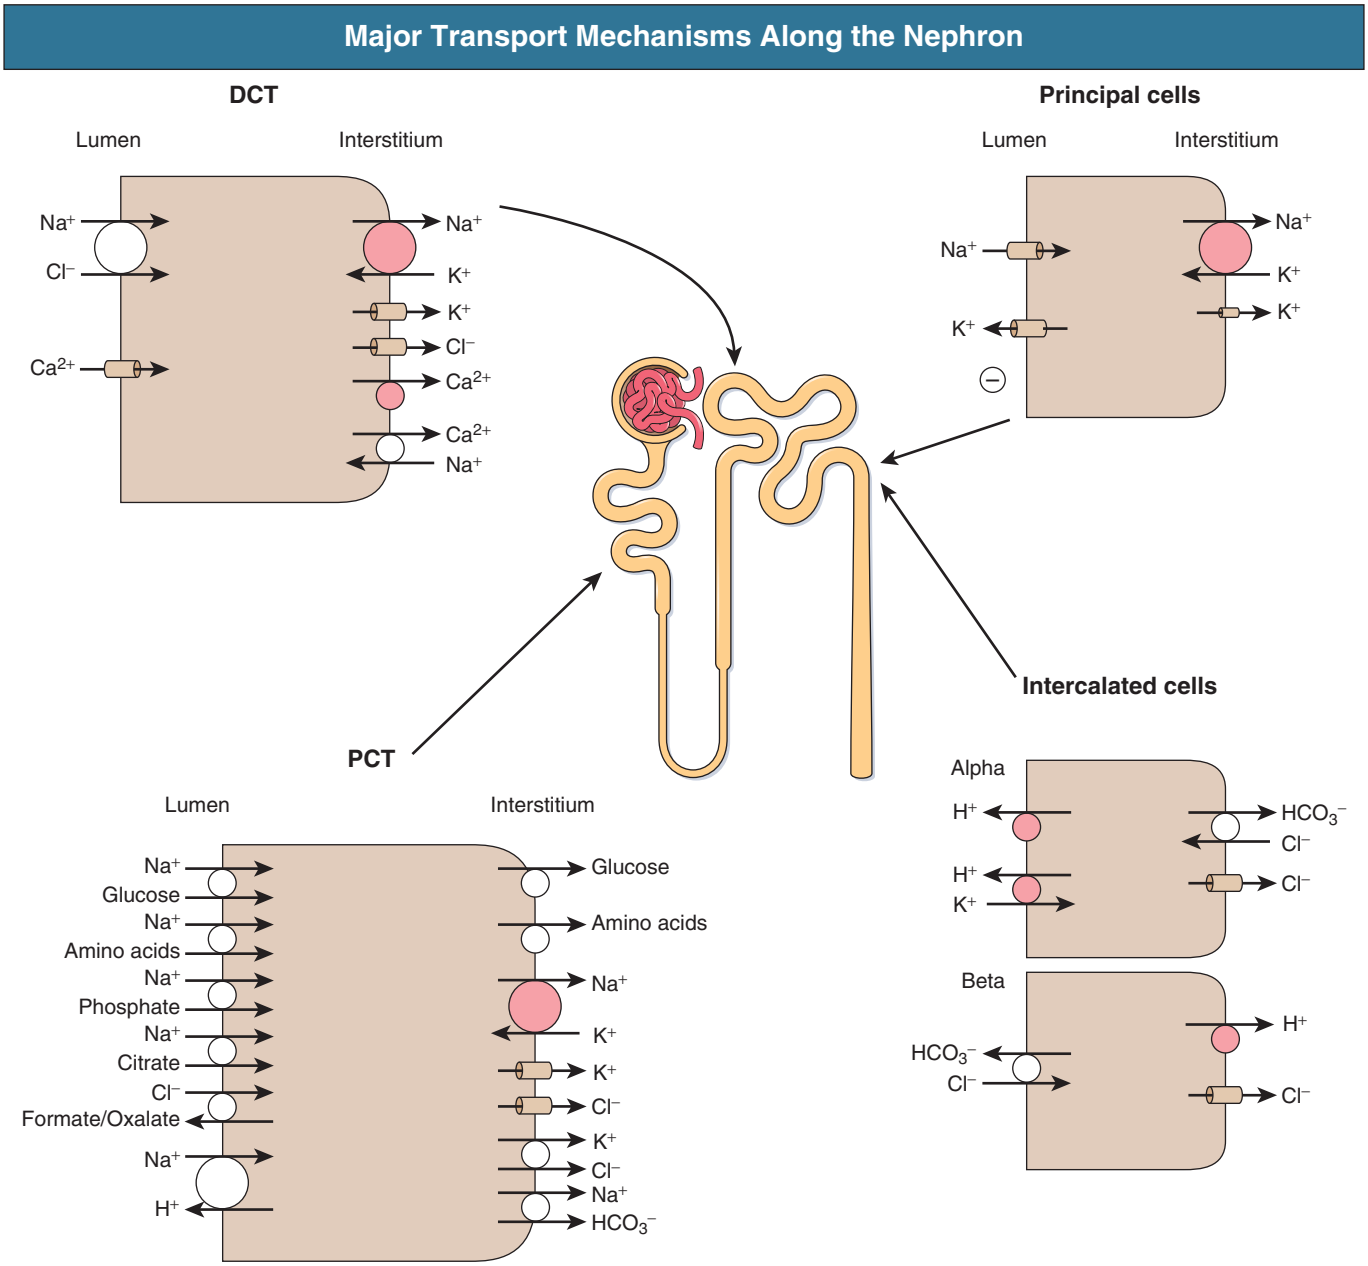

Figure 2-6 Major transport mechanisms along the nephron. Major transport proteins for solutes in the apical and basolateral membranes of tubular cells in specific regions of the nephron. Stoichiometry is not indicated; it is not 1 : 1 in all cases. *Red circles* represent primary active transport; *white circles* represent carrier-mediated transport (secondary active); *cylinders* represent ion channels. In the proximal convoluted tubule *(PCT),* Na^+ enters the cell through an Na^+-H^+ exchanger and a series of cotransporters. In the distal convoluted tubule *(DCT),* Na^+ enters the cell through the thiazide-sensitive Na^+-Cl^- cotransporter. In the principal cells of the cortical collecting duct, Na^+ enters through the epithelial sodium channel (ENaC). In all cases, Na^+ is extruded from the cells through the basolateral Na^+,K^+-ATPase. Transporters in the thick ascending limb of Henle are dealt with separately (see Fig. 2-10).

Proximal Tubule

The proximal tubule is adapted for bulk reabsorption of the glomerular filtrate. The epithelial cells have microvilli (brush border) on their apical surface that provide a large absorptive area, and the basolateral membrane has folds, also increasing the surface area. The cells are rich in mitochondria (concentrated near the basolateral membrane) and rely predominantly on aerobic metabolism, thus rendering the proximal tubule susceptible to hypoxic insult. The proximal convoluted tubule (PCT, pars convoluta) makes up the first two thirds of the proximal tubule; the final third is the proximal straight tubule (pars recta). On the basis of subtle structural and functional differences, the proximal tubule epithelium is subdivided into three segments: S_1 makes up the initial short segment of the PCT; S_2, the remainder of the PCT and the cortical segment of the pars recta; and S_3, the medullary segment of the pars recta.

The NHE3 isoform of the Na^+-H^+ exchanger (antiport) is the main route of Na^+ entry into proximal tubule cells. A battery of specialized transporters is also expressed in the apical membrane, coupling Na^+ entry to that of other species. Thus, the proximal tubule accounts for the bulk of Na^+, K^+, Cl^-, and bicarbonate (HCO_3^-) reabsorption, and almost complete reabsorption of glucose, amino acids, and low-molecular-weight proteins (e.g., retinol binding protein, α- and β-microglobulin) that have passed the filtration barrier. Most other filtered solutes are also reabsorbed to some extent in the proximal tubule (e.g., ~60% of calcium, 80% of phosphate, 50% of urea). Constitutive expression of aquaporin 1 (AQP1) water channels in both membranes confers a large hydraulic permeability.[11] About 65% of the filtered water is reabsorbed in the proximal tubule and is isosmotic because the junctions between cells are leaky and unable to sustain a large transepithelial osmotic gradient. In the final section of the proximal tubule (late S_2 and S_3), there is secretion of weak organic acids and bases, including most diuretics and PAH.

Loop of Henle

The loop of Henle is defined anatomically as comprising the pars recta of the proximal tubule (thick descending limb), the thin descending and ascending limbs (thin ascending limbs are present only in long-looped nephrons), the thick ascending limb, and the macula densa. In addition to its role in the continuing reabsorption of solutes (Na^+, Cl^-, K^+, Ca^{2+}, Mg^{2+}), the loop of Henle is responsible for the kidney's ability to generate a concentrated or dilute urine, which is described in detail later. The thick limb of Henle also produces the Tamm-Horsfall protein, also called *uromodulin,* normally the most abundant protein in the urine. Physiologic roles of uromodulin are not exactly defined. Uromodulin may contribute to sodium homeostasis, act as a constitutive inhibitor of calcium crystallization in tubular fluid and also help protect the kidney from inflammation and infection. Human genetic studies have associated uromodulin expression with altered risk of chronic kidney disease; mutations in the encoding gene cause rare autosomal dominant disorders of renal injury and cyst formation, hyperuricemia, and progressive decline in renal function.[12]

Distal Nephron

The distal tubule comprises three segments: the distal convoluted tubule (DCT), where thiazide-sensitive NaCl reabsorption through an apical NaCl cotransporter (NCC)[13] occurs; the connecting tubule (CNT), whose function is essentially intermediate between that of the DCT and that of the next segment; and the initial collecting duct, made of the same epithelial cell type as the cortical collecting duct (see Fig. 2-6). Two cell types make up the cortical collecting duct. The predominant cell, the *principal* cell (or CD cell), is responsible for Na^+ reabsorption and K^+ secretion (as well as water reabsorption; see later discussion). Na^+ enters the principal cell from the lumen through apical epithelial sodium channels (ENaC) and exits by the basolateral Na^+,K^+-ATPase. This process is electrogenic and sets up a lumen-negative transepithelial potential difference. K^+ enters the principal cell by the same basolateral Na^+,K^+-ATPase and leaves by K^+ transport pathways in both membranes; however, the relative depolarization of the apical membrane (caused by Na^+ entry) favors K^+ secretion into the lumen, the major route for which is through renal outer medullary potassium (ROMK) channels. The other cell type in the late distal tubule and cortical collecting duct, the *intercalated* (IC) cell, is responsible for H^+ secretion (by type A, or α, IC cells) or HCO_3^- secretion (by type B, or β, IC cells) into the final urine (see Fig. 2-6). In the medullary collecting duct there is a gradual transition in the epithelium. There are fewer and fewer IC cells, whereas the principal-like cells are modified such that they reabsorb Na^+ but, lacking apical K^+ channels, do not secrete K^+.

Figures 2-7 and 2-8 show the sites of Na^+ and K^+ reabsorption/secretion along the nephron. Table 2-2 outlines the pathophysiologic consequences of known genetic defects in some of the major transporters in the nephron (see Chapter 49 for details).

Genetic Defects in Transport Proteins Resulting in Renal Disease

Transporter	Consequence of Mutation
Proximal Tubule	
Apical Na^+-cystine cotransporter	Cystinuria
Apical Na^+-glucose cotransporter (SGLT2)	Renal glycosuria
Basolateral Na^+-HCO_3^- cotransporter	Proximal renal tubular acidosis
Intracellular H^+-Cl^- exchanger (ClC5)	Dent disease
Thick Ascending Limb	
Apical Na^+-K^+-$2Cl^-$ cotransporter	Bartter syndrome type 1
Apical K^+ channel	Bartter syndrome type 2
Basolateral Cl^- channel	Bartter syndrome type 3
Basolateral Cl^- channel accessory protein	Bartter syndrome type 4
Distal Convoluted Tubule	
Apical Na^+-Cl^- cotransporter	Gitelman syndrome
Collecting Duct	
Apical Na^+ channel (principal cells)	Overexpression: Liddle syndrome Underexpression: pseudohypoaldosteronism type 1b
Aquaporin 2 channel (principal cells)	Nephrogenic diabetes insipidus
Basolateral Cl^-/HCO_3^- exchanger (intercalated cells)	Distal renal tubular acidosis
Apical H^+-ATPase (intercalated cells)	Distal renal tubular acidosis (with or without deafness)

Table 2-2 Genetic defects in transport proteins resulting in renal disease. For more detailed coverage of these clinical conditions, see Chapter 49.

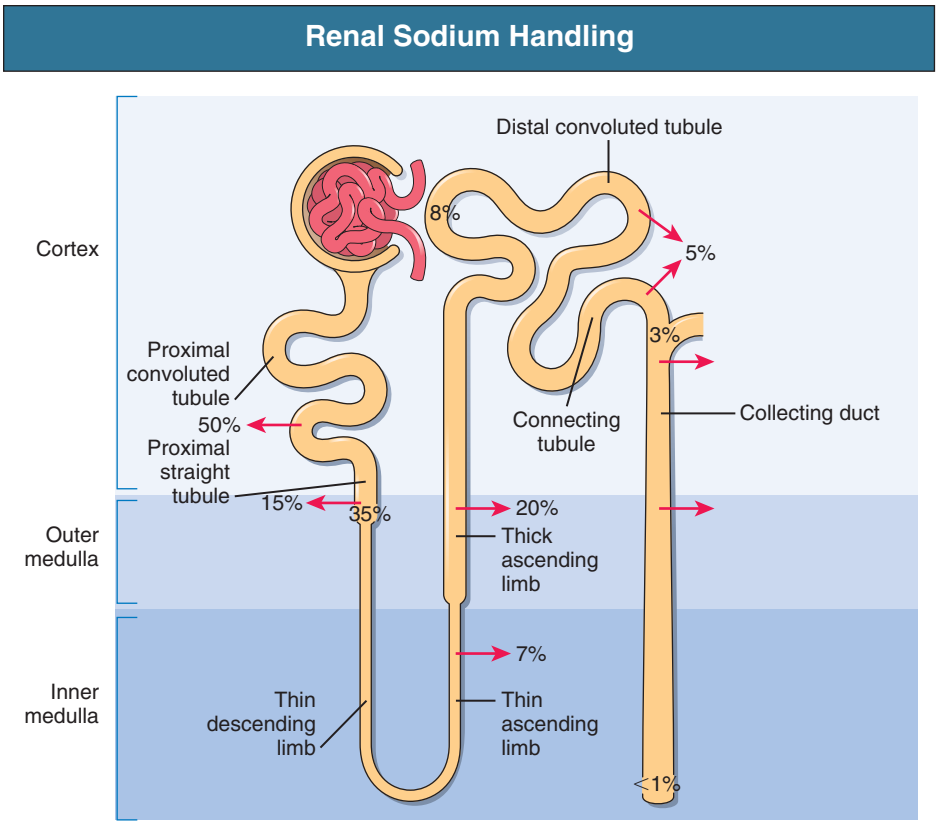

Figure 2-7 Renal sodium handling along the nephron. Figures outside the nephron represent the approximate percentage of the filtered load reabsorbed in each region. Figures within the nephron represent the percentages remaining. Most filtered sodium is reabsorbed in the proximal tubule and loop of Henle; normal day-to-day control of sodium excretion is exerted in the distal nephron.

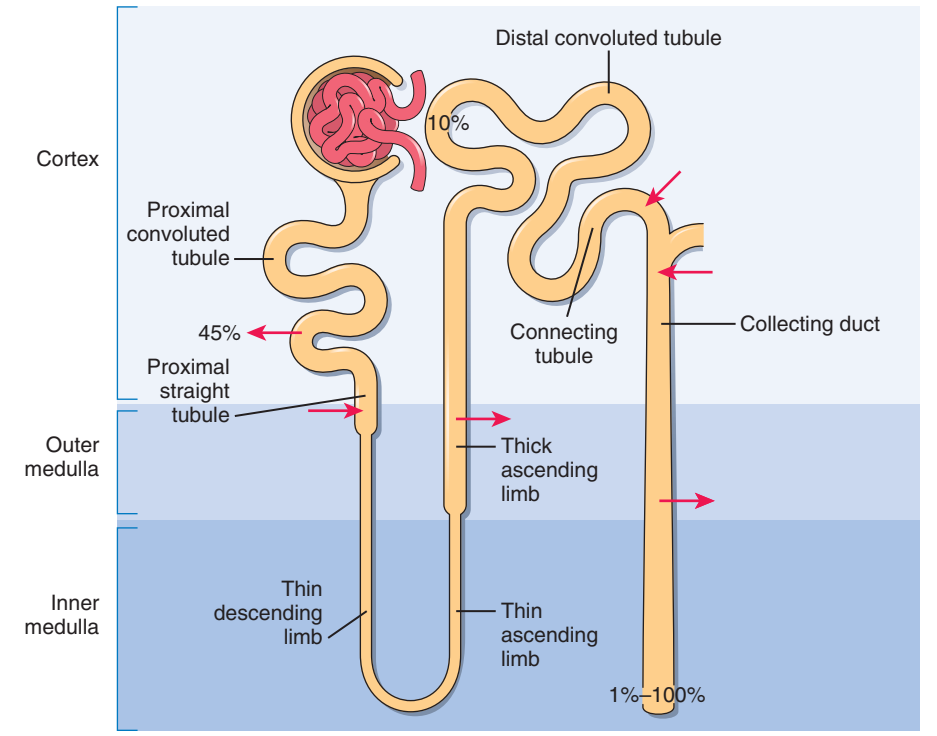

Figure 2-8 Renal potassium handling along the nephron. Figures are not given for percentages reabsorbed or remaining in every region because quantitative information is incomplete, but most filtered potassium is reabsorbed in the proximal convoluted tubule and thick ascending limb of Henle; approximately 10% of the filtered load reaches the early distal tubule. Secretion by connecting tubule cells and principal cells in the late distal tubule–cortical collecting duct is variable and is the major determinant of potassium excretion.

GLOMERULOTUBULAR BALANCE

Because the proportion of filtered Na^+ excreted in the urine is so small (normally <1%), it follows that without a compensatory change in reabsorption, even small changes in the filtered load would cause major changes in the amount excreted. For example, if GFR were to increase by 10%, and the rate of reabsorption remained unchanged, Na^+ excretion would increase more than 10-fold. However, an intrinsic feature of tubular function is that the extent of Na^+ reabsorption in a given nephron segment is about proportional to the Na^+ delivery to that segment. This process is called *glomerulotubular balance*. In perfect balance, both the reabsorption and the excretion of Na^+ would change in exactly the same proportion as the change in GFR, but glomerulotubular balance is usually less than perfect. Most studies have focused on the proximal tubule because glomerulotubular balance by this segment serves to stabilize delivery of Na^+ and fluid to the distal nephron, permitting efficient secretion of K^+ and H^+. However, Na^+ reabsorption in the thick limb of Henle and distal tubule is also delivery dependent. This partly explains why diuretics acting on the proximal tubule are relatively ineffective compared with those acting more distally. With distal-acting diuretics, there is less scope further downstream for compensatory Na^+ reabsorption. This also explains why combining two diuretics (acting at different nephron sites) causes a more striking diuresis and natriuresis.

The mechanism of glomerulotubular balance is not fully understood. In the proximal tubule, physical factors (Starling forces) operating across peritubular capillary walls may be involved. Glomerular filtration of an essentially protein-free fluid means that the plasma leaving the glomeruli in efferent arterioles and supplying the peritubular capillaries has a relatively high oncotic pressure, favoring reabsorption of fluid from the proximal tubules. If GFR were reduced in the absence of a change in renal plasma flow, the *filtration fraction* (GFR-RPF ratio) would fall. Peritubular capillary oncotic pressure would also be reduced, and the tendency of the peritubular vasculature to take up fluid reabsorbed from the proximal tubule would be diminished. Backflux of this fluid is thought to occur through the (leaky) tight junctions, reducing net reabsorption (Fig. 2-9). However, this mechanism could work only if GFR changed in the absence of a corresponding change in RPF; if the two changed in parallel, filtration fraction would stay constant, with no change in oncotic pressure.

A second contributory factor to glomerulotubular balance in the proximal tubule could be the filtered loads of glucose and amino acids; if their loads increase because of increased GFR, the rates of Na^+-coupled glucose and amino acid reabsorption in the proximal tubule will also increase. It has also been proposed that the proximal tubular brush border microvilli serve a "mechanosensing" function, transmitting changes in torque (caused by altered tubular flow rates) to the cells' actin cytoskeleton and thereby modulating transporter activity.[14] The mechanisms are unknown, but the release of paracrine mediators such as ATP,[15] dopamine,[16] or angiotensin II[17] into the lumen fluid may contribute.

Although the renal sympathetic nerves and certain hormones can influence reabsorption in the proximal tubule and loop of Henle, under normal circumstances the combined effects of autoregulation and glomerulotubular balance ensure that a relatively constant load of glomerular filtrate is delivered to the distal tubule. It is the final segments of the nephron that exert normal day-to-day control of Na^+ excretion. Evidence indicates important roles for the late DCT[13] and the CNT,[18] in addition to the collecting duct. Aldosterone, secreted from the adrenal cortex, stimulates mineralocorticoid receptors within principal cells and CNT cells, which leads to generation of

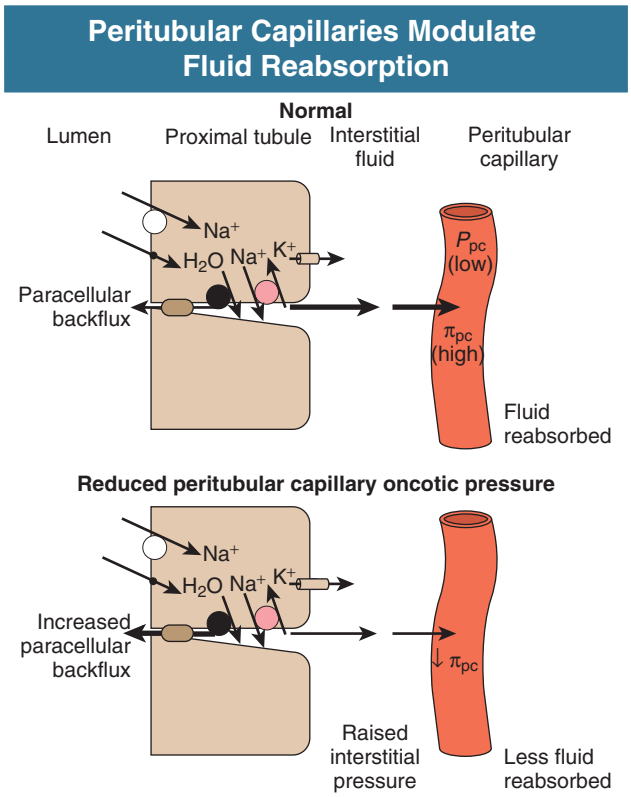

Figure 2-9 Physical factors and proximal tubular reabsorption. Influence of peritubular capillary oncotic pressure on net reabsorption in proximal tubules. Uptake of reabsorbate into peritubular capillaries is determined by the balance of hydrostatic and oncotic pressures across the capillary wall. Compared with those in systemic capillaries, the peritubular capillary hydrostatic (P_{pc}) and oncotic (π_{pc}) pressures are low and high, respectively, so that uptake of proximal tubular reabsorbate into the capillaries is favored. If peritubular capillary oncotic pressure decreases (or hydrostatic pressure increases), less fluid is taken up, interstitial pressure increases, and more fluid may leak back into the lumen paracellularly; net reabsorption in proximal tubules would therefore be reduced.

the regulatory protein serum- and glucocorticoid-inducible kinase 1 (SGK1), which in turn increases the density of Na^+ channels (ENaC) in the apical membrane (see Fig. 2-6). This stimulates Na^+ uptake and further depolarizes the apical membrane, thereby facilitating K^+ secretion in the late distal tubule/cortical collecting duct. Aldosterone also stimulates Na^+ reabsorption and K^+ secretion by upregulating the basolateral Na^+,K^+-ATPase.

The mineralocorticoid receptors have equal affinity *in vitro* for aldosterone and other adrenal corticosteroids, such as cortisol. The circulating concentrations of cortisol vastly exceed those of aldosterone, but *in vivo* the mineralocorticoid receptors show specificity for aldosterone because of the presence along the distal nephron of the enzyme 11β-hydroxysteroid dehydrogenase 2, which inactivates cortisol in the vicinity of the receptor.[19] Mutations in the gene that encodes 11β-hydroxysteroid dehydrogenase 2,[20] or inhibition of the enzyme by derivatives of glycyrrhetinic acid (found in licorice) can cause hypertension[21] from excessive and unregulated stimulation of Na^+ transport by cortisol (see also Chapter 40).

COUNTERCURRENT SYSTEM

A major function of the loop of Henle is the generation and maintenance of the interstitial osmotic gradient that increases from the

renal cortex (~290 mOsm/kg) to the tip of the medulla (~1200 mOsm/kg). As indicated in Chapter 1, the loops of Henle of superficial nephrons turn at the junction between outer and inner medulla, whereas those of deep nephrons (long-looped nephrons) penetrate the inner medulla to varying degrees. The anatomic loops of Henle reabsorb approximately 40% of filtered Na^+, mostly in the pars recta and the thick ascending limb (TAL), and approximately 25% of filtered water, in the pars recta and the thin descending limbs of deep nephrons. Evidence suggests that the thin descending limb of superficial nephrons is relatively impermeable to water.[22] Both the thin ascending limb (found only in deep nephrons) and the TAL are essentially impermeable to water, although Na^+ is reabsorbed—passively in the thin ascending limb, but actively in the TAL. The TAL also operates as a pump-leak system; the basolateral Na^+,K^+-ATPase maintains the electrochemical driving force for passive Na^+ entry from the lumen through the Na^+-$2Cl^-$-K^+ cotransporter (NKCC-2) and, to a much lesser extent, the Na^+-H^+ exchanger (Fig. 2-10). The apical NKCC-2 is the site of action of loop diuretics such as furosemide and bumetanide. Na^+ exits the cell through the Na^+ K^+-ATPase, and Cl^- and K^+ exit through basolateral ion channels and a K^+-Cl^- cotransporter. K^+ also reenters the lumen through apical membrane channels. This "recycling" of K^+ into the tubular lumen is necessary for normal operation of the Na^+-$2Cl^-$-K^+ cotransporter because the availability of K^+ is a limiting factor for the transporter (K^+ concentration in tubular fluid is much lower than Na^+ and Cl^-). Potassium recycling is also partly responsible for generating the lumen-positive transepithelial potential difference found in the TAL, which drives additional Na^+ reabsorption through the paracellular pathway; for each Na^+ reabsorbed by the transcellular route, another is reabsorbed paracellularly (see Fig. 2-10). Other cations (K^+, Ca^{2+}, Mg^{2+}) are also reabsorbed by this route. The reabsorption of NaCl along the TAL in the absence of significant water reabsorption means that the tubular fluid leaving this segment is hypotonic; thus the TAL is also called the *diluting segment*.

The reabsorption in the TAL of solute without water generates a "horizontal" osmotic gradient of about 200 mOsm/kg between the tubule fluid and interstitium. This separation is the *single osmotic effect*. The U-shaped arrangement of the loop of Henle, in which flow in the ascending limb is in the opposite direction to that in the descending limb, multiplies the single effect to generate a much larger vertical (corticomedullary) osmotic gradient by a process called *countercurrent multiplication* (Fig. 2-11). Fluid entering the descending limb from the proximal tubule is isotonic (~290 mOsm/

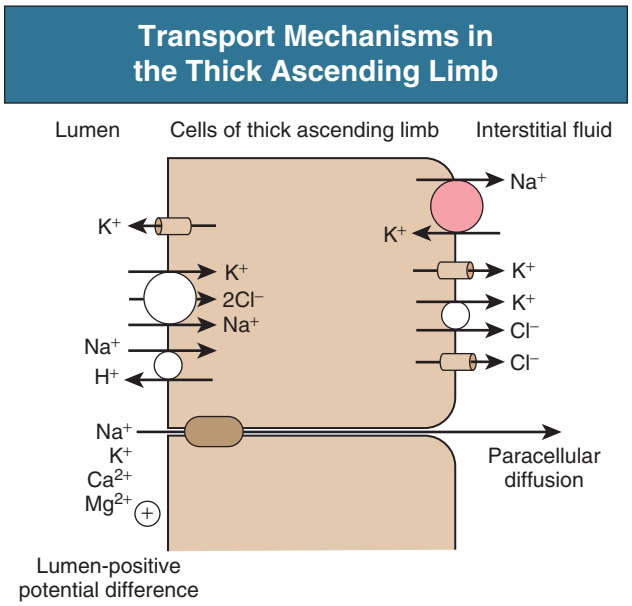

Figure 2-10 Transport mechanisms in the thick ascending limb of Henle. The major cellular entry mechanism is the Na^+-K^+-$2Cl^-$ cotransporter. The transepithelial potential difference drives paracellular transport of Na^+, K^+, Ca^{2+}, and Mg^{2+}.

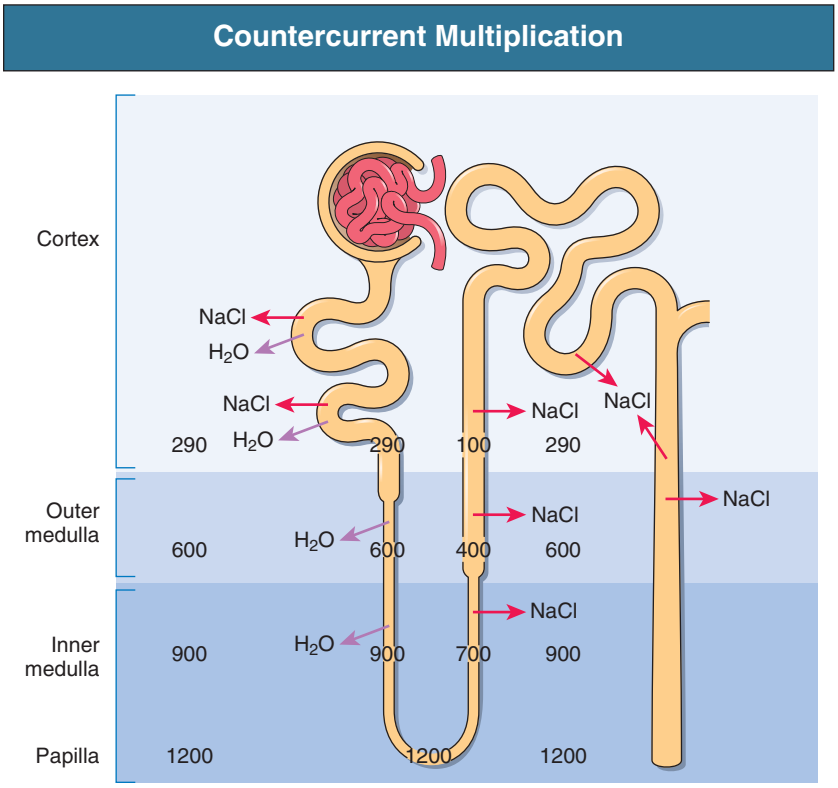

Figure 2-11 Countercurrent multiplication by loop of Henle. The nephron drawn represents a deep (long-looped) nephron. Figures represent approximate osmolalities (mOsm/kg). Osmotic equilibration occurs in the thin descending limb of Henle, whereas NaCl is reabsorbed in the water-impermeable ascending limb; hypotonic fluid is delivered to the distal tubule. In the absence of vasopressin, this fluid remains hypotonic during its passage through the distal tubule and collecting duct, despite the large osmotic gradient favoring water reabsorption. A large volume of dilute urine is therefore formed. During maximal vasopressin secretion, water is reabsorbed down the osmotic gradient, so that tubular fluid becomes isotonic in the cortical collecting duct and hypertonic in the medullary collecting duct. A small volume of concentrated urine is formed.

kg). On encountering the hypertonicity of the medullary interstitial fluid (caused by NaCl reabsorption in water-impermeable ascending limb), the fluid in the descending limb comes into osmotic equilibrium with its surroundings, either by solute entry into the descending limb (superficial nephrons) or by water exit by osmosis (deep nephrons). These events, combined with continuing NaCl reabsorption in the ascending limb, result in a progressive increase in medullary osmolality from corticomedullary junction to papillary tip. A similar osmotic gradient exists in the thin descending limb, while at any level in the ascending limb, the osmolality is less than in the surrounding tissue. Thus, hypotonic fluid (~100 mOsm/kg) is delivered to the distal tubule. Ultimately, the energy source for countercurrent multiplication is active Na^+ reabsorption in the TAL. As indicated earlier, Na^+ reabsorption in the thin ascending limb is passive, although the mechanism is not yet understood.

Role of Urea

The thin limbs of loop of Henle are relatively permeable to urea (ascending more permeable than descending), but the TAL and beyond are urea impermeable up to the final section of the inner medullary collecting duct. During antidiuresis, vasopressin-induced water reabsorption from the collecting ducts concentrates urea such that in the terminal inner medullary collecting duct, there is a large concentration gradient between the luminal fluid and interstitium. This section of the inner medullary collecting duct expresses urea transporters (UT-A1 and UT-A3), allowing passive reabsorption of urea into the inner medullary interstitium. This process is also under the control of vasopressin (ADH).[23] The interstitial urea exchanges with vasa recta capillaries (see next section) and some urea enters the S_3 segment of the pars recta and the descending and ascending thin limbs; it is then returned to the inner medullary collecting ducts to be reabsorbed. The net result of this urea recycling process is to add urea to the inner medullary interstitium, thereby increasing interstitial osmolality. The fact that the high urea concentration within the medullary collecting duct is balanced by a similarly high urea concentration in the medullary interstitium allows large quantities of urea to be excreted without incurring the penalty of an osmotic diuresis, since the urea in the collecting duct is rendered osmotically ineffective. Moreover, the high urea concentration in the medullary interstitium should also increase osmotic water abstraction from the thin descending limbs of deep nephrons, thus raising the intraluminal Na^+ concentration within the thin descending limbs.

Although until recently this process was thought to prepare for passive Na^+ reabsorption from the thin ascending limbs, mice with genetic deletion of UT-A1 and UT-A3 have a greatly reduced urea concentration in the inner medullary interstitium but a normal interstitial NaCl gradient.[23] Therefore the mechanisms responsible for the inner medullary electrolyte gradient are still unclear. It is worth emphasizing, however, that the ultimate driving force for countercurrent multiplication is active Na^+ reabsorption in the TAL. For this reason, loop diuretics disrupt the osmotic gradient, and genetic mutations in the pathways contributing to efficient Na^+ reabsorption in the TAL cause the salt-wasting Bartter syndrome (see Chapter 49).

Vasa Recta

If the capillaries that supply the renal medulla had a more conventional anatomic arrangement, these vessels would soon dissipate the medullary osmotic gradient because of equilibration of the hypertonic interstitium with the isotonic capillary blood. This does not happen to any appreciable extent, because the U-shaped arrangement ensures that solute entry and water loss in the descending vasa recta are offset by solute loss and water entry in the ascending vasa recta. This is the process of *countercurrent exchange* and is entirely passive (Fig. 2-12).

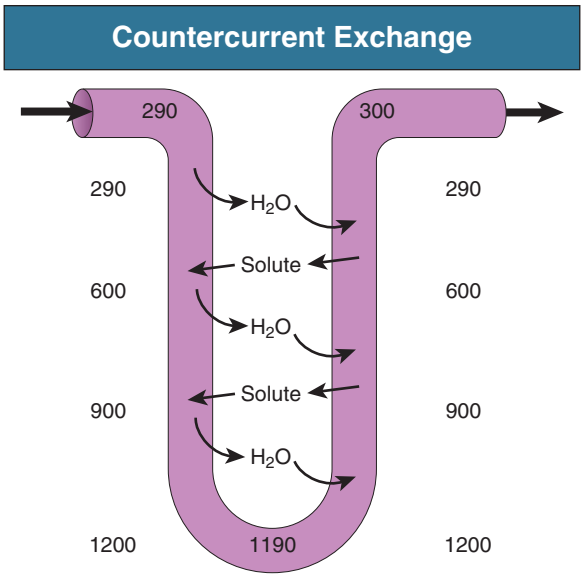

Figure 2-12 Countercurrent exchange by the vasa recta. Figures represent approximate osmolalities (mOsm/kg). The vasa recta capillary walls are highly permeable, but the U-shaped arrangement of the vessels minimizes the dissipation of the medullary osmotic gradient. Nevertheless, because equilibration across the capillary walls is not instantaneous, a certain amount of solute is removed from the interstitium.

Renal Medullary Hypoxia

Countercurrent exchange by the medullary capillaries applies also to oxygen, which diffuses from descending to ascending vasa recta, bypassing the deeper regions. This phenomenon, combined with ongoing energy-dependent Na^+ transport in the (outer medullary) TAL, renders medullary tissue relatively hypoxic. Thus the partial pressure of oxygen normally decreases from about 50 mm Hg in the cortex to 10 mm Hg in the inner medulla.[24] Indeed, administration of furosemide, which inhibits oxygen consumption in the TAL, increases medullary oxygenation. As part of the adaptation to this relatively hypoxic environment, medullary cells have a higher capacity for glycolysis than cortical cells. Moreover, a number of *heat shock proteins* are expressed in the medulla, which assist cell survival by restoring damaged proteins and by inhibiting apoptosis.[24]

The degree of medullary hypoxia depends on the balance between medullary blood flow (influenced by contractile cells called *pericytes*) and oxygen consumption in the TAL. In health, this balance is modulated by a variety of autocrine/paracrine agents (e.g., nitric oxide, eicosanoids, ATP, adenosine; see later discussion), several of which can increase medullary oxygenation by simultaneously reducing pericyte contraction and TAL transport. Some cases of radiocontrast-induced nephropathy result from a disturbance of the balance between oxygen supply and demand, with consequent hypoxic medullary injury in which the normal cellular adaptations are overwhelmed, with subsequent apoptotic and necrotic cell death.

VASOPRESSIN (ANTIDIURETIC HORMONE) AND WATER REABSORPTION

Vasopressin, or antidiuretic hormone (ADH), is a nonapeptide synthesized in specialized neurons of the supraoptic and paraventricular

nuclei. ADH is transported from these nuclei to the posterior pituitary and released in response to increases in plasma osmolality and decreases in blood pressure. Osmoreceptors are found in the hypothalamus, and there is also input to this region from arterial baroreceptors and atrial stretch receptors. The actions of vasopressin are mediated by three receptor subtypes: V_{1a}, V_{1b}, and V_2. The V_{1a} receptors are found in vascular smooth muscle and are coupled to the phosphoinositol pathway; they cause an increase in intracellular Ca^{2+} resulting in contraction. V_{1a} receptors have also been identified in the apical membrane of several nephron segments; activation by luminal vasopressin can influence Na^+ transport in these segments. V_{1b} receptors are found in the anterior pituitary, where vasopressin modulates adrenocorticotropic hormone release. V_2 receptors are found in the basolateral membrane of principal cells in the late distal tubule and the whole length of the collecting duct; they are coupled by a G_s protein to cyclic adenosine monophosphate generation, which ultimately leads to the insertion of aquaporin 2 (AQP2) water channels into the apical membrane of this otherwise water-impermeable segment (Fig. 2-13). In the X-linked form of nephrogenic diabetes insipidus, the most common inherited form, the V_2 receptor is defective.[25]

Several aquaporins have been identified in the kidney.[26] AQP1 is found in apical and basolateral membranes of all proximal tubules and of thin descending limbs of long-looped nephrons; it is largely responsible for the permanently high water permeability of these segments. AQP3 is constitutively expressed in the basolateral membrane of CNT cells and cortical and outer medullary principal cells. AQP4 is constitutively expressed in the basolateral membrane of outer medullary principal cells and inner medullary collecting duct cells; however, AQP2 is responsible for the variable water permeability of the late distal tubule and collecting duct. Acute vasopressin release causes shuttling of AQP2 from intracellular vesicles to the apical membrane, while chronically raised vasopressin levels increase transcription and translation of the gene encoding AQP2. The apical insertion of AQP2 allows reabsorption of water, driven by the high interstitial osmolality that is achieved and maintained by the countercurrent system. Vasopressin also contributes to the effectiveness of this system by stimulating Na^+ reabsorption in the TAL and urea reabsorption through the UT-A1 and UT-A3 transporters in the inner medullary collecting duct. In the (rare) autosomal recessive and (even rarer) autosomal dominant forms of nephrogenic diabetes insipidus, AQP2 is abnormal and/or fails to translocate to the apical membrane.[26]

More frequently, defects in AQP2 shuttling contribute to the urine-concentrating defects associated with both hypokalemia and hypercalcemia. With chronic hypokalemia, AQP2 expression in the collecting duct is reduced,[27] possibly reflecting the generalized suppression of proteins central to urine concentration[28] and reduction in the medullary osmotic gradient. With hypercalcemia, increased intraluminal Ca^{2+} concentrations activate the apical calcium-sensing receptor, thereby preventing insertion of AQP2 in the apical membrane.[29] In addition, stimulation of a calcium receptor in the basolateral membrane of the TAL inhibits solute transport in this nephron segment, through inhibition of the apical NKCC-2 and ROMK channels, thereby reducing the medullary osmotic gradient.[30]

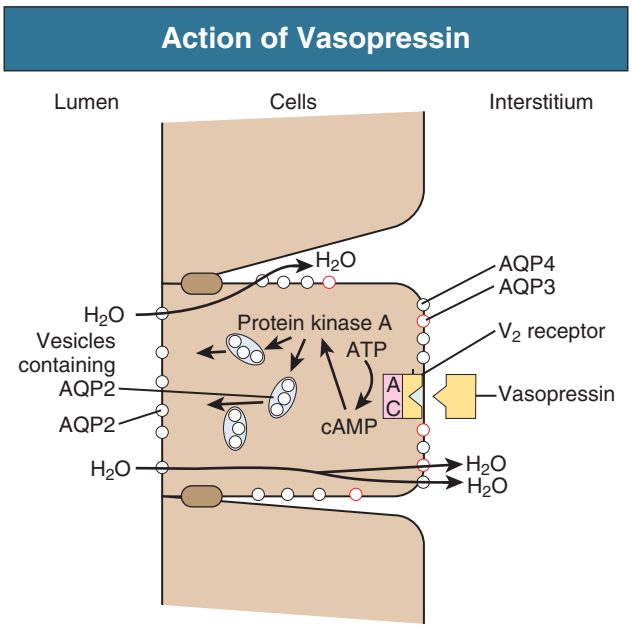

Figure 2-13 Mechanism of action of vasopressin (antidiuretic hormone). Vasopressin binds to V_2 receptors on the basolateral membrane of collecting duct principal cells and increases intracellular cyclic adenosine monophosphate *(cAMP)* production, causing insertion of preformed aquaporin 2 *(AQP2)* water channels into the apical membrane through intermediate reactions involving protein kinase A. The water permeability of the basolateral membrane, which contains aquaporins 3 and 4, is permanently high. Therefore, vasopressin secretion allows transcellular movement of water from lumen to interstitium. *AC,* Adenylate cyclase.

INTEGRATED CONTROL OF RENAL FUNCTION

One of the major functions of the kidneys is the regulation of blood volume, through the regulation of *effective circulating volume,* a conceptual volume reflecting the degree of fullness of the vasculature. This is achieved largely by controlling the sodium content of the body. Chapter 7 describes the mechanisms involved in the regulation of effective circulating volume. This discussion introduces some of the more important mediator systems.

Renal Interstitial Hydrostatic Pressure and Nitric Oxide

Acute increases in arterial blood pressure lead to *pressure natriuresis.* Because autoregulation is not perfect, part of this response is mediated by increases in RBF and GFR (see Fig. 2-3), but the main cause is reduced tubular reabsorption resulting from an increase in *renal interstitial hydrostatic pressure* (RIHP). An elevated RIHP reduces net reabsorption in the proximal tubule by increasing paracellular backflux through the tight junctions of the tubular wall (see Fig. 2-9). The increase in RIHP is thought to depend on intrarenally produced nitric oxide (NO) and modulated by reactive oxygen species.[31] Moreover, increased NO production in macula densa cells, which contain the neuronal (type I) isoform of nitric oxide synthase (nNOS), blunts the sensitivity of TGF, thereby allowing increased NaCl delivery to the distal nephron without incurring a TGF-mediated decrease in GFR.[32]

Another renal action of NO results from the presence of inducible (type II) nitric oxide synthase (iNOS) in glomerular mesangial cells. Local NO production counteracts the mesangial contractile response to agonists such as angiotensin II and endothelin (see later discussion). Furthermore, NO may contribute to the regulation of medullary blood flow. Locally synthesized NO offsets the vasoconstrictor effects of other agents on the pericytes of the descending vasa recta, and it reduces Na^+ reabsorption in the TAL; both actions help to protect the renal medulla from hypoxia. NO also may promote natriuresis and diuresis through direct actions on the renal tubule. Thus, in addition to its effect on the TAL, locally produced NO inhibits Na^+ and water reabsorption in the collecting duct.[33]

Renal Sympathetic Nerves

Reductions in arterial pressure and/or central venous pressure result in reduced afferent signaling from arterial baroreceptors and atrial volume receptors, which elicits a reflex increase in renal sympathetic nervous discharge. This reduces urinary Na^+ excretion in at least three ways: (1) constriction of afferent and efferent glomerular arterioles (predominantly afferent), thereby directly reducing RBF and GFR, and indirectly reducing RIHP; (2) direct stimulation of Na^+ reabsorption in the proximal tubule and the TAL of Henle loop; and (3) stimulation of renin secretion by afferent arteriolar cells (see later discussion). Renal sympathetic overactivity has long been associated with Na^+ retention and experimental hypertension. Recent clinical studies indicate that bilateral sympathetic efferent denervation effects long-lasting reductions in blood pressure in patients with resistant hypertension[34] (see also Chapter 38).

Renin-Angiotensin-Aldosterone System

The renin-angiotensin-aldosterone system (RAAS) is central to the control of extracellular fluid volume (ECFV) and blood pressure. Renin is synthesized and stored in specialized afferent arteriolar cells that form part of the juxtaglomerular apparatus[35] and is released into the circulation in response to (1) increased renal sympathetic nervous discharge, (2) reduced stretch of the afferent arteriole after a reduction in renal perfusion pressure, and (3) reduced delivery of NaCl to the macula densa region of the nephron (see Fig. 2-4).

Renin catalyzes the production of the decapeptide angiotensin I (Ang I) from circulating angiotensinogen (synthesized in the liver). Ang I is in turn converted by the ubiquitous angiotensin-converting enzyme (ACE) to the octapeptide angiotensin II. Ang II influences the control of ECFV and blood pressure as follows:

- Causes general arteriolar vasoconstriction, including renal afferent and (particularly) efferent arterioles, thereby increasing arterial pressure but reducing RBF. The tendency of P_{gc} to increase is offset by Ang II–induced mesangial cell contraction and reduced K_f; thus the overall effect on GFR is unpredictable.
- Directly stimulates sodium reabsorption in the proximal tubule.
- Directly stimulates thiazide-sensitive NaCl cotransport.[36]
- Stimulates aldosterone secretion from the zona glomerulosa of adrenal cortex. As described earlier, aldosterone stimulates sodium reabsorption in the distal tubule and collecting duct.

Eicosanoids

Eicosanoids are a family of metabolites of arachidonic acid (AA) produced enzymatically by three systems: *cyclooxygenase,* with two isoforms, COX-1 and COX-2, both expressed in the kidney; *cytochrome P-450* (CYP-450); and *lipoxygenase*. The major renal eicosanoids produced by the COX system are the prostaglandins E_2 (PGE_2) and I_2 (PGI_2), both of which are renal vasodilators and act to buffer the effects of renal vasoconstrictor agents (e.g., Ang II, norepinephrine) and the vasoconstrictor thromboxane A_2. Under normal circumstances, PGE_2 and PGI_2 have minimal effect on renal hemodynamics, but during stressful situations such as hypovolemia, help to protect the kidney from excessive functional changes. Consequently, nonsteroidal anti-inflammatory drugs (NSAIDs), which are COX inhibitors, can cause dramatic falls in GFR. PGE_2 also has tubular effects, inhibiting Na^+ reabsorption in the TAL of Henle loop, as well as both Na^+ and water reabsorption in the collecting duct.[37] The action of PGE_2 in the TAL, together with a dilator effect on vasa recta pericytes, is another paracrine regulatory mechanism that helps to protect the renal medulla from hypoxia. This may explain why inhibition of COX-2 can reduce medullary blood flow and cause apoptosis of medullary interstitial cells.

The metabolism of AA by renal CYP-450 enzymes yields epoxyeicosatrienoic acids (EETs), 20-hydroxyeicosatetraenoic acid (20-HETE), and dihydroxyeicosatrienoic acids (DHETs). These compounds appear to have multiple autocrine/paracrine/second messenger effects on the renal vasculature and tubules not yet fully unraveled.[38] As with prostaglandins, EETs are vasodilator agents, whereas 20-HETE is a potent renal arteriolar constrictor and may be involved in the vasoconstrictor effect of Ang II, as well as the TGF mechanism. 20-HETE also constricts vasa recta pericytes and may be involved in the control of medullary blood flow. Some evidence suggests that locally produced 20-HETE and EETs can inhibit sodium reabsorption in the proximal tubule and TAL.[39] Indeed, CYP-450 metabolites of AA may contribute to the reduced proximal tubular reabsorption seen in pressure natriuresis.

The third enzyme system that metabolizes AA, the lipoxygenase system, is activated (in leukocytes, mast cells, and macrophages) during inflammation and injury, and is not considered here.

Cyclooxygenase-2 is present in macula densa cells and has a critical role in the release of renin from juxtaglomerular cells (granular cells) in response to reduced NaCl delivery to the macula densa.[37] A low-sodium diet increases COX-2 expression in the macula densa and simultaneously increases renin secretion; the renin response is virtually abolished in COX-2 knockout mice or during pharmacologic inhibition of COX-2. It is therefore likely that the hyporeninemia observed during administration of NSAIDs is largely a consequence of COX-2 inhibition. In addition to COX-2, the enzyme prostaglandin E synthase is expressed in macula densa cells, and the principal COX-2 product responsible for enhancing renin secretion apparently is PGE_2, acting on specific receptors identified in juxtaglomerular cells; it is not clear whether PGI_2 is also synthesized in macula densa cells. As previously discussed, nNOS (type I isomer) is also present in macula densa cells and produces NO that blunts TGF.[40] NO also has a permissive role in renin secretion, although the mechanism is not understood. The increase in macula densa COX-2 expression induced by a low-sodium diet is attenuated during administration of selective nNOS inhibitors, which has led to speculation that NO is responsible for the increase in COX-2 activity and the resulting increase in juxtaglomerular renin secretion.[35] Figure 2-14 diagrams the established and proposed roles of COX-2 and nNOS in the macula densa.

Atrial Natriuretic Peptide

If blood volume increases significantly, the resulting atrial stretch stimulates the release of atrial natriuretic peptide (ANP) from atrial myocytes. This hormone increases sodium excretion, through suppression of renin and aldosterone release and a direct inhibitory effect on sodium reabsorption in the medullary collecting duct. ANP may also increase GFR because high doses cause afferent arteriolar vasodilation and mesangial cell relaxation (thus increasing K_f; see Table 2-1).

Endothelins

Endothelins are potent vasoconstrictor peptides to which the renal vasculature is exquisitely sensitive.[41] Endothelins function primarily as autocrine or paracrine agents. The kidney is a rich source of endothelins, the predominant isoform being endothelin-1 (ET-1). ET-1 is generated throughout the renal vasculature, including afferent and efferent arterioles, where it causes vasoconstriction, possibly mediated by 20-HETE, and mesangial cells, where it causes contraction

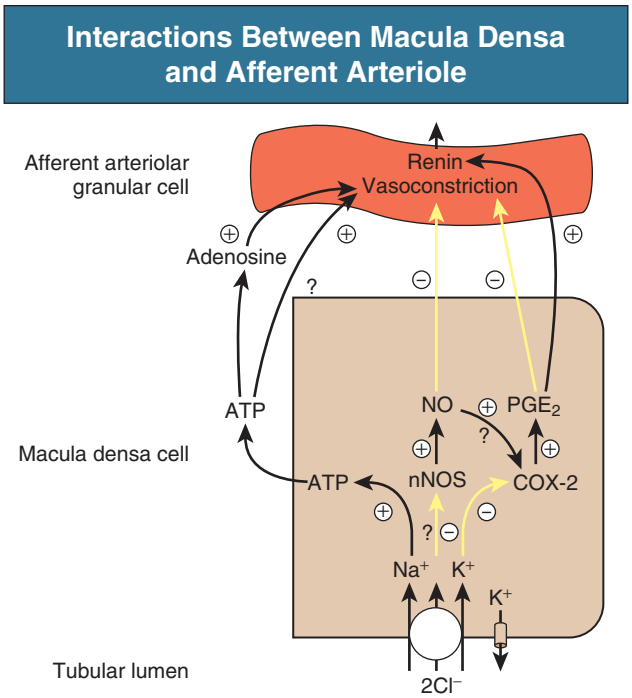

Figure 2-14 Interactions between macula densa and afferent arteriole: proposed mediators of renin secretion and tubuloglomerular feedback. Both cyclooxygenase-2 *(COX-2)* and neuronal nitric oxide synthase *(nNOS)* enzyme systems are present in macula densa cells. Increased NaCl delivery to the macula densa stimulates NaCl entry into the cells through the Na^+-K^+-$2Cl^-$ cotransporter. This causes afferent arteriolar constriction through adenosine or adenosine triphosphate *(ATP)* and also inhibits COX-2 activity; the latter effect might be mediated partly through inhibition of (nNOS-mediated) nitric oxide *(NO)* production. Generation of prostaglandin E_2 *(PGE_2)* by COX-2 stimulates renin release. PGE_2 also modulates vasoconstriction, as does NO.

(i.e., decreases K_f). Consequently, renal ET-1 can cause profound reductions in RBF and GFR (see Table 2-1).

In contrast to its effect on GFR, ET-1 can act on the renal tubule to increase urinary Na^+ and water excretion. ET-1 levels are highest in the renal medulla—in the TAL and, more prominently, the inner medullary collecting duct. The distribution of renal endothelin receptors (ET_A and ET_B) reflects the sites of production; the predominant receptor in the inner medulla is ET_B.[41] Mice with collecting duct–specific deletions of either ET-1 or ET_B receptors exhibit salt-sensitive hypertension, whereas duct-specific ET_A deletion results in no obvious renal phenotype. ET-1 knockout mice also show a greater sensitivity to vasopressin than do wild-type mice. There is mounting evidence that the natriuretic and diuretic effects of medullary ET_B stimulation are mediated by NO.[41] Taken together with evidence that ET-1 can inhibit Na^+ reabsorption in the medullary TAL (also likely mediated by NO),[33] these findings highlight the potential importance of ET-1/NO interactions in the control of Na^+ and water excretion.

Purines

Increasing evidence indicates that extracellular purines such as ATP, adenosine diphosphate (ADP), adenosine, and uric acid can act as autocrine or paracrine agents within the kidneys by activating specific cell surface receptors.[42] *Purinoceptors* are subdivided into P1 and P2 receptors. P1 receptors are responsive to adenosine and are more usually known as *adenosine receptors* (A_1, A_{2a}, A_{2b}, and A_3). P2 receptors are responsive to nucleotides (e.g., ATP, ADP) and are further subdivided into P2X (ligand-gated ion channel) and P2Y (metabotropic) receptors, each category having a number of subtypes. As indicated earlier, A_1 and $P2X_1$ receptors are found in afferent arterioles and mediate vasoconstriction. Purinoceptors are also found in the apical and basolateral membranes of renal tubular cells. Stimulation of A_1 receptors enhances proximal tubular reabsorption and inhibits collecting duct Na^+ reabsorption, whereas stimulation of P2 receptors generally has an inhibitory effect on tubular transport.[42] Thus luminally applied nucleotides, acting on a variety of P2 receptor subtypes, can inhibit Na^+ reabsorption in the proximal tubule, distal tubule, and collecting duct;[43] and stimulation of $P2Y_2$ receptors in the collecting duct inhibits vasopressin-sensitive water reabsorption.

Investigation of Renal Disease

CHAPTER 3

Assessment of Renal Function

Lesley A. Inker, Li Fan, and Andrew S. Levey

GLOMERULAR FILTRATION RATE

Glomerular filtration rate (GFR) is a product of the average filtration rate of each nephron, the filtering unit of the kidneys, multiplied by the number of nephrons in both kidneys. The normal level for GFR is approximately 130 ml/min/1.73 m^2 for men and 120 ml/min/1.73 m^2 for women, with considerable variation among individuals according to age, gender, body size, physical activity, diet, pharmacotherapy, and physiologic states such as pregnancy. To standardize the function of the kidney for differences in kidney size, which is proportional to body size, GFR is adjusted for body surface area (BSA), computed from height and weight, and is expressed per 1.73 m^2 BSA, the mean BSA of young men and women. Even after adjustment for BSA, GFR is approximately 8% higher in young men than in women and declines with age; the mean rate of decline is approximately 0.75 ml/min/yr after age 40 years, but the variation is wide, and the sources of variation are poorly understood. During pregnancy, GFR increases by about 50% in the first trimester and returns to normal immediately after delivery. GFR has a diurnal variation and is 10% lower at midnight compared with the afternoon. Within an individual, GFR is relatively constant over time but varies considerably among people, even after adjustment for the known variables.

Reductions in GFR may result from a decline in the nephron number or in the single-nephron (SN) GFR from physiologic or hemodynamic alterations. An increase in SNGFR caused by increased glomerular capillary pressure or glomerular hypertrophy can compensate for a decrease in nephron number; therefore the level of GFR may not reflect the loss of nephrons. As a result, there may be substantial kidney damage before GFR decreases.

MEASUREMENT OF THE GLOMERULAR FILTRATION RATE

The GFR cannot be measured directly. Instead, it is measured as the urinary clearance of an ideal filtration marker.

Concept of Clearance

Clearance of a substance is defined as the volume of plasma cleared of a marker by excretion per unit of time. The clearance of substance x (C_x) can be calculated as $C_x = A_x/P_x$, where A_x is the amount of x eliminated from the plasma, P_x is the average plasma concentration, and C_x is expressed in units of volume per time. Clearance does not represent an actual volume; rather, it is a virtual volume of plasma that is completely cleared of the substance per unit of time. The value for clearance is related to the efficiency of elimination: the greater the rate of elimination, the higher the clearance. Clearance of substance x is the sum of the urinary and extrarenal clearance; for substances that are eliminated by renal and extrarenal routes, plasma clearance exceeds urinary clearance.

Urinary Clearance

The amount of substance x excreted in the urine can be calculated as the product of the urinary flow rate (V) and the urinary concentration (U_x). Therefore urinary clearance is defined as follows:

$$C_x = (U_x \times V)/P_x$$

Urinary excretion of a substance depends on filtration, tubular secretion, and tubular reabsorption. Substances that are filtered but not secreted or reabsorbed by the tubules are ideal filtration markers because their urinary clearance can be used as a measure of GFR. For substances that are filtered and secreted, urinary clearance exceeds GFR; and for substances that are filtered and reabsorbed, urinary clearance is less than GFR.

Measurement of urinary clearance requires a timed urine collection for measurement of urine volume, as well as urine and plasma concentrations of the filtration marker. Special care must be taken to avoid incomplete urine collections, which will limit the accuracy of the clearance calculation.

Plasma Clearance

Interest in measurement of plasma clearance continues because it avoids the need for a timed urine collection. GFR is calculated from plasma clearance (C_x) after a bolus intravenous injection of an exogenous filtration marker, with the clearance (C_x) computed from the amount of the marker administered (A_x) divided by the average plasma concentration (P_x), which can be computed from the area under the curve of plasma concentration versus time.

$$C_x = A_x/P_x$$

The decline in plasma levels is secondary to the immediate disappearance of the marker from the plasma into its volume of distribution (fast component) and to renal excretion (slow component). Plasma clearance is best estimated by use of a two-compartment model that requires blood sampling early (usually two or three time points until 60 minutes) and late (one to three time points from 120 minutes onward). As with urinary clearance, plasma clearance of a substance depends on filtration, tubular secretion, and tubular reabsorption, but in addition, extrarenal elimination.

Exogenous Filtration Markers

Inulin, an uncharged polymer of fructose with molecular weight of approximately 5000 daltons (d), was the first substance described as an ideal filtration marker and remains the reference (gold standard) against which other markers are evaluated. The classic protocol for inulin clearance requires a continuous intravenous (IV) infusion to achieve a steady state and bladder catheterization with multiple timed urine collections. Because this technique is cumbersome, and inulin measurement requires a difficult chemical assay, this method has not been used widely in clinical practice and remains a research

Exogenous Filtration Markers for Estimation of Glomerular Filtration Rate

Marker	Method of Administration	Comments
Inulin	Continuous IV infusion	Gold standard
Iothalamate	Bolus IV injection or subcutaneous injection	Can be administered as radioactive compound with iodine 125 (^{125}I) as the tracer or in nonradioactive form, with assay using HPLC methods. In radioactive form, potential problem of thyroid uptake of ^{125}I. Iothalamate is secreted, leading to overestimation of GFR
^{99m}Tc-DTPA	Bolus IV injection	Dissociation of ^{99m}Tc leads to plasma protein binding and underestimation of GFR
^{51}Cr-EDTA	Bolus IV injection	10% lower clearance than inulin
Iohexol	Bolus IV injection	Low incidence of adverse effects; comparable to inulin; expensive and difficult to perform assay

Table 3-1 Exogenous filtration markers for estimation of glomerular filtration rate. ^{51}*Cr-EDTA,* Chromium 51–labeled ethylenediaminetetraacetic acid; *GFR,* glomerular filtration rate; *HPLC,* high-performance liquid chromatography; *IV,* intravenous; ^{99m}*Tc-DTPA,* technetium 99m–labeled diethylenetriaminepentaacetic acid.

tool. Alternative exogenous substances include iothalamate, iohexol, ethylenediaminetetraacetic acid, and diethylenetriaminepentaacetic acid, often chelated to radioisotopes for ease of detection (Table 3-1). Alternative protocols to assess clearance have also been validated, including subcutaneous injection and spontaneous bladder emptying. There are advantages to alternative exogenous filtration markers and methods, but also limitations. Understanding the strengths and limitations of each alternative marker and each clearance method will facilitate interpretation of measured GFR.[1]

Endogenous Filtration Markers

Endogenous filtration markers are substances generated in the body at a relatively constant rate and eliminated largely by glomerular filtration. Therefore, the serum level correlates highly with measured GFR after accounting for factors other than GFR that influence the non-GFR determinants. Currently identified endogenous filtration markers include low-molecular-weight metabolites and serum proteins. Filtered metabolites may undergo reabsorption or secretion, which contribute to their urinary excretion. Comparison to urinary clearance of exogenous filtration markers enables inferences about the renal handling of endogenous filtration markers. By contrast, filtered serum proteins are reabsorbed and degraded within the tubule with minimal appearance in the urine. For filtration markers excreted in the urine, urinary clearance can be computed from a timed urine collection and a single measurement of serum concentration. If the serum level is not constant during the urine collection, as in acute kidney disease or when residual kidney function is assessed in dialysis patients, it is necessary to obtain additional blood samples during the urine collection to estimate the average serum concentration.

Creatinine is the most frequently used endogenous filtration marker in clinical practice. Urea was widely used in the past, and cystatin C presently shows great promise (Table 3-2).

Relationship of GFR and Non-GFR Determinants to Serum Levels

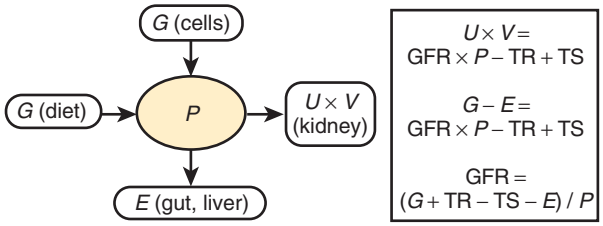

Figure 3-1 Relationship of glomerular filtration rate and non-GFR determinants to serum levels. *G,* Generation; *E,* extrarenal elimination; *P,* plasma; *TR,* tubular reabsorption; *TS,* tubular secretion. *(Modified from reference 1.)*

Estimated Glomerular Filtration Rate from Plasma Levels

Figure 3-1 shows the relationship of plasma concentration of substance x to its generation (G_x) by cells and dietary intake, urinary excretion ($U_x \times V$), and extrarenal elimination (E_x) by gut and liver. The plasma level is related to the reciprocal of the level of GFR, but it is also influenced by generation, tubular secretion and reabsorption, and extrarenal elimination, collectively termed *non-GFR determinants* of the plasma level.[1]

In the steady state, a constant plasma level of substance x is maintained because generation is equal to urinary excretion and extrarenal elimination. *Estimating equations* incorporate demographic and clinical variables as surrogates for the non-GFR determinants and provide a more accurate estimate of GFR than the reciprocal of the plasma level alone. Estimating equations are derived from regression of measured GFR on measured values of the filtration marker and observed values of the demographic and clinical variables. *Estimated* GFR (eGFR) may differ from measured GFR in a patient if a discrepancy exists between the true and average values for the relationship of the surrogate to the non-GFR determinants of the filtration marker. Other sources of errors include measurement error in the filtration marker (e.g., failure to calibrate assay for filtration marker to assay used in development of equation), measurement error in GFR in development of the equation, and regression to the mean. In principle, all these errors are likely to be greater at higher values for GFR.[2]

CREATININE

Metabolism and Excretion

Creatinine is a 113-d end product of muscle catabolism. Advantages of creatinine include its ease of measurement and the low cost and widespread availability of assays. Disadvantages include the large number of non-GFR determinants, leading to a wide range of GFR for a given serum creatinine level (see Table 3-2). For example, a serum creatinine level of 1.5 mg/dl (132 µmol/l) may correspond to a GFR from approximately 20 to 90 ml/min/1.73 m^2.

Creatinine is derived by the metabolism of phosphocreatine in muscle as well as from dietary meat intake or creatine supplements. Creatinine generation is proportional to muscle mass, which can be estimated from age, gender, race, and body size. Table 3-3 lists factors that can affect creatinine generation.[3]

Creatinine is released into the circulation at a constant rate during normal physiologic conditions. It is not protein bound and is freely

Comparison of Creatinine, Urea, and Cystatin C as Filtration Markers			
Variable	**Creatinine**	**Urea**	**Cystatin C**
Molecular Properties			
Weight (d)	113	60	13,000
Structure	Amino acid derivative	Organic molecular product of protein metabolism	Nonglycosylated basic protein
Physiologic Determinants of Serum Level			
Generation	Varies, according to muscle mass and dietary protein; lower in elderly persons, women, and whites	Varies, according to dietary protein intake and catabolism	Thought to be mostly constant by all nucleated cells; increases in hyperthyroid state and with steroid use; lower in elderly persons and women
Handling by kidney	Filtered, secreted, and excreted in urine	Filtered, reabsorbed, and excreted in urine	Filtered, reabsorbed, and catabolized
Extrarenal elimination	Yes; increases at reduced GFR	Yes; increases at reduced GFR	Preliminary evidence of increases at reduced GFR
Use In Estimating Equations for GFR			
Demographic and clinical variables as surrogates for physiologic determinants	Age, gender, and race; related to muscle mass	Not applicable	Age, gender
Accuracy	Accurate for GFR <60 ml/min/1.73 m^2	Not applicable	Unknown
Assay			
Method	Colorimetric or enzymatic	Direct measurement, enzymatic colorimetric and electrochemical	PENIA, PETIA, or ELISA
Assay precision	Very good except at low range	Precise throughout range	Precise throughout range
Clinical laboratory practice	Multiple assays; widely used nonstandard calibration	Multiple assays; enzymatic and colorimetric more common	Not on most autoanalyzers; not standardized
Standardized recommendation materials (SRMs)	SRM 967	SRM 912a	ERM-DA471/IFCC
Reference assay	IDMS	IDMS	PENIA, PETIA, or ELISA

Table 3-2 Comparison of creatinine, urea, and cystatin C as filtration markers. *ELISA,* Enzyme-linked immunosorbent assay; *GFR,* glomerular filtration rate; *IDMS,* isotope-dilution–mass spectroscopy; *PENIA,* particle-enhanced nephelometric immunoassay; *PETIA,* particle-enhanced turbidimetric immunoassay. *(Modified with permission from reference 2.)*

filtered across the glomerulus and secreted by the tubules. Several medications, such as cimetidine and trimethoprim, competitively inhibit creatinine secretion and reduce creatinine clearance. These medications thus lead to a rise in the serum creatinine concentration without an effect on GFR (Table 3-3).

In addition, creatinine is contained in intestinal secretions and can be degraded by bacteria. If GFR is reduced, the amount of creatinine eliminated through this extrarenal route is increased. Antibiotics can raise serum creatinine concentration by destroying intestinal flora, thereby interfering with extrarenal elimination, as well as by reducing the GFR. The rise in serum creatinine concentration after inhibition of tubular secretion and extrarenal elimination is greater in patients with a reduced GFR. Clinically, it can be difficult to distinguish a rise in serum creatinine concentration caused by inhibition of creatinine secretion or extrarenal elimination from a decline in GFR. However, processes other than a decrease in GFR should be suspected if serum urea concentration remains unchanged despite a significant change in serum creatinine concentration in a patient with an initially reduced GFR.

Creatinine clearance is usually computed from the creatinine excretion in a 24-hour urine collection and single measurement of serum creatinine in the steady state. Creatinine excretion rates vary with age, gender, and race and are approximately 20 to 25 mg/kg/day and 15 to 20 mg/kg/day in a complete collection in healthy young men and women, respectively. Equations are available to estimate the creatinine excretion from age, gender, weight, and other variables.[4] Deviations from these expected values can give some indication of errors in timing or completeness of urine collection. Creatinine clearance systematically overestimates GFR because of tubular creatinine secretion. In the past the amount of creatinine excreted by tubular secretion at normal levels of GFR was thought to be relatively small (10% to 15%), but with newer, more accurate assays for low values of serum creatinine, this difference may be substantially greater. At low values of GFR, the amount of creatinine excreted by tubular secretion may exceed the amount filtered.[2]

Creatinine Assay

Historically, the most common assay for measurement of serum creatinine was the alkaline picrate (Jaffe) assay that generates a color reaction. Chromogens other than creatinine are known to interfere with the assay, giving rise to errors of up to approximately 20% in normal individuals. Modern enzymatic assays do not detect noncreatinine chromogens and yield lower serum levels than with the alkaline picrate assays. Until recently, calibration of assays to adjust for this interference was not standardized across laboratories, thereby limiting the estimation of GFR from serum creatinine concentrations, especially at higher GFR.

To address the heterogeneity in creatinine assays, fresh-frozen serum pools with known creatinine levels traceable to an

Factors Affecting Serum Creatinine Concentration		
Factors	**Effect on Creatinine**	**Mechanism/Comment**
Age	Decrease	Reduced creatinine generation caused by age-related decline in muscle mass
Female gender	Decrease	Reduced creatinine generation caused by reduced muscle mass
Race		
African American	Increase	Higher creatinine generation caused by higher average muscle mass in African Americans; not known how muscle mass in other races compares with that of African Americans or Caucasians
Diet		
Vegetarian	Decrease	Decrease in creatinine generation
Ingestion of cooked meats and creatinine supplements	Increase	Transient increase in creatinine generation, although this may be blunted by transient increase in GFR
Body Habitus		
Muscular	Increase	Increased muscle generation caused by increased muscle mass and/or increased protein intake
Malnutrition, muscle wasting, amputation	Decrease	Reduced creatinine generation caused by reduced muscle mass and/or reduced protein intake
Obesity	No change	Excess mass is fat, not muscle mass, and does not contribute to increased creatinine generation.
Medications		
Trimethoprim, cimetidine, fibric acid derivatives other than gemfibrozil	Increase	Reduced tubular secretion of creatinine
Keto acids, some cephalosporins	Increase	Interference with alkaline picrate assay for creatinine

Table 3-3 Factors affecting serum creatinine concentration. *(Modified from reference 3.)*

isotope-dilution–mass spectrometry (IDMS) reference are available for instrument manufacturers to standardize creatinine measurements.[5] Use of standardized assays is recommended.[6] Standardization will reduce, but not completely eliminate, the error in estimating GFR at higher levels (Table 3-3).

Estimated Glomerular Filtration Rate from Serum Creatinine

Again, GFR can be estimated from serum creatinine by equations that use age, gender, race, and body size as surrogates for creatinine generation.[1] Despite substantial advances in the accuracy of estimating equations based on creatinine during the past several years, GFR estimates remain imprecise, and no equation is likely to overcome the limitations of creatinine as a filtration marker. None of the equations is expected to work as well in patients with extreme levels for creatinine generation, such as amputees, large or small individuals, patients with muscle-wasting conditions, or people with high or low levels of dietary meat intake (Table 3-3). Because of differences among racial and ethnic groups according to muscle mass and diet, equations developed in one racial or ethnic group are unlikely to be accurate in multiethnic populations. As discussed later, further improvements will probably require additional filtration markers.

Cockcroft-Gault Formula

The Cockcroft-Gault formula estimates creatinine clearance from age, gender, and body weight, in addition to serum creatinine (Box 3-1).[7] An adjustment factor for women is based on a theoretical assumption of 15% lower creatinine generation because of lower muscle mass. Comparison to normal values for creatinine clearance requires computation of BSA and adjustment to 1.73 m^2. Because of the inclusion of a term for "weight" in the numerator, this formula systematically overestimates creatinine clearance in edematous or obese patients.

The Cockcroft-Gault formula has three main limitations. First, it is not precise, in particular in the GFR range above 60 ml/min. Second, it estimates creatinine clearance rather than GFR and thus is expected to overestimate GFR, while normal values for creatinine secretion are not well known. Third, the formula was derived by older assay methods for serum creatinine, which cannot be calibrated to newer assay methods, which would be expected to lead to a systematic bias in estimating creatinine clearance.

Importantly, before standardization of creatinine assays, the Cockcroft-Gault formula was widely used to assess pharmacokinetic properties of drugs in patients with impaired kidney function. The accuracy of drug dosing recommendations based on the Cockcroft-Gault formula using creatinine values from modern assays remains controversial. One study suggested that drug dosage adjustment guided by the Cockcroft-Gault formula is slightly less accurate than adjustments based on more accurate estimating equations.[8]

Modification of Diet in Renal Disease Study

The Modification of Diet in Renal Disease (MDRD) study equation uses age, gender, and race (African American vs. Caucasian or other) and standardized serum creatinine to estimate GFR[9] (Box 3-1). It was derived from a study population with chronic kidney disease (CKD) and underestimates the measured GFR in populations with higher levels of GFR (Fig. 3-2). It has not been validated in children or pregnant women. The MDRD study equation had greater precision and greater overall accuracy than the Cockcroft-Gault formula. Modifications of the MDRD have now been reported in racial and ethnic populations other than African American and Caucasian, including those in China, Japan, Thailand, and South Africa.[10,11] In general, these modifications improve the accuracy of the MDRD equation in the study population but do not generalize well to other populations.

Organizations in several countries now recommend GFR estimates (eGFR) as the primary method of clinical assessment of

Equations for Estimating Glomerular Filtration Rate

Cockroft-Gault Formula[6]

Male

$$C_{cr}(\text{ml/min}) = \frac{(140 - \text{Age}) \times \text{Weight}}{72 \times S_{cr}(\text{mg/dl})} \quad \text{or} \quad C_{cr}(\text{ml/min}) = \frac{(140 - \text{Age}) \times \text{Weight}}{0.814 \times S_{cr}(\mu\text{mol/l})}$$

Female

$$C_{cr}(\text{ml/min}) = \frac{(140 - \text{Age}) \times \text{Weight} \times 0.85}{72 \times S_{cr}(\text{mg/dl})} \quad \text{or} \quad C_{Cr}(\text{ml/min}) = \frac{(140 - \text{Age}) \times \text{Weight} \times 0.85}{0.814 \times S_{cr}(\mu\text{mol/l})}$$

MDRD Study Equation for Use with Standardized Serum Creatinine (Four-Variable Equation)[8]

$$\text{GFR (ml/min/1.73 m}^2) = 175 \times \text{Standardized } S_{cr}(\text{mg/dl})^{-1.154} \times \text{Age}^{-0.203} \times 0.742 \text{ (if female)} \times 1.210 \text{ (if black)}$$

$$\text{GFR (ml/min/1.73 m}^2) = 30{,}849 \times \text{Standardized } S_{cr}(\mu\text{mol/l})^{-1.154} \times \text{Age}^{-0.203} \times 0.742 \text{ (if female)} \times 1.210 \text{ (if black)}$$

CKD-EPI Equation for Use with Standardized Serum Creatinine[11]

$$\text{GFR (ml/min/1.73 m}^2) = 141 \min(S_{cr}/\kappa, 1)^{\alpha} \times \max(S_{cr}/\kappa, 1)^{1.209} \times 0.993^{\text{Age}} \times 1.018 \text{ (if female)} \times 1.157 \text{ (if black)}$$

where κ is 0.7 for females and 0.9 for males, α is –0.329 for females and –0.411 for males, *min* indicates the minimum of S_{cr}/κ or 1, and *max* indicates the maximum of S_{cr}/κ or 1.

Female

$$\leq 0.7 \rightarrow \text{GFR} = 144 \times (S_{cr}/0.7)^{-0.329} \times (0.993)^{\text{Age}} \times 1.157 \text{ (if black)}$$

$$> 0.7 \rightarrow \text{GFR} = 144 \times (S_{cr}/0.7)^{-1.209}$$

The Modification of Diet in Renal Disease (MDRD) study and Chronic Kidney Disease Epidemiology (CKD-EPI) equation calculator can also be found online at *http://www.kidney.org/professionals/kdoqi/gfr_calculator.cfm*.

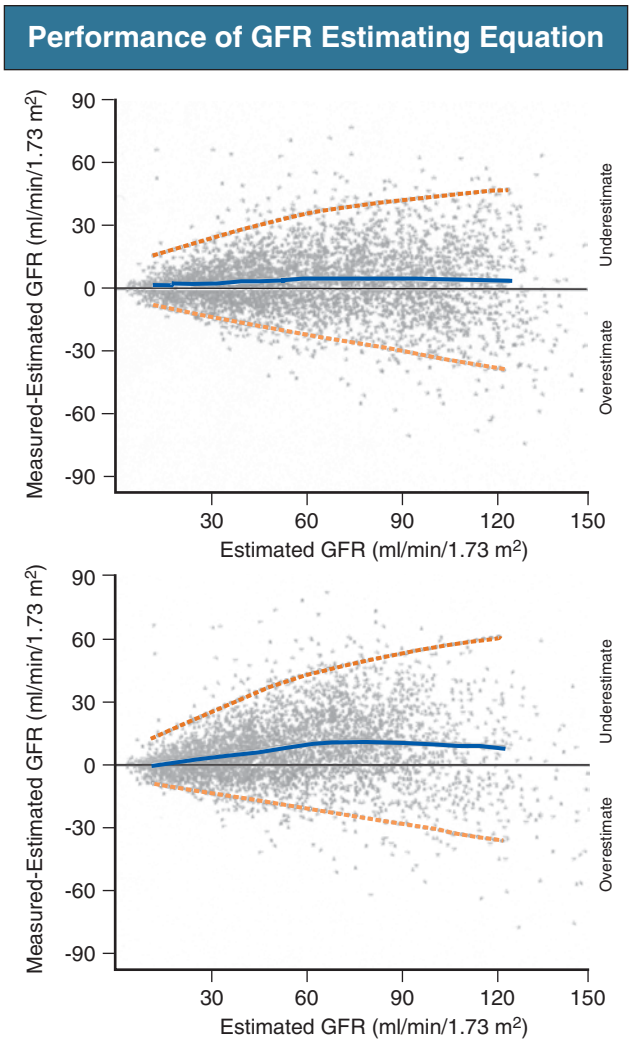

Figure 3-2 Comparison of performance of Chronic Kidney Disease Epidemiology Collaboration (CKD-EPI) and Modification of Diet in Renal Disease (MDRD) study equations. Difference between measured GFR (mGFR) and estimated GFR (eGFR) versus eGFR for CKD-EPI equation *(top panel)* and MDRD equation *(bottom panel),* showing smoothed regression line and 95% confidence interval (CI, computed from lowest smoothing function in *R*) and using quantile regression, excluding lowest and highest 2.5% of eGFR values. For the two equations, median bias (percentage of estimates within 30% of measured GFR, P_{30}) is 2.5 (84) and 5.5 (81), respectively. To convert GFR from ml/min/1.73 m^2 to ml/s/m^2, multiply by 0.0167. *(Modified from reference 12.)*

kidney function.[6] Because of limitations in accuracy at higher levels, recommendations include reporting eGFR as a numerical value only if the GFR estimate is less than 60 ml/min/1.73 m^2 and reporting eGFR as "greater than 60 ml/min/1.73 m^2" for higher values.[6]

Chronic Kidney Disease Epidemiology Collaboration

The 2009 Chronic Kidney Disease Epidemiology Collaboration (CKD-EPI) creatinine equation (Box 3-1) has been developed from a large database of participants in research studies and patients from clinical populations with diverse characteristics, including those with and without kidney disease, diabetes, and a history of organ transplantation, to overcome the limitations of the MDRD Study equation.[12] The CKD-EPI equation is based on the same four variables as the MDRD equation but uses a two-slope "spline" to model the relationship between GFR and serum creatinine, which partially corrects the underestimation of GFR at higher levels seen with the MDRD study equation. The CKD-EPI creatinine equation also incorporates slightly different relationships for age, gender, and race. As a result, the CKD-EPI equation is as accurate as the MDRD at eGFR of less than 60 ml/min/1.73 m^2 and is more accurate at higher levels (Fig. 3-2). The CKD-EPI is also more accurate across a wide range of characteristics, including age, gender, race, body mass index, and presence or absence of diabetes or history of organ transplantation. As with the MDRD, modifications of the CKD-EPI equations in Japan improve accuracy in these study populations.[11]

The CKD-EPI creatinine equation now allows reporting of eGFR across the entire range of values, without substantial bias. It is currently reported by the two major nationwide laboratories in the United States, as well as by laboratories in France. The 2012 Kidney Disease: Improving Global Outcomes (KDIGO) guidelines recommend that clinical laboratories report eGFR in all adults using CKD-EPI creatinine equations, or using other equations if shown to be superior to CKD-EPI equation in that population.[13]

UREA

The serum urea level has limited value as an index of GFR, in view of widely variable non-GFR determinants, primarily urea generation and tubular reabsorption (see Table 3-2).

Urea is a 60-d end product of protein catabolism by the liver. Factors associated with the increased generation of urea include protein loading from hyperalimentation and absorption of blood after a gastrointestinal hemorrhage. Catabolic states caused by infection, corticosteroid administration, or chemotherapy also increase urea generation. Decreased urea generation is seen in patients with severe malnutrition and liver disease.

Urea is freely filtered by the glomerulus and then passively reabsorbed in both proximal and distal nephrons. As a result of tubular reabsorption, urinary clearance of urea underestimates GFR. Reduced kidney perfusion in the patient with volume depletion and states of antidiuresis are associated with increased urea reabsorption. This leads to a greater decrease in urea clearance than the concomitant decrease in GFR. At GFR of less than about 20 ml/min/1.73 m^2, the overestimation of GFR by creatinine clearance resulting from creatinine secretion approximates the underestimation of GFR by urea clearance from urea reabsorption; thus the average of creatinine and urea clearance approximates the measured GFR.

CYSTATIN C

Metabolism and Excretion

Cystatin C is a 122–amino acid protein with molecular weight of 13 kd (see Table 3-2). Its multiple biologic functions include extracellular inhibition of cysteine proteases, modulation of the immune system, antibacterial and antiviral activities, and modification of the body's response to brain injury. The serum concentration of cystatin C remains constant from about 1 to 50 years of age. In analyses of the Third National Health and Nutrition Examination Survey (NHANES III), the median and upper 99th percentile levels of serum cystatin C for people age 20 to 39 without history of hypertension and diabetes were 0.85 mg/l and 1.12 mg/l, respectively, with levels lower in women than in men, higher in non-Hispanic whites than in blacks and Mexicans, and increasing steeply with age.[14]

Cystatin C has been thought to be produced at a constant rate by a "housekeeping" gene expressed in all nucleated cells. It is freely filtered at the glomerulus because of its small size and basic pH. Approximately 99% of the filtered cystatin C is reabsorbed by the

proximal tubular cells, where it is almost completely catabolized, with the remainder eliminated in the urine largely intact.[15] Some evidence suggests the existence of tubular secretion as well as extrarenal elimination, the latter estimated at 15% to 21% of renal clearance.[16]

Because cystatin C is not excreted in the urine, it is difficult to study its generation and renal handling. Thus, understanding non-GFR determinants of cystatin C relies on epidemiologic associations. Some suggest that inflammation, adiposity, thyroid diseases, certain malignant neoplasms, and use of glucocorticoids may increase cystatin C levels. Two studies found that key factors leading to higher cystatin C levels after adjustment for creatinine clearance or measured GFR were older age, male gender, fat mass, white race, diabetes, higher C-reactive protein level, increased white blood cell count, and lower serum albumin level.[17,18] Therefore factors other than GFR must be considered in interpreting cystatin C levels.

Cystatin C Assay

Available assays to analyze cystatin C all can result in different values. The International Federation of Clinical Chemists (IFCC) made a reference material for standardization of cystatin C, but international standardization of the assay is still in process.[19] The assays are considerably more expensive than those for creatinine determination.

Estimated Glomerular Filtration Rate from Serum Cystatin C

Numerous studies have found that serum cystatin C levels are a better estimate of GFR than serum creatinine concentration because cystatin C is less affected than creatinine by age, gender, or race. However, cystatin C or equations based on cystatin C are not more accurate than creatinine-based estimating equations, due to variation in non-GFR determinants of serum cystatin C.[20] Several studies, though, have demonstrated that equations combining both these filtration markers with age, gender, and race appear to be more precise than equations using either marker alone, probably because of smaller effects of the non-GFR determinants of both markers when used in combination. The 2012 CKD-EPI cystatin C and creatinine–cystatin C equations (see Box 3-1) are expressed for use with standardized serum creatinine and cystatin C and are recommended by the 2012 KDIGO guidelines (Fig. 3-3).[20] The equation

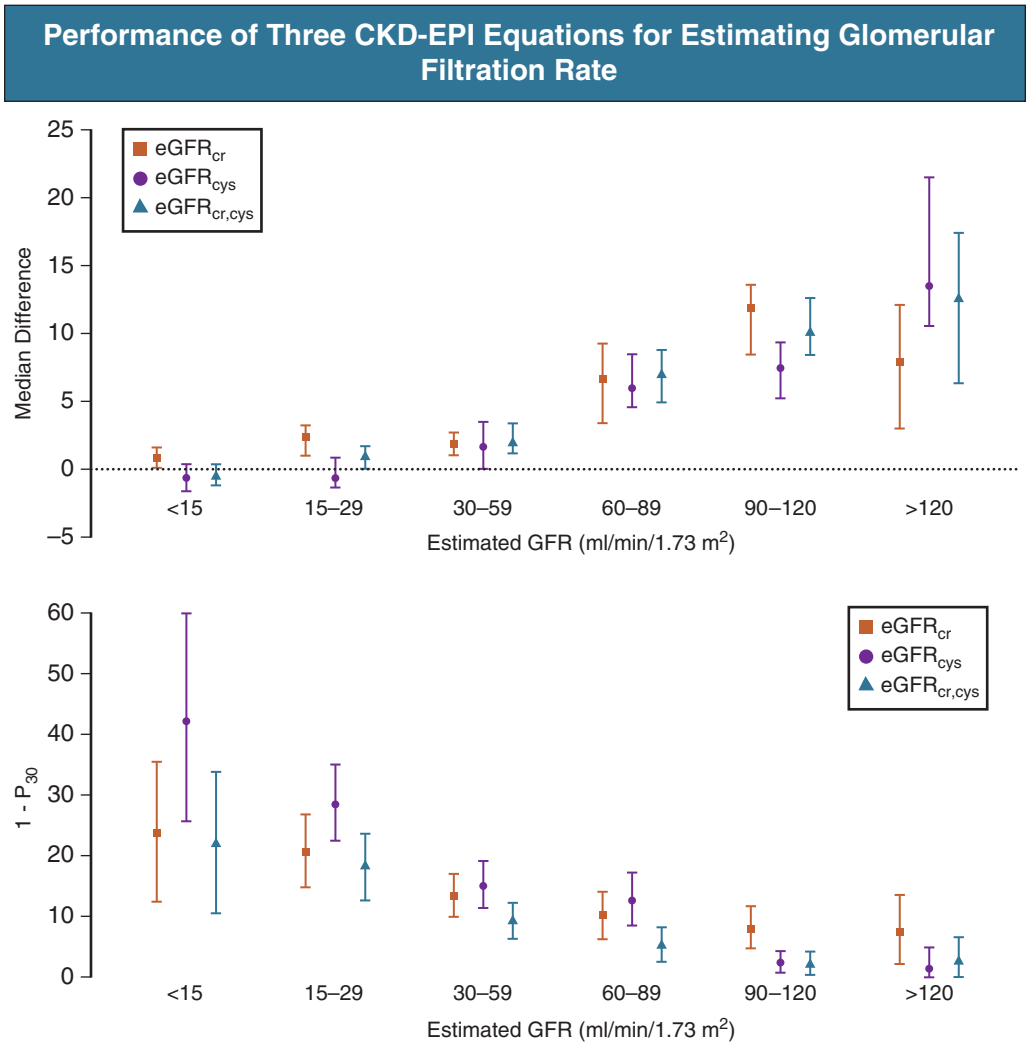

Figure 3-3 Performance of three equations for estimating GFR. GFR was estimated using the Chronic Kidney Disease Epidemiology estimating equations. *Top,* Median difference between measured GFR and estimated glomerular filtration rate *(eGFR).* The bias is similar with the equation using creatinine alone ($eGFR_{cr}$), that using cystatin C alone ($eGFR_{cys}$), and the combined creatinine–cystatin C equation ($eGFR_{cr,cys}$). *Bottom,* Accuracy of the three equations according to percentage of estimates greater than 30% of measured GFR ($1 - P_{30}$). *I bars* indicate 95% CI. *(Modified from reference 20.)*

using cystatin C without creatinine does not appear to require specification of race. Also, in patients with reduced muscle mass (e.g., neuromuscular or liver disease, low body mass index) or in patients with diabetes, cystatin C may result in more accurate GFR estimates than creatinine.

Some studies show that a lower eGFR based on serum cystatin C is a better predictor of the risk of cardiovascular disease and total mortality than is a lower eGFR based on serum creatinine concentration.[21] Whether this is caused by its superiority as a filtration marker or the confounding by non-GFR determinants of cystatin C and creatinine remains to be determined. In the future, GFR estimating equations using the combination of serum cystatin C and creatinine may be useful as a confirmatory test for CKD. However, this is feasible only after standardization, widespread availability, and cost reductions of cystatin C assays, as well as further investigation of non-GFR determinants of serum cystatin C.

OTHER FILTRATION MARKERS

β_2-Microglobulin (β_2M) and β-trace protein (βTP) are two other low-molecular-weight serum proteins being evaluated as filtration markers for estimating GFR and for their role in prognosis. However, β_2M and βTP are not recommended for use at this time. An 11.8-kd subunit of major histocompatibility complex (MHC) class I molecules, β_2M is present on all nucleated cells and plays a central role in cellular immunology. βTP, also known as lipocalin prostaglandin D_2 synthase, is a 168–amino acid glycoprotein of 23 to 29 kd. As with cystatin C, β_2M and βTP are freely filtered by the glomerulus and extensively reabsorbed and degraded by the proximal tubule, with only small amounts excreted in the urine under normal conditions.

In NHANES-III analyses, the median (upper 99th percentile) levels of serum β_2M and βTP for people age 20 to 39 without history of hypertension or diabetes were 0.52 mg/l (0.81 mg/l) and 1.59 mg/l (2.80 mg/l), respectively, with levels lower in women than in men and higher in non-Hispanic whites than in blacks and Mexicans;[22] levels were higher in older people. Several studies found correlations of serum β_2M and βTP levels with directly measured GFR that were better or similar to those observed with creatinine and that were similar to cystatin C.[23-26] In addition, studies have shown that β_2M and βTP are better predictors of adverse health outcomes than creatinine and are potentially as accurate as cystatin C in the general population and in patients with CKD.[23,27,28] However, some factors may limit their use as a filtration marker; serum β_2M concentration may be increased in several malignancies and inflammatory states, and corticosteroid administration may decrease serum βTP concentration.[28,29]

CLINICAL APPLICATION OF ESTIMATED GLOMERULAR FILTRATION RATE

Chronic Kidney Disease

Estimation of GFR is necessary for the detection, evaluation, and management of patients with CKD. Current guidelines recommend testing of patients at increased risk of CKD for albuminuria, as a marker of kidney damage, or a reduced eGFR to assess kidney function and staging of disease severity by eGFR level. Use of serum creatinine alone as an index of GFR is unsatisfactory and can lead to delays in detection of CKD and misclassification of the severity of CKD. Use of estimating equations allows direct reporting of eGFR by clinical laboratories whenever serum creatinine is measured. Current estimating equations will be less accurate in people with factors affecting serum creatinine concentration other than GFR (see Table 3-3). In these patients, more accurate GFR estimates require additional testing, such as measurement with an endogenous filtration marker (e.g., cystatin C, β_2M, βTP), a timed urine creatinine clearance measurement, or clearance measurement using an exogenous marker.

Acute Kidney Injury

In the nonsteady state, there is a lag before the rise in serum level because of the time required for retention of an endogenous filtration marker (Fig. 3-4). Conversely, after recovery of GFR, there is a lag before the excretion of the retained marker. During this time, neither the serum level nor the GFR estimated from the serum level accurately reflects the measured GFR. Nonetheless, a change in the eGFR in the nonsteady state can be a useful indication of the magnitude and direction of the change in measured GFR. If the eGFR is decreasing, the decline in eGFR is less than the decline in measured GFR. Conversely, if the eGFR is increasing, the rise in eGFR is greater than the rise in measured GFR. The more rapid the change in eGFR, the greater is the change in measured GFR. When eGFR reaches a new steady state, it more accurately reflects measured GFR. In patients with acute kidney injury, serum cystatin C appears to increase more rapidly than serum creatinine.[30] More data are required to establish whether changes in serum cystatin C are a more sensitive indicator of rapidly changing kidney function than changes in serum creatinine.

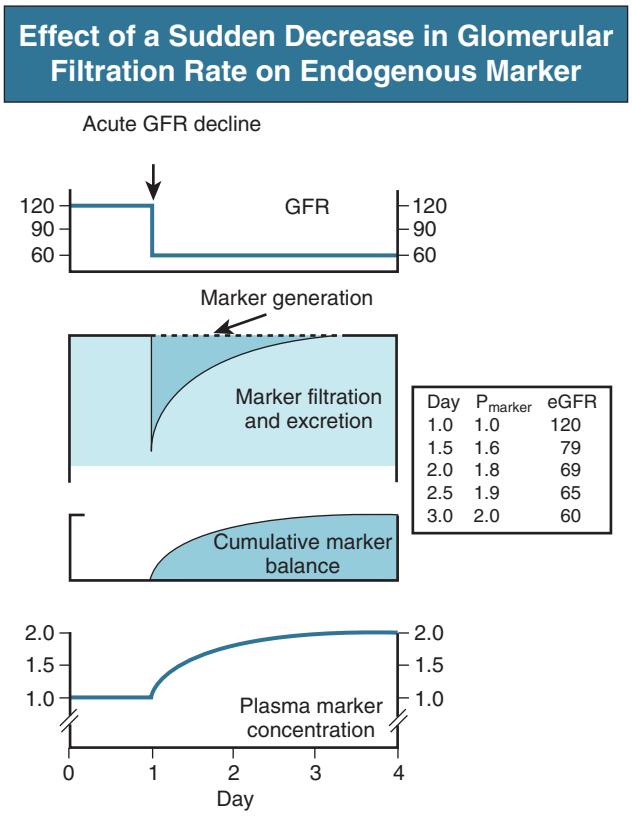

Figure 3-4 Sudden decrease in glomerular filtration rate. Graphs show effect of acute GFR decline *(top)* on generation, filtration/excretion, and balance of endogenous marker *(middle)* and concentration of plasma marker *(bottom). (Modified from reference 1.)*

MARKERS OF TUBULAR DAMAGE

The urinary excretion of low-molecular-weight serum proteins may increase when proximal tubular reabsorption is impaired, which may serve as a marker of proximal tubular damage. Examples include cystatin C and β_2M, as previously described, as well as interleukin-18 (18,000 d), retinol-binding protein (21,000 d) and α_1-macroglobulin (33,000 d). In contrast, other markers of tubular damage are produced in the kidney in response to injury, such as *N*-acetyl-β-glucosaminidase (NAG) and urinary kidney injury molecule 1 (KIM-1). Increased excretion of neutrophil gelatinase–associated lipocalin (NGAL), a 25,000-d protein in kidney disease, may reflect impaired reabsorption of filtered NGAL or increased production by the kidney. These and other urinary markers of tubular damage under investigation are discussed further in Chapter 71.

CHAPTER 4

Urinalysis

Giovanni B. Fogazzi and Giuseppe Garigali

DEFINITION

Urinalysis is one of the key tests to evaluate kidney and urinary tract disease. When a patient is first seen by a nephrologist, urinalysis should always be performed. Dipsticks are the most widely used method for urinalysis, but the nephrologist should be aware of their limitations. Urine sediment examination is an integral part of urinalysis, which is performed routinely in general clinical laboratories. Ideally, however, urine microscopy should be performed by trained nephrologists rather than clinical laboratory personnel, who are at times unable to identify important elements,[1] and who are not always aware of the clinical correlates of the findings.[2]

This chapter describes the main aspects of urinalysis, including urine collection, evaluation of physical and chemical features of urine, and urine microscopy.

URINE COLLECTION

The way urine is collected and handled can greatly influence the results (Box 4-1). Written instructions for performing a urine collection should be given to the patient. First, strenuous physical exercise (e.g., running, soccer) should be avoided for at least 24 hours before the collection to avoid exercise-induced proteinuria and hematuria or cylindruria. In women, urinalysis should also be avoided during menstruation because blood contamination can easily occur.

If a midstream sample of the first morning urine is used, lysis of cells and casts may occur in the bladder overnight, which may lead to false-negative results at urine sediment examination. For this reason, for renal patients, we suggest performing a combined dipstick and urine microscopy on the second morning urine.

For the measurement of 24-hour protein excretion, a 24-hour urine collection is needed. Errors caused by improper timing and missed samples can lead to overcollection or undercollection of urine. Errors can be minimized by giving the patient simple written instructions. Written instructions should also be provided for other types of urine collection, such as that needed for the evaluation of orthostatic proteinuria, which implies the collection of one sample produced while the patient has been recumbent for some hours, and another sample produced while the patient has been standing.

Spot urine samples are widely recommended[3] because they are easy to obtain, although timed urines are still recommended by some authorities (see Chapter 80).

After the washing of hands, women should spread the labia of the vagina and men withdraw the foreskin of the glans. The external genitalia are washed and wiped dry with a paper towel, and the "midstream" urine is collected after the first portion is discarded. The same procedures can also be used for children. For small infants, bags for urine are often used, even though these carry a high probability of contamination. A suprapubic bladder puncture may occasionally be necessary. In special situations, urine can also be collected through a bladder catheter, although the catheter may cause hematuria. Permanent indwelling catheters are often associated with bacteriuria, leukocyturia, hematuria, and candiduria.

The container for urine should be provided by the laboratory or bought in a pharmacy. It should be clean, have a capacity of at least 50 to 100 ml, and have a diameter opening of at least 5 cm to allow easy collection. It should have a wide base to avoid accidental spillage and should be capped. The label should identify the patient as well as the hour of urine collection.

Several elements (but especially leukocytes) can lyse rapidly after collection, thus ideally the sample should be handled and examined as soon as possible. In everyday practice, we suggest the samples be analyzed within 3 hours from collection. If this is not possible, refrigeration of specimens at +4° to +8°C assists preservation but may cause precipitation of phosphates or urates, which can hamper examination. Alternatively, chemical preservatives such as formaldehyde or glutaraldehyde can be used.

PHYSICAL CHARACTERISTICS

Color

The color of normal urine ranges from pale to dark yellow and amber, depending on the concentration of the urochrome. Abnormal changes in color can be caused by pathologic conditions, drugs, or foods.

The most frequent pathologic conditions that can cause color changes of the urine are gross hematuria, hemoglobinuria, or myoglobinuria (pink, red, brown, or black urine); bilirubinuria (dark-yellow to brown urine); and massive uric acid crystalluria (pink urine). Less frequent causes are urinary infection, mainly from *Klebsiella* spp., *Proteus mirabilis, Escherichia coli, Providencia stuartii,* or *Enterococcus* spp. in patients with permanent bladder catheter (purple urine, sometimes called "purple urine bag syndrome")[4]; chyluria (white milky urine); and porphyrinuria (associated with the excretion in the urine of porphobilinogen) and alkaptonuria (red urine turning black on standing).

The main drugs responsible for abnormal urine color are rifampin (yellow-orange to red urine); desferrioxamine (pinkish urine); phenytoin (red urine); chloroquine and nitrofurantoin (brown urine); triamterene, propofol, and blue dyes of enteral feeds (green urine); methylene blue (blue urine); and metronidazole, methyldopa, and imipenem-cilastatin (darkening on standing).

Among foods are beetroot (red urine), senna and rhubarb (yellow to brown or red urine), and carotene (brown urine).

Turbidity

Normal urine is transparent. Urine can be turbid because of a high concentration of any urine particle, especially cells, crystals, and

Procedures for Preparation and Examination of Urine Sediment

- Written instructions to the patients for urine collection.
- Collection in disposable containers of the second urine of the morning after discarding the first few milliliters of urine (i.e., midstream urine).
- Sample handling and examination within 3 hours of collection.
- Centrifugation of a 10-ml aliquot of urine at 400 g for 10 minutes.
- Removal by suction of 9.5 ml of supernatant urine.
- Gentle but thorough resuspension with a Pasteur pipette of sediment in remaining 0.5 ml of urine.
- Transfer by a precision pipette of 50 µl of resuspended urine to a slide.
- Covering of sample with a 24 × 32–mm coverslip.
- Examination of the urine sediment by a phase contrast microscope at ×160 and ×400.
- Use of polarized light to identify suspected lipids and crystals.
- Matching of the microscopic findings with dipstick for pH, specific gravity, hemoglobin, leukocyte esterase, nitrites, and albumin (presence of albumin orients examination of sample toward a glomerular disease).
- Cells expressed as lowest/highest number seen per high-power field (hpf), casts as number per low-power field (lpf), and all other elements (e.g., bacteria, crystals) on scale from 0 to ++++.

Box 4-1 Preparation and examination of urine sediment. Procedures used in the authors' laboratory.

bacteria. The most frequent causes of turbidity are urinary tract infection, heavy hematuria, and contamination of urine from genital secretions. The absence of turbidity is not a reliable criterion by which to judge a urine sample because pathologic urine can be transparent.

Odor

A change in urine odor may be caused by the ingestion of some foods, such as asparagus. A pungent odor, caused by the production of ammonia, is typical of most bacterial urinary tract infection, whereas there is often a sweet or fruity odor with ketones in the urine. Some rare conditions confer a characteristic odor to the urine. These include maple syrup urine disease (maple syrup odor), phenylketonuria (musty or mousy odor), isovaleric acidemia (sweaty feet odor), and hypermethioninemia (rancid butter or fishy odor).

Relative Density

The relative density parameter can be measured by specific gravity or osmolality. *Specific gravity* (SG) refers to the weight of a volume of urine compared with the weight of the same volume of distilled water and depends on the mass and number of the dissolved particles. SG is most frequently evaluated by dipstick, which measures the ionic concentration of urine. In the presence of ions, protons are released by a complexing agent and produce a color change in the indicator bromthymol blue from blue to blue-green to yellow. Underestimation occurs with urine pH above 6.5, whereas overestimation is found with urine protein concentration above 7.0 g/L. Because nonionized molecules, such as glucose and urea, are not detected by dipstick, this method does not strictly correlate with the results obtained by refractometry and osmolality.

Refractometry measures SG through the refraction of light while it passes through a drop of urine on a glass plate. This measures the number of solutes per unit volume and measures all solutes rather than just ionic substances. Therefore, refractometry is more accurate than dipstick, despite being influenced by urine temperature, although temperature-compensated refractometers are available. Refractometers are inexpensive, simple to use, and have the major advantage of requiring only 1 drop of urine. For these reasons, we suggest the use of refractometry for everyday practice.

An SG of 1.000 to 1.003 is consistent with marked urinary dilution, as observed in patients with diabetes insipidus or water intoxication. SG of 1.010 is often called *isosthenuric* urine because it is of similar SG (and osmolality) to plasma, so it is often observed in conditions in which urinary concentration is impaired, such as acute tubular necrosis (ATN) and chronic kidney disease. SG above 1.040 almost always indicates the presence of some extrinsic osmotic agent, such as radiocontrast.

Osmolality is measured by an osmometer, which evaluates the freezing-point depression of a solution and supplies results as milliosmoles per kilogram (mOsm/kg) of water. Osmolality depends only on the number of particles present and is not influenced by urine temperature or protein concentrations. However, high glucose concentrations significantly increase osmolality (10 g/l of glucose = 55.5 mOsm/l). The measurement of osmolality is more reliable than SG by either dipstick or refractometry for the evaluation of pathologic urine.

CHEMICAL CHARACTERISTICS

Chemical characteristics of urine are most frequently evaluated by dipstick. Dipsticks have the advantages of simplicity, low cost, and stability. Disadvantages include qualitative or semiquantitative results only, susceptibility to interference by substances, and urine discoloration. When the reading is visual and not by automated instruments, the interval between removal of the dipstick from urine and the reading of results indicated by the manufacturer must be respected to avoid false results.

Sensitivity and specificity of dipsticks greatly differ among studies and depend on the brand used and different clinical conditions and patient populations investigated. False results can also be caused by the use of time-expired dipsticks. Table 4-1 summarizes the main false-negative and false-positive results that can occur with urine dipstick testing.

pH

The pH is determined by dipsticks that cover the pH range of 5.0 to 8.5 or to 9.0. With use of dipsticks, significant deviations from true pH are observed for values below 5.5 and above 7.5. Therefore, a pH meter with a glass electrode is mandatory if an accurate measurement is necessary.

Urine pH reflects the presence of hydrogen ions (H^+), but this does not necessarily reflect the overall acid load in the urine because most of the acid is excreted as ammonia. A low pH is often observed with metabolic acidosis (in which acid is secreted), with high-protein meals (which generate more acid and ammonia), and with volume depletion (in which aldosterone is stimulated, resulting in an acid urine). Indeed, low urine pH may help distinguish pre-renal acute kidney injury (AKI) from ATN, which is typically associated with a higher pH. High pH is often observed with renal tubular acidosis (especially distal, type 1; see Chapter 12), with vegetarian diets (caused by minimal nitrogen and acid generation), and with infection with urease-positive organisms (e.g., *Proteus*) that generate ammonia from urea.

Urine Dipstick Testing		
Constituent	**False-negative Results**	**False-positive Results**
Specific gravity (SG)	Urine pH >6.5	Urine protein >7.0 g/l
pH	Reduced values in presence of formaldehyde	—
Hemoglobin	Ascorbic acid High SG of urine Formaldehyde (0.5 g/l) used to preserve samples	Myoglobin Microbial peroxidases
Glucose	Ascorbic acid Bacteria	Oxidizing detergents
Albumin	Immunoglobulin light chains Tubular proteins Globulins	Urine pH ≥9.0 Quaternary ammonium detergents Chlorhexidine Polyvinylpyrrolidone
Leukocyte esterase	Glucose ≥20.0 g/l Protein >5.0 g/l Cephalothin (+++) Tetracycline (+++) Cephalexin (++) Tobramycin (+) High SG of urine	Formaldehyde (0.4 g/l) ?Imipenem ?Meropenem ?Clavulanate Abnormally colored urine
Nitrites	Bacteria that do not reduce nitrates to nitrites No vegetables in diet Short bladder incubation time	Abnormally colored urine
Ketones	Improper storage	Free sulfhydryl groups (e.g., captopril) Levodopa Abnormally colored urine

Table 4-1 Urine dipstick testing. Main false-negative and false-positive results of urine dipsticks. False results may also occur when time-expired dipsticks are used.

Measurement of urine pH is also needed for the interpretation of urinalysis (see Leukocyte Esterase and Urine Microscopy).

Hemoglobin

Hemoglobin is detected by a dipstick on the basis of the pseudoperoxidase activity of the heme moiety of hemoglobin, which catalyzes the reaction of a peroxide and a chromogen to form a colored product. The presence of hemoglobin is shown as green spots, which result from intact erythrocytes, or as a homogeneous, diffuse green pattern. This can result from marked hematuria because of the high number of erythrocytes that cover the whole pad surface; from lysis of erythrocytes favored by delayed examination, alkaline urine pH, or low SG; or from hemoglobinuria secondary to intravascular hemolysis.

False-negative results are mainly caused by (1) ascorbic acid, a strong reducing agent, which can result in low-grade microscopic hematuria being completely missed,[5] and (2) high SG.

The most important causes of false-positive results are myoglobinuria, resulting from rhabdomyolysis, and a high concentration of bacteria with pseudoperoxidase activity (Enterobacteriaceae, staphylococci, and streptococci).[6]

Glucose

Glucose is also often detected by dipstick. With glucose oxidase as catalyst, glucose is first oxidized to gluconic acid and hydrogen peroxide. Through the catalyzing activity of a peroxidase, hydrogen peroxide then reacts with a reduced colorless chromogen to form a colored product. This test detects concentrations of 0.5 to 20 g/l. When more precise quantification of urine glucose is needed, enzymatic methods such as hexokinase must be used.

False-negative results with glucose detection occur in the presence of ascorbic acid and bacteria. False-positive findings may be observed in the presence of oxidizing detergents.

Protein

Although there is no consistent definition of proteinuria,[7] it is accepted that physiologic proteinuria does not exceed 150 mg/24 h for adults and 140 mg/m^2 for children. Three different approaches can be used for the evaluation of proteinuria, as described next.

Albumin Dipstick

The albumin dipstick test is based on the presence of protein in a buffer causing a change in pH proportional to the concentration of protein itself. The dipstick changes its color, from pale green to green and blue, according to the pH changes induced by the protein. The dipstick for protein is sensitive to albumin but has a very low sensitivity to other proteins, such as tubular proteins and light-chain immunoglobulins; thus the dipstick will not detect the overflow proteinuria that can occur in myeloma. Moreover, the detection limit is 0.25 to 0.3 g/l, which may be too high to identify the early phases of kidney disease (i.e., microalbuminuria) and is influenced by hydration status (false-negative results may occur at low urine SG, and vice versa) and urine pH (false-positive results at strongly alkaline pH). Also, dipstick supplies only a semiquantitative measurement of urine albumin, which is expressed on a scale from 0 to +++ or ++++.[7] Some manufacturers also supply numerical results, although these represent only approximate quantitative measurements. Thus, for accurate quantification, other methods are needed. Recently, a creatinine test pad has been added to some dipsticks, which supplies a protein-creatinine ratio (PCR) and reduces the variability caused by changing diuresis and urine dilution.[8]

24-Hour Protein Excretion

The 24-hour urine collection for protein excretion remains the reference (gold standard) method. It is based on chemical assay (e.g., biuret or Folin-Lowry reaction), turbidimetric technique (e.g., trichloroacetic acid, benzethonium chloride, ammonium chloride), or dye-binding technique (e.g., ponceau S, Coomassie brilliant blue G-250, pyrogallol red molybdate), which quantify total proteins rather than simply albumin. The 24-hour protein excretion averages the variation of proteinuria caused by the circadian rhythm and is the most accurate for monitoring of proteinuria during treatment. However, it can be impractical in some settings (e.g., children, outpatients, elderly patients) and is subject to error from overcollection or undercollection. For this reason, we give our patients written, simple but definitive instructions on how to collect urine (see earlier discussion).

Protein-Creatinine Ratio on Random Urine Sample

This PCR is obtained by the ratio between urine protein excretion (measured by methods in 24-Hour Protein Excretion) and creatinine excretion, expressed as mg/mg or mg/mmol. PCR represents a practical alternative to the 24-hour urine collection because it is easy to obtain and is not influenced by variation in water intake or rate of

diuresis.[3] Also, the same sample can also be used for microscopic investigation.

A close correlation between the PCR in a random urine sample and the 24-hour protein excretion has been demonstrated in a wide range of patients,[7,9] including those with different types of glomerulonephritis (GN) evaluated longitudinally during treatment.[10] However, the results may be influenced by a reduced creatinine excretion because of reduced muscle mass. Thus, in elderly and female patients, PCR values can be higher than in young men. Another factor to be considered is the timing of the sample, which is influenced by the daily circadian fluctuation of protein excretion in the presence of minimal corresponding variation of creatinine excretion. Thus, the best estimates are probably obtained with morning samples, but not the first void.[11]

Some consider that a normal PCR is sufficient to rule out pathologic proteinuria, but that an elevated PCR should be confirmed and quantified with a 24-hour collection.[12] Other investigators have found poor correlation between PCR and 24-hour proteinuria at high levels of protein excretion,[10] or that PCR is an unreliable method to monitor some patients with lupus nephritis[13,14] (see also Chapter 80).

A possible alternative to PCR is the measurement of albumin-creatinine ratio (ACR), especially to screen and monitor diabetic patients.[9] However, with ACR false-negative results may occur,[15] as a consequence of the variable proportion of albumin present in the urine, which may depend on the underlying renal disease. An elevated PCR with a negative ACR for example suggests the diagnosis of myeloma.

The ratio of urinary albumin to total protein excretion (urine albumin/protein ratio, uAPR) has recently been proposed as a method to distinguish proteinuric patients with a pure glomerular disease from patients with a glomerular disease associated with tubulointerstitial damage or with a tubulointerstitial nephropathy. However, uAPR is not yet validated for routine clinical practice.[16,17]

Specific Proteins

Microalbuminuria Defined as the presence of albumin in the urine in a range of 30 to 299 mg/24 h, microalbuminuria identifies diabetic patients at increased risk of developing overt diabetic nephropathy. Also, in the general population, microalbuminuria identifies patients at increased risk of chronic kidney disease, cardiovascular morbidity, and overall mortality. The 24-hour urine collection, initially considered the gold standard method for the detection of microalbuminuria, currently has been replaced by the use of early-morning urine, which minimizes the changes caused by diurnal volume variations. A number of semiquantitative dipstick tests are available to screen for microalbuminuria.

Once microalbuminuria is found by dipstick, a standard quantitative method is then used for confirmation, usually immunoassay.[18] Because of its great simplicity, immunoturbidometry is the method most frequently used.

Tubular Proteins Low-molecular-weight tubular proteins such as α_1-microglobulin, retinol-binding protein, and β_2-microglobulin are identified by a qualitative analysis of urine proteins, using electrophoresis on cellulose acetate or agarose after protein concentration or using very sensitive stains such as silver and gold. Sodium dodecyl sulfate–polyacrylamide gel electrophoresis (SDS-PAGE) can be used to identify tubular proteins in the urine of patients with glomerular diseases, which may have therapeutic and prognostic implications.[19]

Bence Jones Proteinuria The Bence Jones protein indicates the presence in the urine of free immunoglobulin light chains, as occurs in patients with monoclonal gammopathies. Bence Jones proteinuria is revealed by urine electrophoresis, whereas light-chain identification requires urine immunofixation.[20]

Selectivity of Proteinuria Selectivity can be assessed in nephrotic patients by the ratio of the clearance of IgG (molecular weight of 160,000 d) to the clearance of transferrin (88,000 d).[21] Although now used infrequently, highly selective proteinuria (ratio <0.1) in nephrotic children suggests the diagnosis of minimal change disease and predicts corticosteroid responsiveness.

Leukocyte Esterase

The leukocyte esterase dipstick test evaluates the presence of leukocytes based on the activity of an indoxyl esterase released from lysed neutrophil granulocytes. Leukocyte esterase may be positive when microscopy is negative and when leukocytes are lysed, because of low relative density, alkaline pH, or a delay in sample handling and examination.

False-negative results derive from high glucose (≥20 g/l) or high protein (≥5 g/l) concentration or from the presence of antibiotics such as cephalothin and tetracycline (strong inhibition), cephalexin (moderate inhibition), or tobramycin (mild inhibition). The sensitivity is also reduced by high SG because this prevents leukocyte lysis. False-positive results may occur when formaldehyde is used as a urine preservative and, according to one report, from the presence in the urine of imipenem, meropenem, or clavulanate.[22]

Nitrites

The dipstick nitrites test detects bacteria that reduce nitrates to nitrites by nitrate reductase activity. This includes most gram-negative uropathogenic bacteria, but not *Pseudomonas*, *Staphylococcus albus*, or *Enterococcus*. A positive test result also occurs with a diet rich in nitrates (vegetables), which form the substrate for nitrite production, and sufficient bladder incubation time. Thus, not surprisingly, the sensitivity of the dipstick nitrites test is low, but specificity is high.[23]

Bile Pigments

Measurement of urinary urobilinogen and bilirubin concentrations has lost its clinical value in the detection of liver disease after the introduction of serum tests of liver enzyme function.

Ketones

The ketone dipstick tests for acetoacetate and acetone (but not β-hydroxybutyrate), which are excreted into urine during diabetic acidosis or during fasting, vomiting, or strenuous exercise. It is based on the reaction of the ketones with nitroprusside.

URINE MICROSCOPY

Methods

The second urine specimen of the morning should be collected because it avoids the lysis of particles that can occur in the bladder overnight (see Urine Collection and Box 4-1). We centrifuge an aliquot of urine within 3 hours from collection and concentrate it by removal of a fixed aliquot of supernatant urine. After this, the sediment is resuspended with a Pasteur pipette, and a fixed aliquot is transferred to the slide and prepared using a coverslip with a fixed surface.

Phase contrast microscopy is recommended because it improves the identification of almost all particles, whereas polarized light is mandatory for the correct identification of some lipids and crystals.[24] At least 20 microscopic fields, in different areas of the sample, should be examined at both low magnification (e.g., ×100 or ×200) and high magnification (e.g., ×400). More extensive examination may be required in certain clinical settings, such as isolated microhematuria of unknown origin, for which we suggest examination of 50 low-power fields (lpf) to look for erythrocyte casts.

For correct examination, both pH and SG of the sample should be known. Both alkaline pH (≥7.0) and low SG (especially <1.010) favor the lysis of erythrocytes and leukocytes, which can cause discrepancies between dipstick readings and the microscopic examination (see earlier discussion). Alkaline pH also impairs the formation of casts and favors the precipitation of phosphates.

The various elements observed are quantified as number per microscopic field, and if counting chambers are used, the elements are quantified as number per milliliter. Counting chambers allow a precise quantitation but are rarely used in everyday practice.

Cells

Erythrocytes

Urinary erythrocytes have a diameter of 4 to 10 µm. In the urine, there are two main types of erythrocytes: *isomorphic,* with regular shapes and contours, derived from the urinary excretory system; and *dysmorphic,* with irregular shapes and contours, which are of glomerular origin (Fig. 4-1, *A* and *B*).[25] Thus, according to the proportion of isomorphic and dysmorphic erythrocytes found in the sample, hematuria is defined as nonglomerular or glomerular. Unfortunately, there is no agreement on the criteria to use for such classification. Some authors define glomerular hematuria as more than 80% of erythrocytes being dysmorphic; others define the discriminating cutoff as being as low as 10% or 14%.[24] Still others define hematuria as glomerular when at least 5% of erythrocytes examined are *acanthocytes,*[26] a subtype of dysmorphic erythrocytes with a distinguishing appearance easily identifiable by the presence of one or more blebs of different size and shape protruding from a ring-shaped body (Fig. 4-1, *B, inset*).

In our laboratory, glomerular hematuria is diagnosed when there are 40% or more dysmorphic erythrocytes and/or 5% or more acanthocytes and/or one or more red blood cell casts/50 lpf (×160). With this criterion, a good correlation was found between urinary sediment and renal biopsy findings in 16 patients with longstanding isolated microhematuria.[27]

Erythrocyte dysmorphism is thought to result from deformation of the erythrocytes as they pass through gaps in the glomerular basement membrane, followed by physicochemical insults occurring while the erythrocytes pass through the tubular system.[28]

The distinction between glomerular and nonglomerular hematuria is of special value in the evaluation of patients with isolated microhematuria. In these patients, it is important to decide from the early phases of the diagnostic workup whether nephrologic or urologic investigation is needed.

Leukocytes

Urinary *neutrophils* range from 7 to 15 µm in diameter and are the most frequently found leukocytes in the urine. Neutrophils are identified by their granular cytoplasm and lobulated nucleus (Fig. 4-1, *C*). In most patients, neutrophils indicate lower or upper urinary tract infection, but they may also result from urine contamination caused by genital secretions, especially in young women. Variable numbers of neutrophils are often, but not always, found in acute interstitial nephritis. Neutrophils can be found in low numbers in chronic interstitial nephritis and in proliferative GN, intermingled with high numbers of erythrocytes.[29]

Eosinophils, which can be identified only by the use of stains (e.g., Hansel), were once considered a marker of acute allergic interstitial nephritis. Currently, however, eosinophils are seen as nonspecific because they may be present in various types of GN, prostatitis, chronic pyelonephritis, urinary schistosomiasis, and cholesterol embolism (see Chapter 66).[30,31]

Lymphocytes, whose identification also requires staining of the sample, may indicate acute cellular rejection in renal allograft recipients. However, finding lymphocytes in the urine cannot replace more reliable diagnostic tools such as renal biopsy. Lymphocytes are also a typical finding in patients with chyluria.

Macrophages are mononucleated or multinucleated cells of variable size (13 to 95 µm in diameter) and variable appearance: granular (Fig. 4-1, *D*), vacuolar, phagocytic (when cytoplasm contains bacterial debris, cell fragments, destroyed erythrocytes, crystals, etc.), or homogeneous (when cytoplasm does not contain granules or other particles). In patients with the nephrotic syndrome, macrophages may be engorged with lipid droplets, appearing as "oval fat bodies."[32] Macrophages have been found in the urine of patients with active GN. In our experience, macrophages are frequently seen in the urine of kidney transplant recipients with BK virus infection (see later discussion). However, urinary macrophages are not yet considered diagnostic of any specific condition.

Renal Tubular Epithelial Cells

The renal tubular epithelial cells (RTECs) derive from the exfoliation of the tubular epithelium. In the urine, RTECs can differ in size (diameter ~9 to 25 µm) and shape, from roundish to rectangular or columnar, with a central or peripheral large nucleus (Fig. 4-1, *E*). RTECs are not found in the normal individual but can be found in all patients with conditions associated with acute tubular damage, such as ATN,[33] acute interstitial nephritis, and acute cellular rejection of a renal allograft. In smaller numbers, RTECs can also be found in glomerular diseases.[29] In ATN, these cells are frequently damaged and necrotic and may be present in casts (so-called epithelial casts).

Transitional Epithelial Cells

The transitional epithelial cells derive from the exfoliation of the uroepithelium, which lines the urinary tract from calyces to the bladder in women and to the proximal urethra in men. This multilayered epithelium has small cells in the deep layers and larger cells in the superficial layers. When present in large numbers (e.g., ≥1/high-power field [hpf]), cells of the deep epithelial layers (diameter ~10 to 38 µm; Fig. 4-1, *F*) suggest severe damage of uroepithelium, as caused by neoplasia, stones, obstruction, or longstanding bladder catheters or ureteral stents.[24] Transitional cells of the superficial layers (diameter ~17 to 43 µm; Fig. 4-1, *G*) are a common finding, being associated with mild damage of uroepithelium, as may occur in cystitis.

Squamous Epithelial Cells

The squamous epithelial cells (diameter, 17 to 118 µm; Fig. 4-1, *H*) derive from the urethra or from the external genitalia. In small numbers, squamous cells are a normal finding, but in large numbers, they indicate urine contamination from genital secretions.

Lipids

Lipids are found in the urine as *drops,* which are spherical, translucent, yellowish particles of different size that can be isolated or in

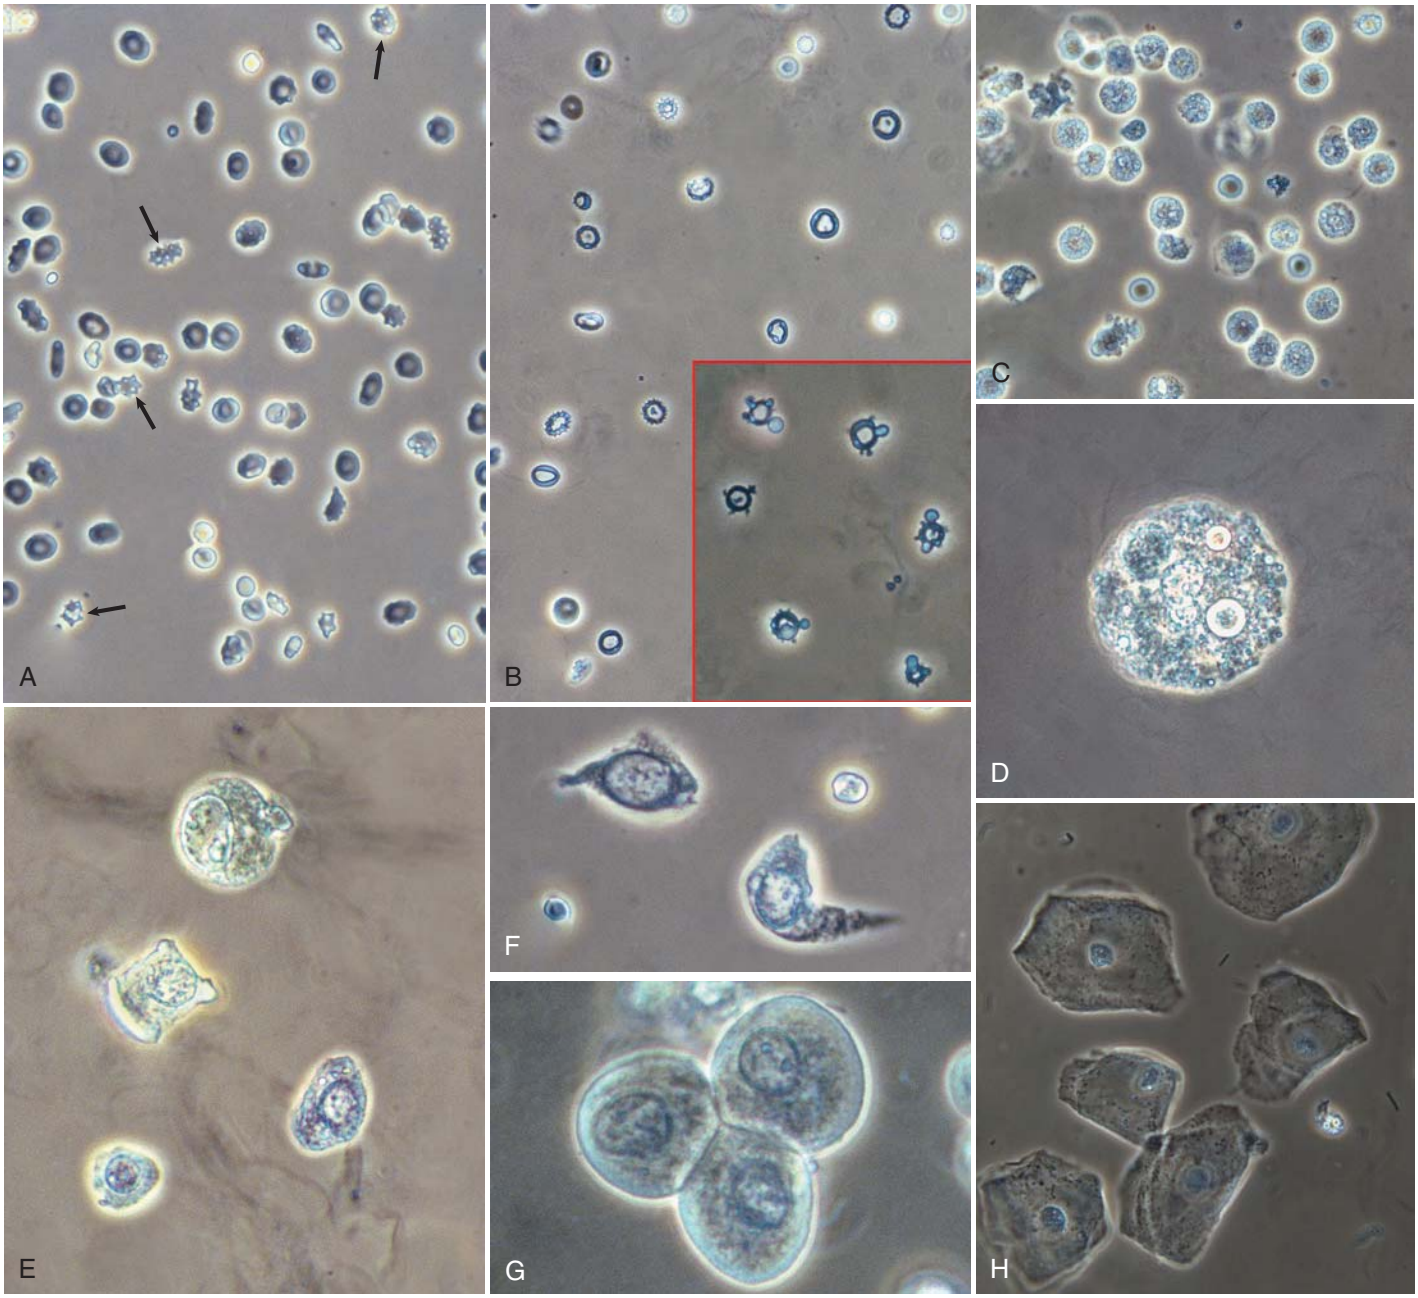

Figure 4-1 Urinary sediment cells. A, Isomorphic nonglomerular erythrocytes. The *arrows* indicate the so-called crenated erythrocytes, which are a finding in nonglomerular hematuria. **B,** Dysmorphic glomerular erythrocytes. The dysmorphism consists mainly of irregularities of the cell membrane. *Inset,* Acanthocytes, with their typical ring-formed cell bodies with one or more blebs of different sizes and shapes. **C,** Neutrophils. Note their typical lobulated nucleus and granular cytoplasm. **D,** Granular phagocytic macrophage (diameter ~60 µm). **E,** Different types of renal tubular epithelial cells. **F,** Two cells from deep layers of uroepithelium. **G,** Three cells from superficial layers of uroepithelium. Note the difference in shape, size, and ratio of nucleus to cytoplasm between the two types of uroepithelial cells. **H,** Squamous epithelial cells. (All images by phase contrast microscopy; original magnification ×400.)

clusters (Fig. 4-2, *A*); as *oval fat bodies,* which are RTECs or macrophages gorged with lipid droplets[32]; as *fatty casts,* cylindrical structures containing variable amounts of fatty droplets or even oval fat bodies; and cholesterol crystals (see Crystals). All these particles contain mainly cholesterol esters and free cholesterol and under polarized light have the appearance of Maltese crosses with symmetric arms (Fig. 4-2, *B*).

These lipids are typical of glomerular diseases associated with marked proteinuria, usually but not invariably in the nephrotic range.

In Fabry disease, urine sediment contains fatty particles even in the absence of proteinuria (see Chapter 48). These particles differ from those previously described because they contain *glycosphingolipids* (especially globotriaosylceramide-3) and have irregular shape and size, variable protrusions or an internal lamellar structure, and irregular or truncated Maltese crosses under polarized light (Fig. 4-2, *C*). It has recently been demonstrated that these fatty particles are of diagnostic importance.[34]

Casts

Casts are cylindrical structures that form in the lumen of distal renal tubules and collecting ducts. Their matrix is made of Tamm-Horsfall glycoprotein, also called uromodulin, which is secreted by

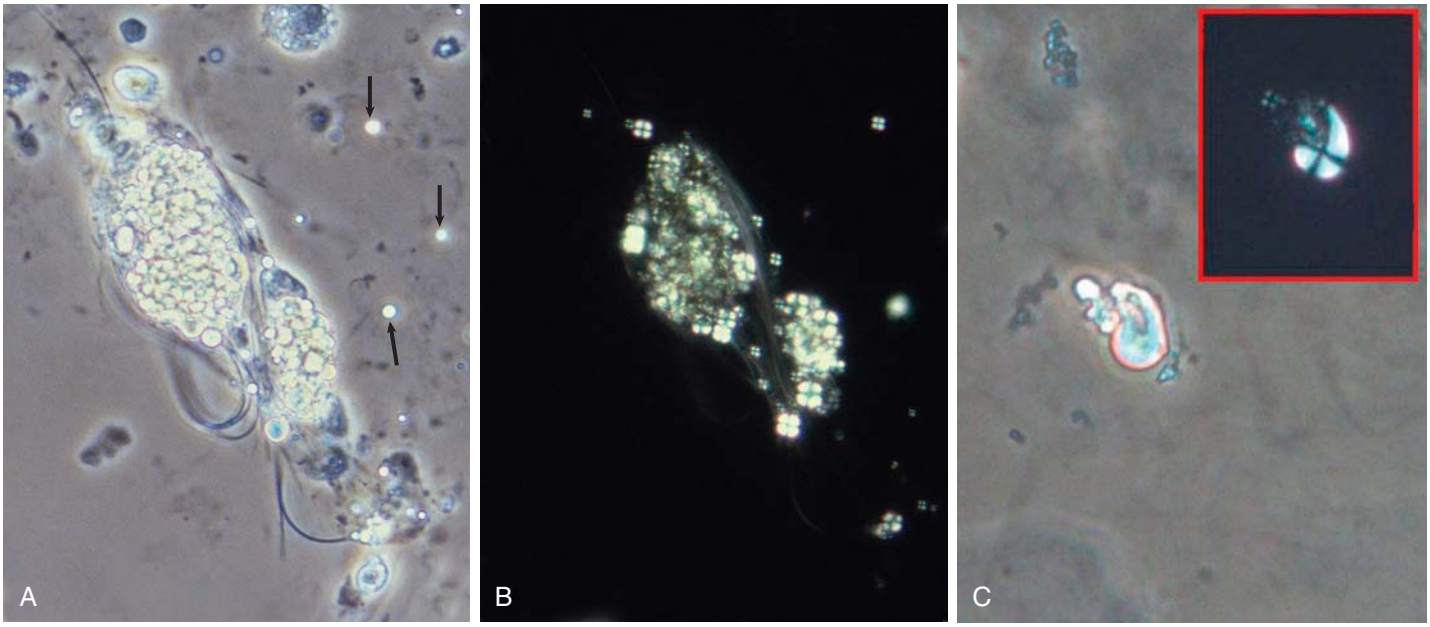

Figure 4-2 Fatty particles. A, Aggregated and isolated *(arrows)* round lipid droplets by phase contrast microscopy. **B,** Same lipid droplets in *A* under polarized light, showing typical Maltese crosses with symmetric arms. **C,** Fatty particle with protrusions, as found in Fabry disease (phase contrast microscopy). *Inset*, Same particle under polarized light. Note the truncated Maltese cross. (Original magnification ×400.)

Clinical Significance of Urinary Casts

Cast	Main Clinical Associations
Hyaline	Normal individual; renal disease
Hyaline-granular	Normal individual; renal disease
Granular	Renal disease; acute tubular necrosis
Waxy	Renal disease with function impairment
Fatty	Proteinuria; nephrotic syndrome
Erythrocyte	Glomerular hematuria; proliferative/ necrotizing GN
Leukocyte	Acute interstitial nephritis; acute pyelonephritis; proliferative GN
Renal tubular epithelial cell (so-called epithelial casts)	Acute tubular necrosis; acute interstitial nephritis; proliferative GN; nephrotic syndrome
Hemoglobin	Same as for erythrocyte cast; hemoglobinuria caused by intravascular hemolysis
Myoglobin	Rhabdomyolysis
Bilirubin	Jaundice caused by increased direct bilirubin
Bacterial, fungal	Bacterial or fungal infection in the kidney
Containing crystals	Normal individual; renal stone disease; crystalluric AKI
Mixed	According to components present in the cast

Table 4-2 Types of casts and their main clinical associations. *GN,* Glomerulonephritis; *AKI,* acute kidney injury.

the cells of the thick ascending limb of Henle loop. Trapping of particles within the cast matrix results in casts with different appearances, each of which may have specific clinical significance (Table 4-2). Because casts form in the renal tubules, whatever particle is contained in a cast derives from the kidneys. Specific casts include the following:

- *Hyaline casts* are colorless with a low refractive index (Fig. 4-3, *A*). They are easily seen with phase contrast microscopy but can be overlooked when bright-field microscopy is used. Hyaline casts may occur in normal urine, especially when it is concentrated and acid (both conditions favoring precipitation of Tamm-Horsfall protein). In patients with renal disease, hyaline casts are usually associated with other types of casts.
- *Hyaline-granular casts* contain variable amounts of granules within the hyaline matrix (Fig. 4-3, *B*) and are the most common mixed casts (described later). Hyaline-granular casts are rare in normal individuals but are common in patients with renal diseases such as GN[29] and acute interstitial nephritis.[35]
- *Granular casts* can be finely granular (Fig. 4-3, *C*) or coarsely granular. Both types are typical of renal disease. Recent studies have demonstrated that granular casts together with RTECs[33,36] or with epithelial casts[37] are a sensitive marker of ATN.
- *Waxy casts* derive their name from their appearance, which is similar to that of melted wax (Fig. 4-3, *D*). They are typically found in patients with renal disease associated with renal impairment, whether acute, rapidly progressive, or chronic.
- *Fatty casts* contain variable amounts of lipid droplets, isolated, in clumps, or packed, or even oval fat bodies or cholesterol crystals. Fatty casts are typical of glomerular diseases associated with marked proteinuria or the nephrotic syndrome.
- *Erythrocyte casts* may contain a few erythrocytes (Fig. 4-3, *E*) or so many that the matrix of the cast cannot be identified. Erythrocyte casts are usually considered a marker of glomerular bleeding, even though a recent report found them in 28% of patients with acute interstitial nephritis.[35]
- *Hemoglobin casts* have a brownish hue and usually a coarsely granular appearance, which derives from the degradation of erythrocytes entrapped within the cast matrix (Fig. 4-3, *F*). Therefore, hemoglobin casts have the same clinical significance as erythrocyte casts. Hemoglobin casts may also derive from hemoglobinuria, as may occur in intravascular hemolysis from any cause. In these patients, hemoglobin casts have a smooth surface.

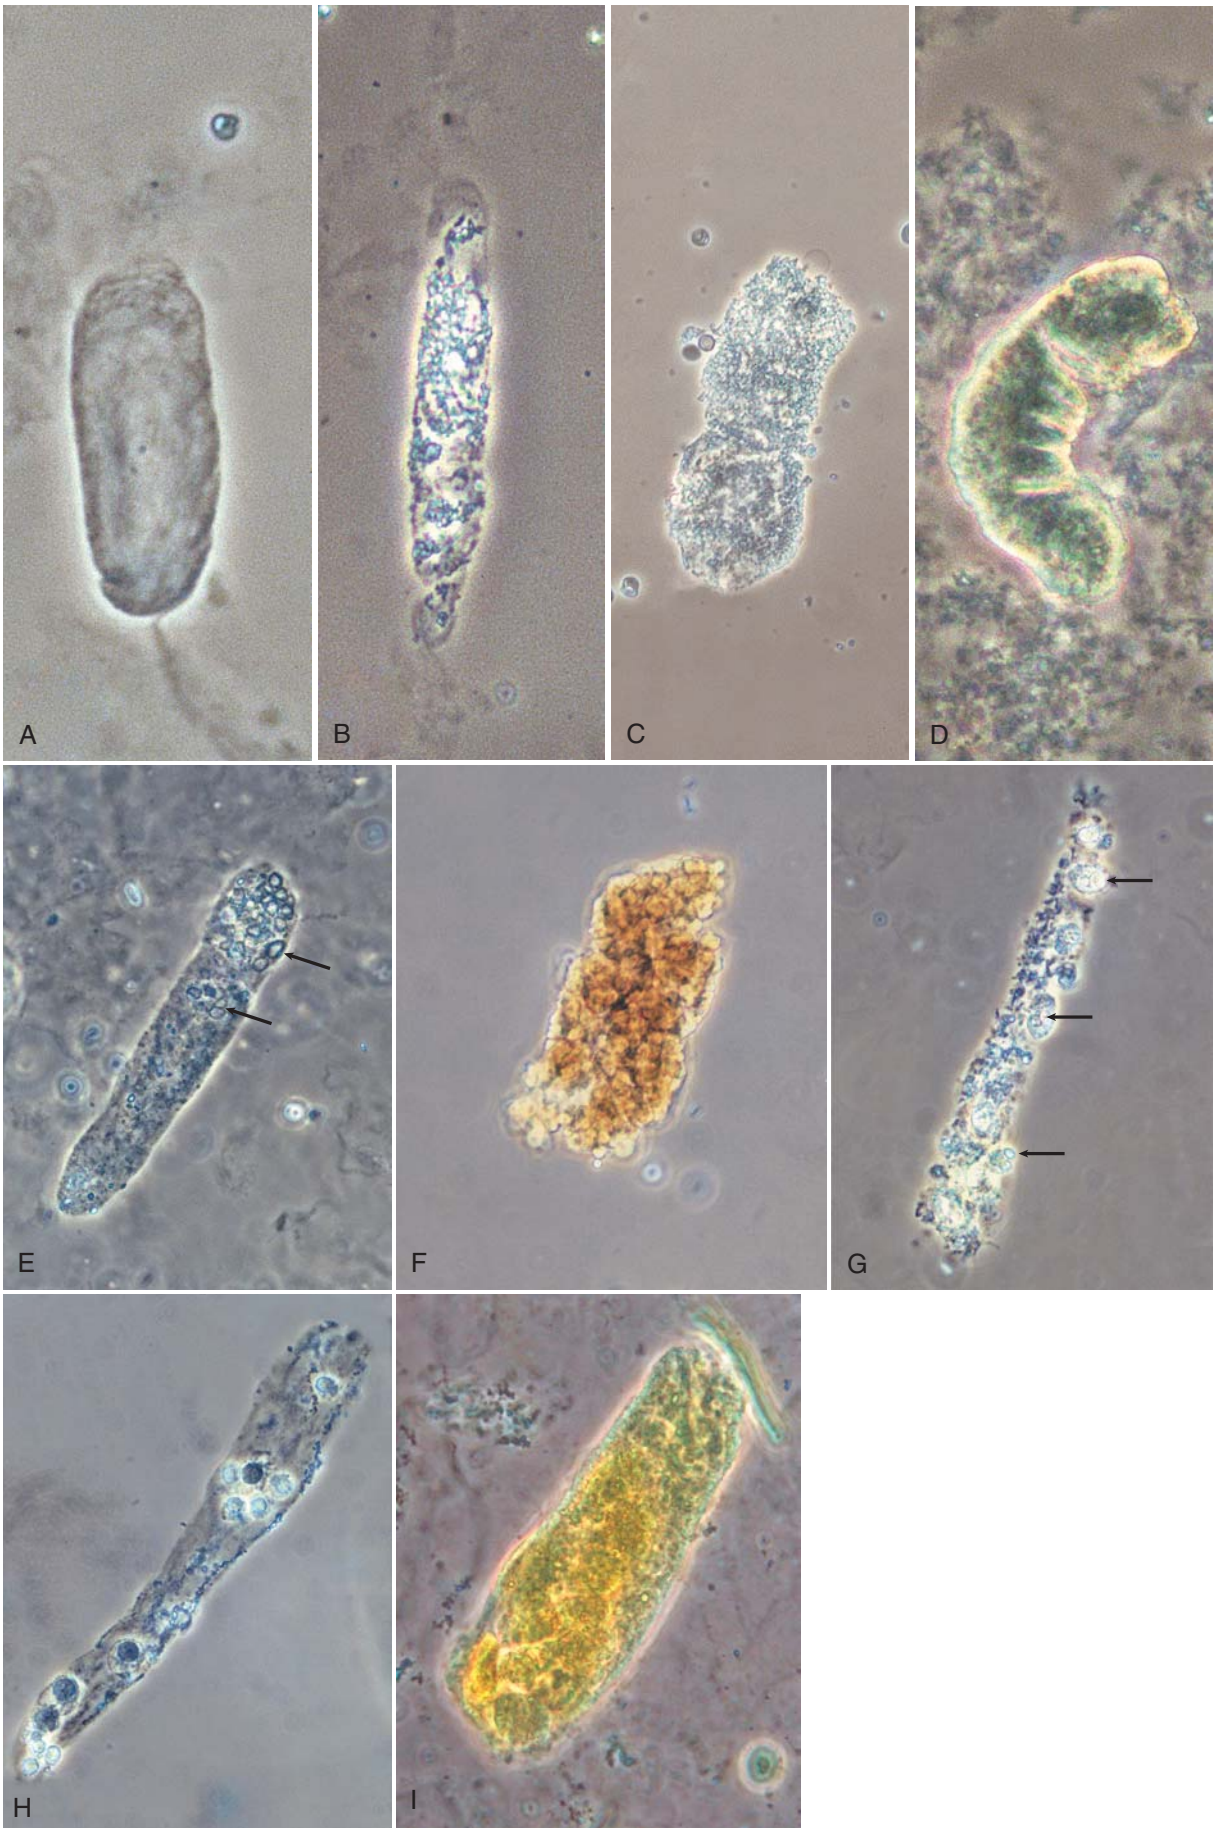

Figure 4-3 **Casts. A,** Hyaline cast. **B,** Hyaline-granular cast. **C,** Finely granular cast. **D,** Waxy cast. **E,** Erythrocyte cast, with erythrocytes *(arrows)* plunged into the cast matrix. **F,** Hemoglobin cast with a coarsely granular appearance and typical brownish hue. **G,** Leukocyte cast. Note the lobulated nucleus of polymorphonuclear leukocytes *(arrows)*. **H,** Epithelial cell cast. Note the large nucleus of the renal tubular epithelial cells. **I,** Bilirubin cast with a coarsely granular appearance and typical yellow color. (All images by phase contrast microscopy; original magnification ×400.)

- *Leukocyte casts* contain variable amounts of polymorphonuclear leukocytes (Fig. 4-3, *G*). They can be found in patients with acute pyelonephritis and acute interstitial nephritis, but are rare in GN.[29]
- *Renal tubular epithelial cell casts* (so-called epithelial casts) contain variable numbers of RTECs, which can be identified by their prominent nucleus (Fig. 4-3, *H*). Epithelial casts indicate damage of the renal tubular epithelium and can therefore be found in the urine of patients with ATN,[37] acute interstitial nephritis, and even glomerular disease.[29]
- *Myoglobin casts* are pigmented cylinders, with the myoglobin providing their color. They may be similar to hemoglobin casts (Fig. 4-3, *F*), from which myoglobin casts can be distinguished by the clinical setting. Myoglobin casts are observed in the urine of patients with AKI associated with rhabdomyolysis.
- *Bilirubin casts* are cylinders pigmented with bilirubin, which can stain any particle contained in the cast (Fig. 4-3, *I*). They are observed in the urine of patients with jaundice associated with increased direct (conjugated) bilirubin.
- Casts containing microorganisms (bacteria and yeasts) indicate renal infection.
- Casts containing crystals indicate that crystals derive from the renal tubules. Crystal casts are an important diagnostic element in crystalluric forms of AKI, such as acute urate nephropathy.
- *Mixed casts* contain components of different nature, such as granules, cells, and lipids. This causes the appearance of pleomorphic cylinders, whose clinical significance is the same as that for the pure types of casts, of which mixed casts contain some components.

Crystals

Correct identification of urine crystals requires knowledge of crystal morphology, urine pH, and appearance under polarizing light. Examination of the urine for crystals is informative in the assessment of patients with stone disease, with some rare inherited metabolic disorders (e.g., cystinuria, oxalosis, phosphoribosyltransferase deficiency), and with suspected drug nephrotoxicity.[24] Crystals can be classified in four categories: common, pathologic, caused by drugs, and other crystals.

Common Crystals

Uric Acid Crystals and Amorphous Urates Uric acid crystals have an amber color and a wide spectrum of appearances, including rhomboids and barrels (Fig. 4-4, *A*). These crystals are found only in acid urine (pH 5.0 to 5.8) and are polychromatic under polarizing light.

Amorphous urates are tiny granules of irregular shape that also precipitate in acid urine. They are identical to amorphous phosphates, which, however, precipitate in alkaline urine. In addition, whereas uric acid crystals polarize light, phosphates do not.

Calcium Oxalate Crystals There are two types of calcium oxalate crystals: bihydrated (or weddellite) crystals, which most often have a bipyramidal appearance (Fig. 4-4, *B*), and monohydrated (or whewellite) crystals, which are ovoid, dumbbell shaped, or biconcave disks (Fig. 4-4, *C*). Both types of calcium oxalate crystals precipitate at pH 5.4 to 6.7. Monohydrated crystals always polarize light, whereas bihydrated crystals usually do not.

Brushite (Calcium Phosphate Crystals) and Amorphous Phosphates Brushite crystals are pleomorphic, appearing as prisms, star-like particles, or needles of various sizes and shapes (Fig. 4-4, *D*). Brushite crystals can also appear as plates with a granular surface. Calcium phosphate crystals precipitate in alkaline urine (pH ≥7.0) and, with the exception of plates, polarize light intensely.

Amorphous phosphates are tiny particles identical to amorphous urates, but these phosphates precipitate at a pH of 7.0 or higher and do not polarize light.

Struvite (Triple Phosphate) Crystals Struvite crystals contain magnesium ammonium phosphate and typically have the appearance of "coffin lids" (Fig. 4-4, *E*). Triple phosphate crystals are found in alkaline urine (pH ≥7.0) and almost always polarize light strongly.

Pathologic Crystals

Cholesterol Crystals Cholesterol crystals are thin, transparent plates, often clumped together, with sharp edges (Fig. 4-4, *F*).

Cystine Crystals Cystine crystals occur in patients with cystinuria and are hexagonal plates with irregular sides that are often heaped on one another (Fig. 4-4, *G*). They precipitate in acid urine. Evaluation of their size can be used to predict the recurrence of cystine stones.[38]

2,8-Dihydroxyadenine Crystals These spherical, brownish crystals have a central umbilicus and a birefringent cross-like appearance under polarized light (Fig. 4-4, *H*).[39] 2,8-Dihydroxyadenine crystals are a marker of homozygotic deficiency of the enzyme adenine phosphoribosyltransferase. This rare condition causes crystalluria in about 96% of untreated patients, who frequently also have radiolucent urinary stone formation, AKI, or chronic kidney disease.[39,40]

Other rare pathologic crystals are *tyrosine,* found in patients with acute liver disease and the rare hereditary disease tyrosinemia, and *leucine,* found in acute liver disease.

Crystals Caused by Drugs

Many drugs can cause crystalluria, especially in a setting of drug overdose, dehydration, or hypoalbuminemia in the presence of a specific urinary pH favoring drug crystallization. Examples include the antibiotics sulfadiazine, amoxicillin (Fig. 4-4, *I*), and ciprofloxacin (Fig. 4-4, *J*)[24]; the antiviral agents acyclovir and indinavir (Fig. 4-4, *K*); the vasodilators pyridoxylate and naftidrofuryl oxalate; the barbiturate primidone; the antiepileptic felbamate; the inhibitor of gastroenteric lipase orlistat; and intravenous vitamin C.[24] Most of these drugs cause crystals that are made of the drug itself, with unusual morphologies that differ from those of the crystals previously described. However, naftidrofuryl oxalate, orlistat, and vitamin C cause calcium oxalate crystals, which are indistinguishable from calcium oxalate crystals resulting from other causes.

Other Crystals

Hippuric acid crystals, calcium carbonate crystals, and ammonium biurate crystals are rare and devoid of clinical significance.

Clinical Significance of Crystals

Uric acid, calcium oxalate, and calcium phosphate (brushite) crystals may have no clinical significance because they can reflect transient supersaturation of the urine caused by ingestion of some foods (e.g., meat for uric acid, spinach or chocolate for calcium oxalate, milk or cheese for calcium phosphate) or mild dehydration. However, the persistence of calcium oxalate or uric acid crystalluria may reflect hypercalciuria, hyperoxaluria, or hyperuricosuria. In calcium stone formers, the evaluation of crystalluria may be used to assess calcium stone disease activity.[41]

Large numbers of uric acid crystals may be associated with AKI caused by acute urate nephropathy, whereas large numbers of monohydrated calcium oxalate crystals, especially with a spindle shape, may be associated with AKI from ethylene glycol intoxication.

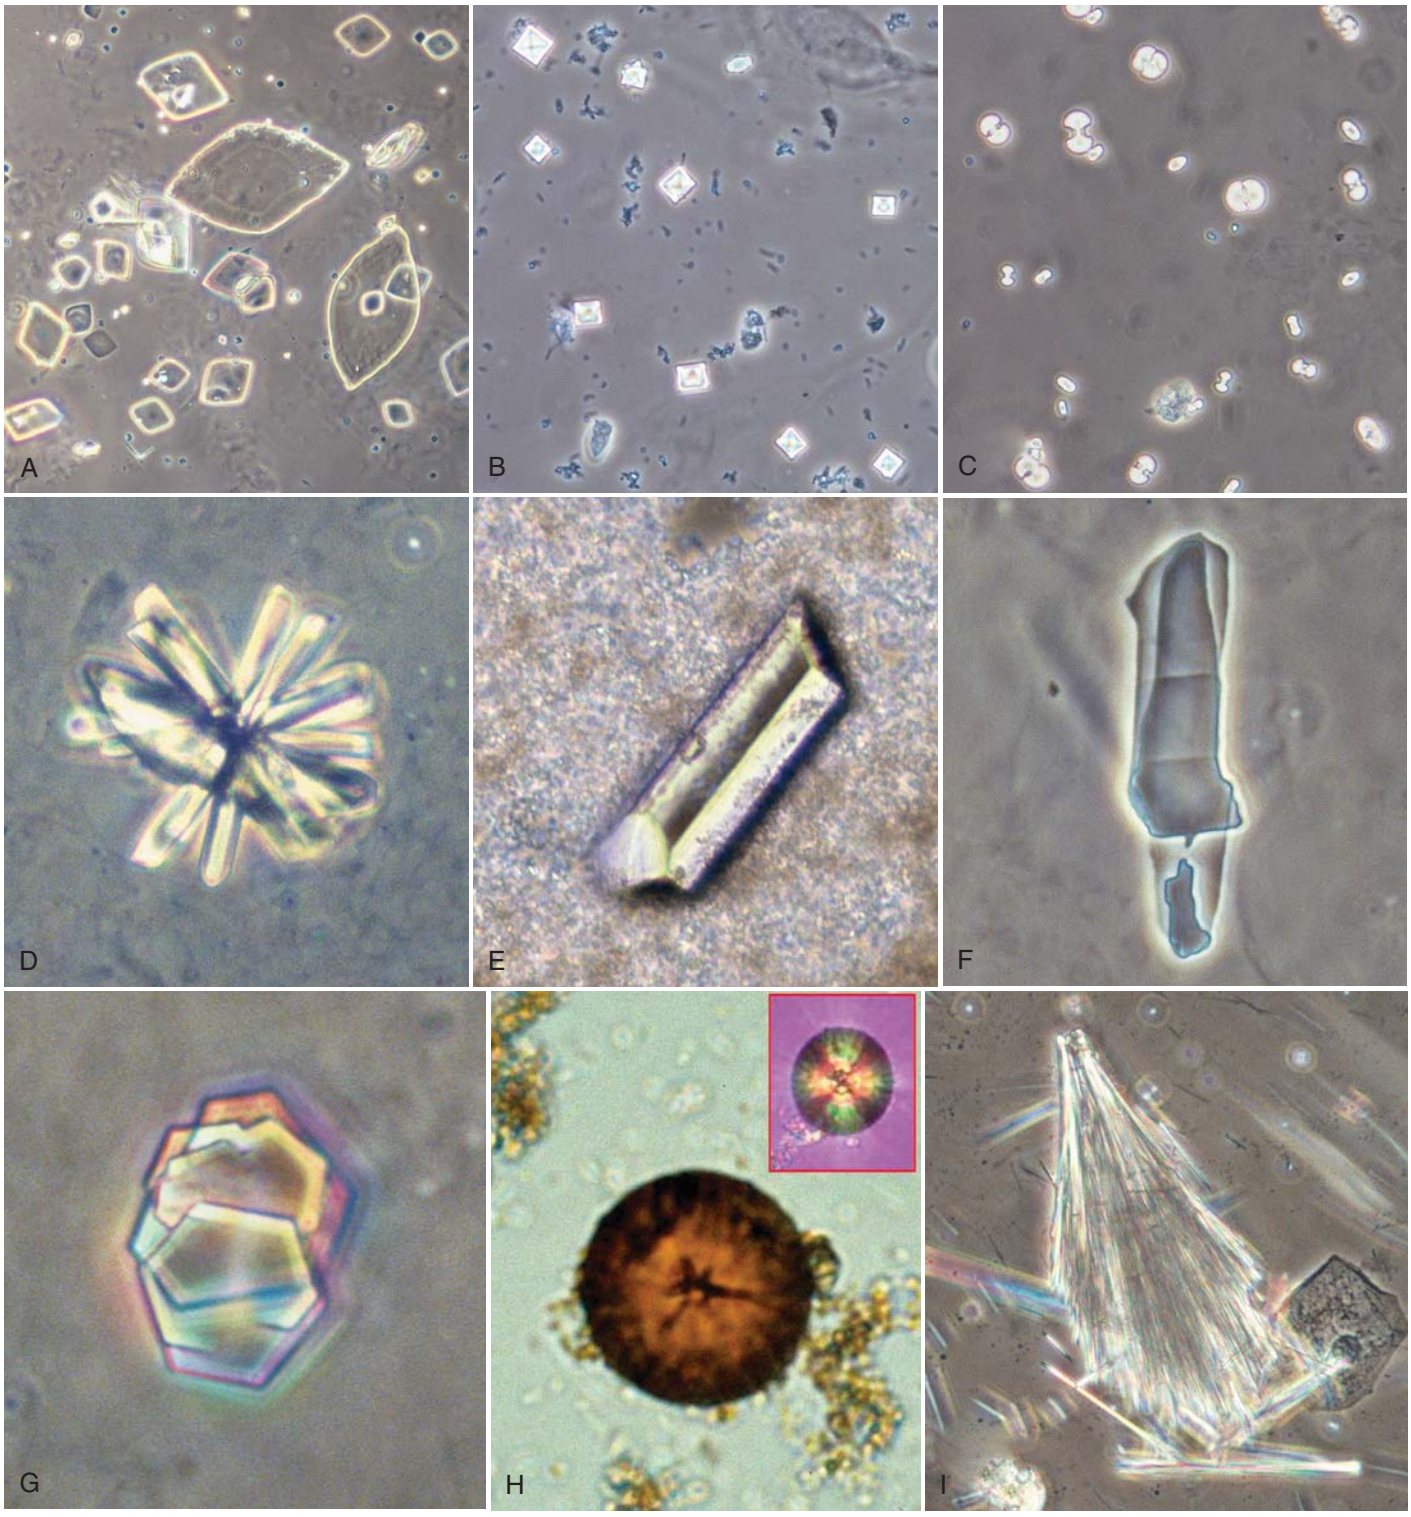

Figure 4-4 **Crystals. A,** Uric acid crystals. This rhomboid shape is the most common. **B,** Bihydrated calcium oxalate crystals with typical "letter envelope" appearance. **C,** Different types of monohydrated calcium oxalate crystals. **D,** Star-like brushite (calcium phosphate) crystal. **E,** Struvite (triple phosphate) crystal, on the background of a massive amount of amorphous phosphate particles. **F,** Cholesterol crystal. **G,** Cystine crystals heaped one on the other. **H,** 2,8-Dihydroxyadenine crystal by bright-field microscopy; *inset*, by polarized light. **I,** Amoxicillin crystal resembling a branch of a broom bush.

Struvite crystals are often associated with urinary tract infection caused by urea-splitting microorganisms such as *Ureaplasma urealyticum* and *Corynebacterium urealyticum.*

Cholesterol crystals are found in association with other fatty particles in patients with marked proteinuria. Again, cystine crystals are a marker of cystinuria, and 2,8-dihydroxyadenine crystals are associated with phosphoribosyltransferase enzyme deficiency. Crystalluria resulting from drugs must be suspected whenever crystals with unusual morphology are seen. In this setting, crystalluria may be isolated and asymptomatic or associated with hematuria, obstructive uropathy, or AKI caused by the precipitation of crystals within the renal tubules.[24]

Organisms

Bacteria are a frequent finding because urine is usually collected and handled under nonsterile conditions and examination is often delayed. Urine infection should be suspected only if bacteria are found in noncontaminated, freshly voided midstream urine and especially if leukocytes are also present. *Candida* (yeasts), *Trichomonas vaginalis* (protozoon), and *Enterobius vermicularis* (parasite) are usually present as contaminants derived from genital secretions.

The parasite *Schistosoma haematobium* is responsible for urinary schistosomiasis (see Chapter 56). The examination of the urinary sediment is the most widely used method for diagnosis of schistosomiasis, which causes microhematuria with recurrent bouts of macrohematuria and obstructive uropathy. The diagnosis is based on the finding of the parasite eggs, with their typical terminal spike (Fig. 4-5). The eggs are especially found between 10 AM and 2 PM and after physical exercise, which favors the detachment of the eggs from the bladder mucosa.

Contaminants

A large number of particles can contaminate urine. These particles may come from the patient (e.g., spermatozoa; erythrocytes from menstruation; leukocytes from vaginitis, cloth or synthetic fibers, creams or talcum), the laboratory (e.g., starch particles, glass fragments from coverslips), or the environment (e.g., pollens, plant cells, fungal spores).[24] Correct identification of these particles is important to avoid misinterpretation and false results (e.g., misdiagnosis of hematuria due to urine contamination from menstrual blood).

Figure 4-5 **Egg of *Schistosoma haematobium.*** Note the typical terminal spike *(arrow)*. (Phase contrast microscopy; original magnification ×400.)

INTERPRETATION OF URINE SEDIMENT FINDINGS

Examination of the urine sediment, coupled with the quantity of proteinuria and other urine and blood findings, results in urine sediment profiles that aid in the diagnosis of urinary tract diseases (Table 4-3).

Nephrotic Syndrome

The typical nephrotic sediment contains lipids, casts, and renal tubular epithelial cell. Fatty, epithelial, granular, hyaline, and hyaline-granular casts are seen, and erythrocyte or hemoglobin casts, leukocyte casts, and waxy casts are absent or few. Erythrocytes may be totally absent, especially in minimal change disease, or may be in low to moderate numbers (e.g., 3-5/hpf to 20-30/hpf), which is seen especially in membranous nephropathy and focal segmental glomerulosclerosis. Leukocytes are usually not found.

Nephritic Syndrome

Erythrocytes with erythrocyte and hemoglobin casts are the hallmark of the nephritic sediment. Usually, the number of erythrocytes ranges from 30 to 40 cells/hpf to more than 100 cells/hpf, with the

Main Urinary Sediment Profiles

Renal Disease	Hallmark	Associated Findings
Nephrotic syndrome (proteinuria: ++++)	Fatty particles	Renal tubular epithelial cells (RTECs) RTEC casts Erythrocytes (absent to moderate number)
Nephritic syndrome (proteinuria: + → ++++)	Erythrocytes (moderate to high number) Erythrocyte/hemoglobin casts	Leukocytes (low number) RTECs (low number) RTEC casts Waxy casts
Acute tubular necrosis (ATN; proteinuria: absent to trace)	RTECs RTEC casts Granular casts	Variable according to cause of ATN (e.g., myoglobin casts in rhabdomyolysis; uric acid crystals in acute urate nephropathy; erythrocytes in proliferative/active glomerulonephritis)
Urinary tract infection (proteinuria: absent)	Bacteria Leukocytes	Isomorphic erythrocytes Superficial transitional epithelial cells Struvite crystals (for infections caused by urease-producing bacteria) Leukocyte casts (in renal infection)
Urologic diseases (proteinuria: absent)	Isomorphic erythrocytes (low to high number) Leukocytes	Transitional cells (deep, superficial, atypical)
Polyomavirus BK infection (proteinuria: absent)	Decoy cells	Decoy cell casts (in BK virus nephropathy)

Table 4-3 **Main urinary sediment profiles.**

higher figure found especially in patients with extracapillary or necrotizing glomerular lesions. Leukocyturia is also common and is mild (e.g., 3-5/hpf) in most patients, but in those with acute postinfectious GN or active proliferative lupus nephritis, we have seen samples with up to 30 to 40 leukocytes/hpf. Leukocyte casts and waxy casts also may be observed.

The nephritic sediment may clear with treatment, but its reappearance usually indicates relapse of the disease, such as lupus nephritis[42] or systemic vasculitis.[43] Rarely, patients may have an active proliferative GN without nephritic sediment.

Acute Tubular Necrosis

RTECs associated with epithelial casts and granular casts are the hallmark of the sediment of ATN but are not found in functional pre-renal AKI.[33,36,37] In addition to RTECs, depending on the cause of the tubular damage, other elements can be seen. These include myoglobin-pigmented casts in rhabdomyolysis, uric acid crystals (usually in massive amounts) in acute uric acid nephropathy, and erythrocytes (high numbers) and erythrocyte casts in active proliferative glomerular diseases.

Urinary Tract Infection

Bacteria and leukocytes are the hallmarks of urinary tract infection, in association with superficial transitional epithelial cells and isomorphic erythrocytes. Struvite crystals can also be present when the infection is caused by urease-producing bacteria, such as *U. urealyticum* and *C. urealyticum.* In patients with renal infection, leukocyte casts and casts containing microorganisms may be found.

The correlation between the urine sediment findings and the urine culture is usually good. False-positive results may be caused by urine contamination from genital secretions or bacterial overgrowth on standing. False-negative results may be caused by the lysis of leukocytes or misinterpretation of bacteria, especially with cocci.

BK Virus Infection

The serial examination of the urinary sediment, coupled with the measurement of viremia, is useful to diagnose and monitor the reactivation of BK virus (BKV) in kidney transplant recipients,[44] an event which may lead to BKV nephropathy and graft loss (see Chapter 105). In BKV infection, the urine sediment contains variable numbers of "decoy cells," which are cells with nuclear changes caused by virus invasion. The four decoy phenotypes identified[45] are (1) nuclear ground-glass or gelatinous appearance; (2) intranuclear inclusion surrounded by a clear halo (cytomegalovirus-like); (3) multinucleated cells; and (4) vesicular nuclei with clumped chromatin and nucleoli. In addition, cells with eccentric nucleus and comet-like appearance are frequently seen in BKV infection, as well as hybrid forms that represent transitions between the different phenotypes.

Decoy cells are best identified by Papanicolaou stain performed on cytocentrifuged or smeared samples[45] (Fig. 4-6, *A*). In our experience, decoy cells can easily be seen also by phase contrast microscopy in unstained samples[46] (Fig. 4-6, *B*).

The finding of decoy cells may indicate reactivation of BKV only or BKV nephropathy. Nephropathy is suspected when the number of decoy cells is high and persistent over time or casts containing decoy cells are found, in the presence of BK viremia and renal dysfunction.[44,45,47] However, a definite diagnosis of BKV nephropathy can be obtained only with renal biopsy.

Urologic Diseases

Urinary tract disorders such as cancer, urolithiasis, and hydronephrosis are associated with the finding in the urine sediment of variable numbers of isomorphic erythrocytes, which are often associated with leukocytes or transitional epithelial cells (from deep or superficial layers of uroepithelium). In addition, in uroepithelial cancer, malignant transitional cells can be found, with abnormal size and shape, increased number and size of nuclei, and enlarged nucleoli. These cells can also be identified in unstained samples by phase contrast microscopy.

Nonspecific Urinary Abnormalities

Some urine sediment findings are nonspecific. This occurs when variable numbers of hyaline or hyaline-granular casts are found with or without low numbers of erythrocytes, leukocytes, common crystals, or small numbers of superficial transitional epithelial cells. In such patients, especially if the findings persist over time, the correct interpretation of the urinary findings requires adequate clinical information and the knowledge of other laboratory tests.

AUTOMATED ANALYSIS OF URINE SEDIMENT

Instruments for the automated analysis of the urinary sediment are based on flow cytometry or digital imaging. Flow cytometry uses

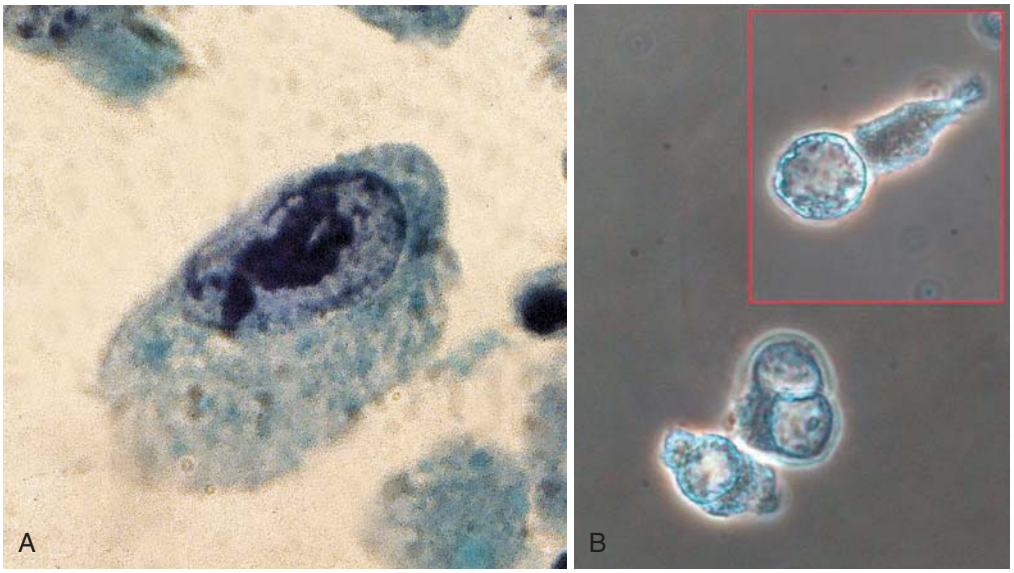

Figure 4-6 Decoy cells resulting from polyomavirus BK infection. A, Decoy cell with coarse, clumped chromatin, as seen by Papanicolaou stain. **B,** Decoy cells with the nuclear ground-glass phenotype as seen by phase contrast microscopy. *Inset*, Decoy cell with comet-like appearance. (Original magnification: **A,** ×1000; **B,** ×400.)

stains for nucleic acid and cell membranes in uncentrifuged urine samples to identify cells, bacteria, and casts.[48] Accuracy is good for leukocytes and erythrocytes, even though the erythrocytes can be overestimated because of the interference from bacteria, crystals, and yeasts. False-negative results for casts are common, ranging from about 13% to 43%.

Digital imaging systems supply quantitative results and black-and-white images of urine particles, which can be used to review the results. Currently, two main instruments are based on this technology. The first shows the particles identified on the screen by categories (e.g., all epithelial squamous cells, all crystals), with a good precision and accuracy for erythrocytes and leukocytes but rather low sensitivity for casts.[49] The other instrument supplies whole-field images, similar to those obtained by bright-field manual microscopy, and has good sensitivity for casts and epithelial cells as well.[50]

Automated instruments are now used in large laboratories to screen large numbers of samples in a short time and to identify the samples that are normal or that contain only minor changes. This approach greatly reduces the number of samples that require manual microscopy. As yet, however, these instruments do not recognize a number of particles of clinical importance, such as lipids, cellular casts, deep epithelial transitional cells, RTECs, and various types of crystals. Therefore, for the proper evaluation of the renal patient, manual microscopy with phase contrast and polarized-light devices is still the recommended approach.

CHAPTER 5

Imaging

David C. Wymer

Imaging evaluation of patients with renal disease has changed significantly in recent years. Intravenous urography is infrequently used and has mostly been replaced by ultrasound, computed tomography (CT), magnetic resonance imaging (MRI), and nuclear medicine scanning. Rapidly changing computer-based data manipulation has resulted in major technologic advances in each of these modalities. Three-dimensional or even four-dimensional (time-sensitive) image analysis is now available. *Molecular imaging,* which visualizes cellular function using biomarkers, is providing functional as well as anatomic information.

The American College of Radiology (ACR) has published Appropriateness Criteria,[1] guidelines that suggest the choice of imaging to provide a rapid answer to the clinical question while minimizing cost and potential adverse effects to the patient, such as contrast-induced nephrotoxicity and radiation exposure. Tables 5-1, 5-2, and 5-3 list relative radiation exposures, first-choice imaging modalities in renal disease, and risk estimates, respectively. Risks of imaging and cost need to be balanced against benefits.

ULTRASOUND

Ultrasound is relatively inexpensive and provides a rapid way to assess renal location, contour, and size without radiation exposure. Nephrologists are increasingly undertaking straightforward ultrasound examination; the practical techniques as well as the appropriate interpretative skills are discussed in Chapter 92. Portable ultrasound is available and is essential in the pediatric or emergency setting. Obstructing renal calculi can be readily detected, and renal masses can be identified as cystic or solid. In cases of suspected obstruction, the progression or regression of hydronephrosis is readily evaluated. Color Doppler imaging permits assessment of renal vascularity and perfusion. Unlike the other imaging modalities, ultrasound is highly dependent on operator skills. Limitations of ultrasound include lack of an acoustic window, body habitus, and poor patient cooperation.

Kidney Size

The kidney is imaged in transverse and sagittal planes and is normally 9 to 12 cm in length in adults. Differences in kidney size can be detected with all imaging modalities. Figure 5-1 diagrams the common causes of enlarged and shrunken kidneys.

Renal Echo Pattern

The normal renal cortex is hypoechoic compared with the fat-containing echogenic renal sinus (Fig. 5-2, *A*). The cortical echotexture is defined as isoechoic or hypoechoic compared with the liver or spleen. In children, the renal pyramids are hypoechoic (Fig. 5-2, *B*), and the cortex is characteristically hyperechoic compared with the liver and the spleen.[2] In adults, an increase in cortical echogenicity is a sensitive marker for parenchymal renal disease but is nonspecific (Fig. 5-3). Decreased cortical echogenicity can be found in acute pyelonephritis and acute renal vein thrombosis.

The normal renal contour is smooth, and the cortical mantle should be uniform and slightly thicker toward the poles. Two common benign pseudomasses that can be seen with ultrasound are the dromedary hump and the column of Bertin. The column of Bertin results from bulging of cortical tissue into the medulla; it is seen as a mass with an echotexture similar to that of the cortex, but it is found within the central renal sinus (Fig. 5-4). The renal pelvis and proximal ureter are anechoic. An *extrarenal pelvis* refers to the renal pelvis location outside the renal hilum. The ureter is not identified beyond the pelvis in nonobstructed patients.

Obstruction can be identified by the presence of hydronephrosis (Fig. 5-5). Parenchymal and pelvicalyceal nonobstructing renal calculi as well as ureteral obstructing calculi can be readily detected (Fig. 5-6). The upper ureter will also be dilated if obstruction is distal to the pelviureteral junction (see Fig. 5-5, *C*). False-negative ultrasound examination findings with no hydronephrosis occasionally occur in early obstruction. Obstruction without ureteral dilation may also occur in retroperitoneal fibrosis and in transplanted kidneys as a result of periureteral fibrosis.

Renal Cysts

Cysts can be identified as anechoic lesions and are a frequent coincidental finding during renal imaging. Ultrasound usually readily identifies renal masses as cystic or solid (Figs. 5-7 and 5-8). However, hemorrhagic cysts may be mistakenly called solid because of increased echogenicity. Differentiation of cysts as simple or complex is required to plan intervention.

Simple Cysts

A simple cyst on ultrasound is anechoic, has a thin or imperceptible wall, and demonstrates through-transmission because of the relatively rapid progression of the sound wave through fluid compared with adjacent soft tissue.

Complex Cysts

Complex cysts contain calcifications, septations, and mural nodules. Instead of being anechoic, these masses may contain internal echoes representing hemorrhage, pus, or protein. Complex cysts may be benign or malignant; cyst wall nodularity, septations, and vascularity strongly suggest malignancy. The Bosniak classification of cystic renal masses is widely used (see Table 61-5). Complex cysts identified by ultrasound require further evaluation by contrast-enhanced CT (or MRI) to identify abnormal contrast enhancement of the cyst wall, mural nodule, or septum.

Relative Radiation Doses of Imaging Examinations	
Examination	**Effective Dose (mSv)**
Chest: PA x-ray film	0.02
Lumbar spine	1.8
KUB abdomen	0.53
CT abdomen	10
CT chest	20-40
PET-CT	25
Ultrasound or MRI	0

Table 5-1 Relative radiation doses of imaging examinations. *PA,* Posteroanterior; *mSv,* millisieverts; *KUB,* kidney, ureter, bladder (plain film); *CT,* computed tomography; *PET,* positron emission tomography; *MRI,* magnetic resonance imaging.

Recommended Imaging in Renal Disease	
Renal Pathology	**First-Choice Imaging**
Acute kidney injury, chronic kidney disease	Ultrasound
Hematuria	Ultrasound or CT
Proteinuria, nephrotic syndrome	Ultrasound CT urography
Hypertension with normal renal function	Ultrasound Consider CTA or MRA
Hypertension with impaired renal function	Ultrasound with Doppler
Renal infection	Contrast-enhanced CT
Hydronephrosis identified on ultrasound	Nuclear renogram
Retroperitoneal fibrosis	Contrast-enhanced CT
Papillary or cortical necrosis	Contrast-enhanced CT
Renal vein thrombosis	Contrast-enhanced CT
Renal infarction	Contrast-enhanced CT
Nephrocalcinosis	CT

Table 5-2 Suggested imaging in renal disease. These recommendations assume availability of all common imaging modalities. *CT,* Computed tomography; *CTA,* computed tomographic angiography; *MRA,* magnetic resonance angiography. *(Modified from reference 1.)*

Risk Estimates in Diagnostic Imaging	
Imaging Risk	**Estimated Risk**
Cancer from 10 mSv of radiation (1 body CT)[3]	1 in 1000
Contrast-induced nephropathy in patient with renal impairment[4]	1 in 5
Nephrogenic systemic fibrosis[5,6]	1 in 25,000 to 1 in 30,000 (depends on gadolinium agent) 1 in 5 if GFR <30/ml
Death from iodine contrast anaphylaxis[7]	1 in 130,000
Death from gadolinium contrast anaphylaxis[8]	1 in 280,000

Table 5-3 Risk estimates in diagnostic imaging.

Bladder

Real-time imaging can be used to evaluate for bladder wall tumors and bladder stones. Color flow Doppler evaluation of the bladder in well-hydrated patients can be used to identify a ureteral jet, produced when peristalsis propels urine into the bladder. The incoming urine has a higher specific gravity relative to the urine already in the bladder (Fig. 5-9). Absence of the ureteral jet can indicate total ureteral obstruction.

Renal Vasculature

Color Doppler investigation of the kidneys provides a detailed evaluation of the renal vascular anatomy. The main renal arteries can be identified in most patients (Fig. 5-10). Power Doppler imaging is a more sensitive indicator of flow, but unlike color Doppler imaging, power Doppler provides no information about flow direction and cannot be used to assess vascular waveforms. However, power Doppler imaging is exquisitely sensitive for detection of renal parenchymal flow and has been used to identify cortical infarction.

Renal Artery Duplex Scanning

The role of gray-scale and color Doppler sonography in screening for renal artery stenosis is controversial. The principle is that a narrowing in the artery will cause a velocity change commensurate with the degree of stenosis as well as a change in the normal renal artery waveform downstream from the lesion. The normal renal artery waveform demonstrates a rapid systolic upstroke and an early systolic peak (Fig. 5-11, *A*). The waveform becomes dampened downstream from a stenosis. This consists of a slow systolic acceleration (tardus) and a decreased and rounded systolic peak (parvus) (Fig. 5-11, *B*). It also results in a decrease in the *resistive index,* defined as the end-diastolic velocity (EDV) subtracted from the peak systolic velocity (PSV) divided by PSV: (PSV – EDV)/PSV. The normal resistive index is 0.70 to 0.72.

The entire length of the renal artery should be examined for the highest velocity signal. The origins of the renal arteries are important to identify because this area is often affected by atherosclerosis, but the arteries are often difficult to visualize because of overlying bowel gas. Within the kidney, medullary branches and cortical branches in the upper, middle, and lower thirds should be included to attempt detection of stenosis in accessory or branch renal arteries.

Proximal and distal criteria exist for diagnosis of significant renal artery stenosis, usually defined as stenosis greater than 60%. The *proximal* criteria detect changes in the Doppler signal at the site of stenosis and provide sensitivities and specificities ranging from, respectively, 0% to 98% and 37% to 98%.[9,10] Technical failure rates are typically 10% to 20%.[11] Renal artery stenosis may also be missed if PSV is low because of poor cardiac output or aortic stenosis. False-positive results can occur when renal artery velocity is increased because of high-flow states, such as hyperthyroidism or vessel tortuosity.[12] The *distal* criteria are related to detection of a tardus-parvus waveform distal to a stenosis; sensitivities and specificities of 66% to 100% and 67% to 94%, respectively, have been reported.[13,14] Technical failure with distal criteria is much lower than with proximal evaluation (<5%). False-negative results can occur from stiff poststenotic vessels, which will decrease the tardus-parvus effect.[15] The tardus-parvus effect may also be a result of aortic stenosis, low cardiac output, or collaterals in complete occlusion, giving a false-positive result.

Combining the proximal and distal criteria improves the detection of stenoses. Sensitivity of 97% and specificity of 98% can be achieved when both the extrarenal and the intrarenal arteries are examined.[16] When it is technically successful, Doppler ultrasound

has a negative predictive value of more than 90%.[16] However, reliable results require a skilled and experienced sonographer and a long examination time. Despite these limitations, Doppler studies also have several advantages. Noninvasive, inexpensive, and widely available, Doppler studies also allow structural and functional assessment of the renal arteries and imaging without exposure to radiation or nephrotoxic agents.

Some physicians prefer CT angiography (CTA) or magnetic resonance angiography (MRA) as a faster and more reliable screening tool than ultrasound, but at present the choice should depend on local expertise and preference. For further discussion of the diagnosis and management of renovascular disease, see Chapters 39 and 66.

Contrast-Enhanced and Three-Dimensional Ultrasound

Ultrasound contrast agents, initially introduced to assess cardiac perfusion, are now being used to evaluate perfusion to other organs, such as the kidney. These intravenous agents are microbubbles 1 to 4 μm in diameter (smaller than erythrocytes) that consist of a shell surrounding the echo-producing gas core. The microbubbles oscillate in response to the ultrasound beam frequency and give a characteristic increased echo signal on the image. Preliminary studies evaluating renal perfusion in dysfunctional kidneys show reduced flow compared with normal kidneys as well as improved lesion detection (Fig. 5-12). However, the clinical adoption of microbubble imaging in the kidney remains uncertain, particularly with the general availability and robustness of CT and MRI, and its use is off-label in the United States and not presently reimbursed.

Two-dimensional ultrasound images can be reconstructed into three-dimensional (3D) volume images by a process similar to 3D reconstructions for MRI and CT. Although the current techniques are time-consuming, technical improvements should decrease 3D reconstruction time. Potential applications include vascular imaging and fusion with MRI or positron emission tomography (PET).

PLAIN RADIOGRAPHY AND INTRAVENOUS UROGRAPHY

The use of intravenous urography (IVU) has receded as cross-sectional imaging by CT or MRI has become more widely applied to the urinary tract. Although now with few primary indications in many centers, contrast urography may still be a key investigation in parts of the world where economic limitations mean that cross-sectional imaging is not available. However, plain radiography, often called a KUB (kidneys, ureter, bladder), still has an important role

in the identification of soft tissue masses, bowel gas pattern, calcifications, and renal location.

Renal Calcification

Most renal calculi are radiodense, although only about 60% of urinary stones detected on CT are visible on plain films.[17] CT demonstrates nonopaque stones, which include uric acid, xanthine, and struvite stones. However, neither CT nor plain radiography may detect calculi associated with protease inhibitor therapy.[18] Oblique films are sometimes obtained to confirm whether a suspicious upper quadrant calcification is renal in origin. Calculi that are radiolucent on plain films are usually detected as filling defects on IVU. IVU has higher sensitivity than radiography but lower sensitivity than CT. If available, CT is the imaging modality of choice for detection of urinary calculi.[19]

Nephrocalcinosis may be medullary (Fig. 5-13, *A* and *B*) or cortical *(C)* and is localized or diffuse. The common causes of nephrocalcinosis are discussed in Chapter 59 (see Box 59-7).

Intravenous Contrast Urography

Before contrast material is administered, an abdominal compression device may be placed, to compress the midureters against the bony pelvis. This retains the excreted contrast material in the upper tract and distends the renal pelvis and calyces. The first film is usually performed at 30 seconds after contrast injection, when the renal parenchyma is at peak enhancement. Subtle renal masses are often detected only on these early films. The compression device is then removed, and films of the entire abdomen are obtained at 5 minutes, when there is renal excretion of the contrast agent and the ureters are best evaluated. Films with the patient prone may be required to visualize the entirety of the ureter. A filled-bladder film is obtained. A postvoid film of the bladder assesses emptying and assists in evaluation of the distal ureters, which may be obscured by a distended contrast-filled bladder. The usual contrast volume injected for IVU is similar to that for routine abdominal CT. The primary difference is timing of imaging. IVU is contraindicated in patients with a history of allergic reactions to radiographic contrast agents. When the glomerular filtration rate (GFR) is less than 60 ml/min, IVU

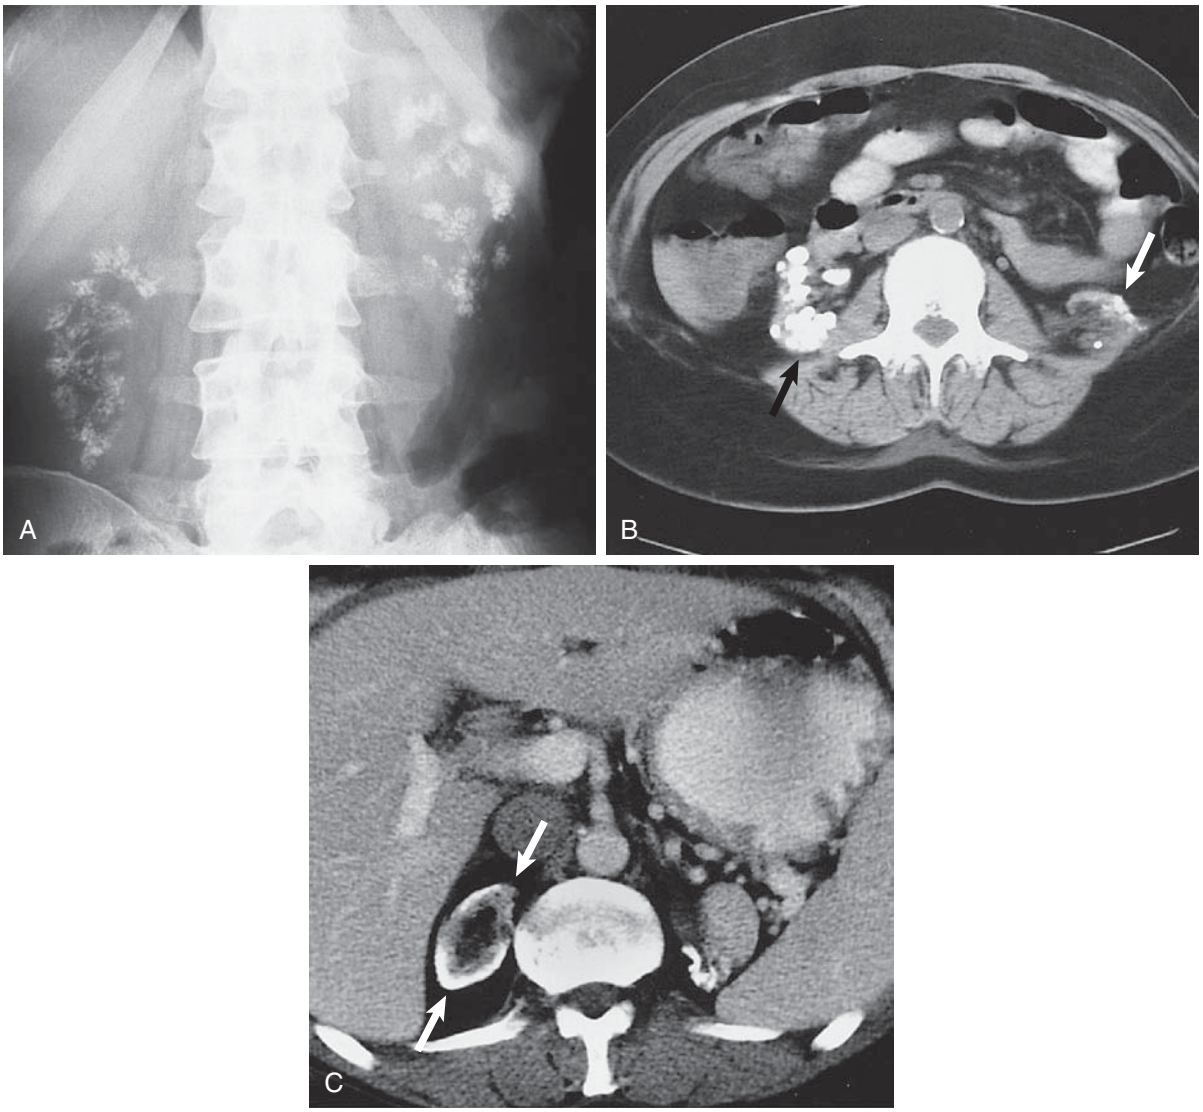

Figure 5-13 Nephrocalcinosis. A, Plain x-ray film shows bilateral medullary nephrocalcinosis in a patient with distal renal tubular acidosis. **B,** Noncontrast CT scan in a patient with hereditary oxalosis and dense bilateral renal calcification *(arrows)*. The left kidney is atrophic. **C,** Noncontrast CT scan shows cortical nephrocalcinosis in the right kidney *(arrows)* after cortical necrosis.

yields increasingly poor images, and the risk of nephrotoxicity also increases.

Kidneys

Evaluation of the kidneys on IVU (as well as CT and MRI) should include their number, location, axis, size, contour, and degree of enhancement. Renal size is variable, but a normal kidney should be about three to four lumbar vertebral bodies in length. The renal outline should be smooth and sharply demarcated from the retroperitoneal fat. Renal enhancement after contrast administration should be symmetric and progress centrally from the cortex, with excretion evident in the ureters by 5 minutes. Asymmetry of renal enhancement may indicate renal artery disease.

Pelvicalyceal System

The pelvicalyceal system is best evaluated on the early postcontrast films. Normally, there are about 10 to 12 calyces per kidney. The calyces drain into the infundibula, which in turn empty into the renal pelvis (Fig. 5-14). The infundibulum and renal pelvis should have smooth contours without filling defects. In a common variant, vessels can cross the pelvicalyceal system or ureters, causing extrinsic compression defects that should not be mistaken for tumors or other urothelial lesions. When more than one calyx drains into an infundibulum, it is known as a *compound calyx,* most frequently seen in the poles. The normal calyx is gently cupped. Calyceal distortion occurs with papillary necrosis and reflux nephropathy.

Ureters

The ureters are often seen segmentally because of active peristalsis. The ureters should be free of filling defects and smooth. In the abdomen, the ureters lie in the retroperitoneum, passing anterior to the transverse processes of the vertebral bodies. In the pelvis, the ureters course laterally and posteriorly, eventually draining into the posteriorly located vesicoureteral junction. At the vesicoureteral junction, the ureters gently taper. Medial bowing or displacement of the ureter is often abnormal and can be seen secondary to ureter displacement from retroperitoneal masses, lymphadenopathy, and retroperitoneal fibrosis.

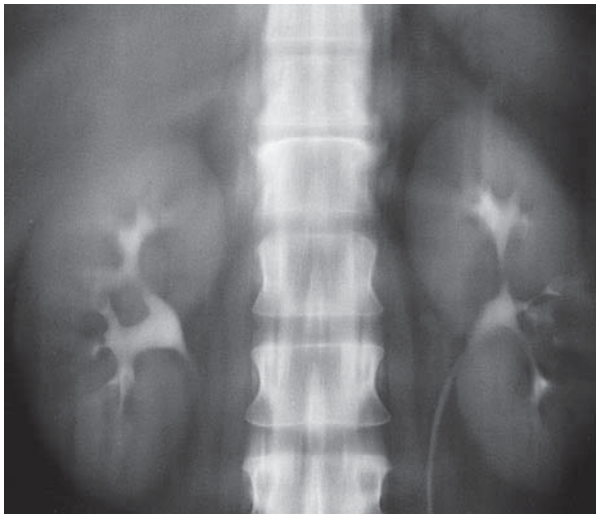

Figure 5-14 Normal parenchymal enhancement and normal renal excretion. Early postcontrast tomogram in intravenous urography.

Bladder

The bladder should be rounded and smooth walled. Benign indentations on the bladder include the uterus, prostate gland, and bowel. In chronic bladder outlet obstruction and neurogenic bladder, numerous trabeculations and diverticula may be seen around the bladder outline.

RETROGRADE PYELOGRAPHY

Retrograde pyelography is performed when the ureters are poorly visualized on other imaging studies or when samples of urine need to be obtained from the kidney for cytology or culture. Patients who have severe allergies to contrast agents or impaired renal function can be evaluated with retrograde pyelography. The examination is performed by placing a catheter through the ureteral orifice under cystoscopic guidance and advancing it into the renal pelvis. With use of fluoroscopy, the catheter is slowly withdrawn while radiocontrast is injected (see Figs. 60-2 and 60-11). This technique provides excellent visualization of the renal pelvis and ureter and can also be used for cytologic sampling from suspect areas.

ANTEGRADE PYELOGRAPHY

Antegrade pyelography is performed through a percutaneous renal puncture and is used when retrograde pyelography is not possible. Ureteral pressures can be measured, hydronephrosis evaluated, and ureteral lesions identified (see Fig. 60-14). The examination is often performed as a prelude to nephrostomy placement. Both antegrade pyelography and retrograde pyelography are invasive and should be performed only when other studies are inadequate.

ILEAL CONDUITS

After cystectomy or bladder failure, numerous types of continent or incontinent urinary diversions can be surgically created. One of the most common diversions is the ileal conduit; an ileal loop is isolated from the small bowel, and the ureters are implanted into the loop. This end of the loop is closed, and the other end exits through the anterior abdominal wall. This type of conduit can be evaluated by an excretory or a retrograde study. The excretory or *antegrade* study is performed and monitored in the same way as an IVU. A *retrograde* examination, also referred to as a loop-o-gram, is obtained when the ureters and conduit are suboptimally evaluated on the excretory study. A Foley catheter is placed into the stoma and contrast slowly instilled. The ureters should fill by reflux because the ureteral anastomoses are not of the antireflux variety (Fig. 5-15).

CYSTOGRAPHY

A cystogram is obtained when more detailed radiographic evaluation of the bladder is required. *Voiding* cystography is performed to identify ureteral reflux and to assess bladder function and urethral anatomy. A urethral catheter is placed into the bladder, the urine drained, contrast infused, and bladder filled under fluoroscopic guidance. Early frontal and oblique films with the patient supine are obtained while the bladder is filling. Ureteroceles are best identified on early films. When the bladder is full, multiple films are obtained with varying degrees of obliquity. Reflux may be seen on these films. To obtain a voiding cystogram, the catheter is removed, the patient

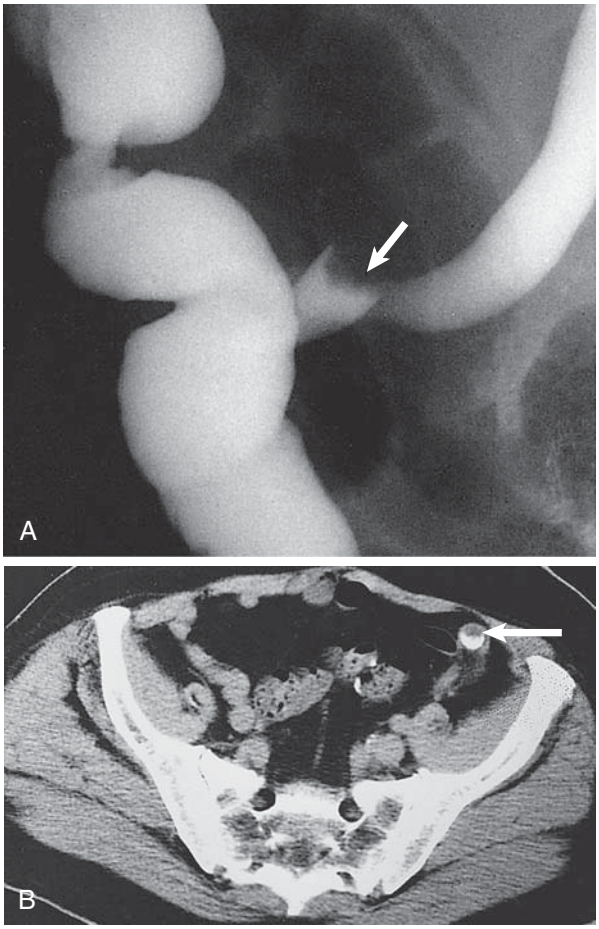

Figure 5-15 Imaging of an ileal conduit. A, Loop-o-gram. A recurrent transitional carcinoma is present in the reimplanted left ureter *(arrow)*. **B,** CT scan clearly shows the tumor as a filling defect in anterior aspect of the opacified ureter *(arrow)*.

voids, and contrast is followed into the urethra. Occasionally, bladder diverticula are seen only on the voiding films. When the patient has completely voided, a final film is used to assess the amount of residual urine as well as the mucosal pattern.

Radionuclide cystography is an alternative often used in children. It is useful in the diagnosis of reflux, but it does not provide the detailed anatomy that is seen with contrast cystography.

COMPUTED TOMOGRAPHY

Computed tomography examination of the kidneys is performed to evaluate suspect renal masses, to locate ectopic kidneys (Figs. 5-16 and 5-17), to investigate calculi, to assess retroperitoneal masses, and to evaluate the extent of parenchymal involvement in patients with acute pyelonephritis (Figs. 5-18 and 5-19). Helical CT scanners allow the abdomen and pelvis to be scanned at 3-mm to 5-mm intervals with one or two breath-held acquisitions, which eliminates motion artifact. Newer multidetector row CT results in multiple slices of information (64-slice and even 320-slice machines are now common) being acquired simultaneously, allowing the entire abdomen and pelvis to be covered in one breath-hold, using even submillimeter intervals. However, the improved CT imaging comes at a price of significant radiation exposure to the patient. The CT data can be reconstructed in multiple planes and even 3D for improved anatomic visualization and localization.

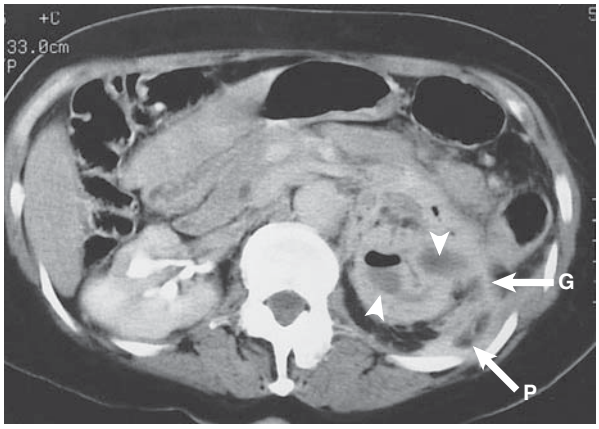

Figure 5-18 Emphysematous pyelonephritis. Contrast-enhanced CT scan shows gas *(arrowheads)* within an enlarged left kidney and marked enhancement of Gerota fascia *(G)* and posterior perirenal space *(P)*, indicative of inflammatory involvement.

Tissue Density

The Hounsfield unit (HU) scale is a measurement of relative densities determined by CT. Distilled water at standard pressure and temperature is defined as 0 HU; the radiodensity of air is defined as −1000 HU. All other tissue densities are derived from this (Table 5-4). Tissues can vary in their exact HU measurements and will also change with contrast enhancement. Water, fat, and soft tissue can often look identical on the scan, depending on the window and level settings of the image, so actual HU measurement is essential to characterize the tissues accurately.

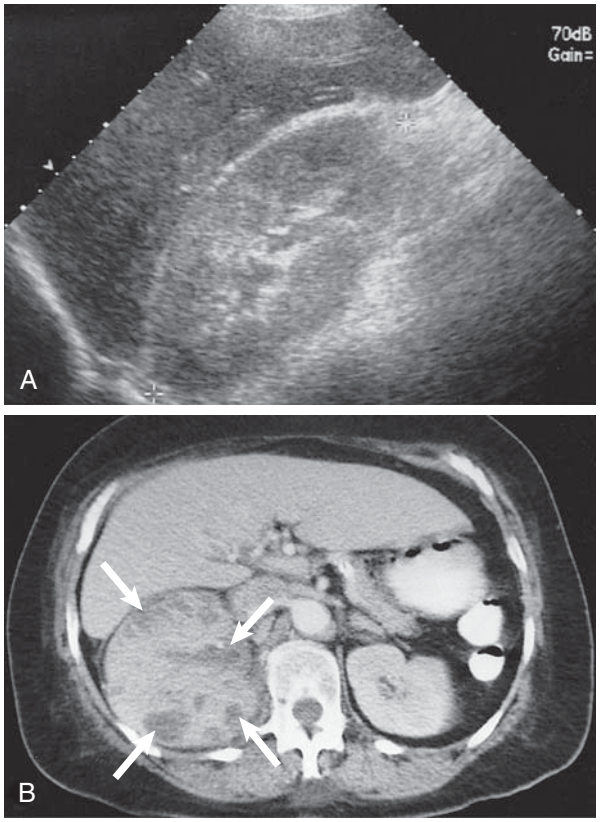

Figure 5-19 Acute pyelonephritis. A, Ultrasound image demonstrates an enlarged echogenic kidney. Bipolar length of kidney is 12.9 cm. **B,** CT scan with contrast enhancement obtained 24 hours later demonstrates multiple nonenhancing abscesses *(arrows)*.

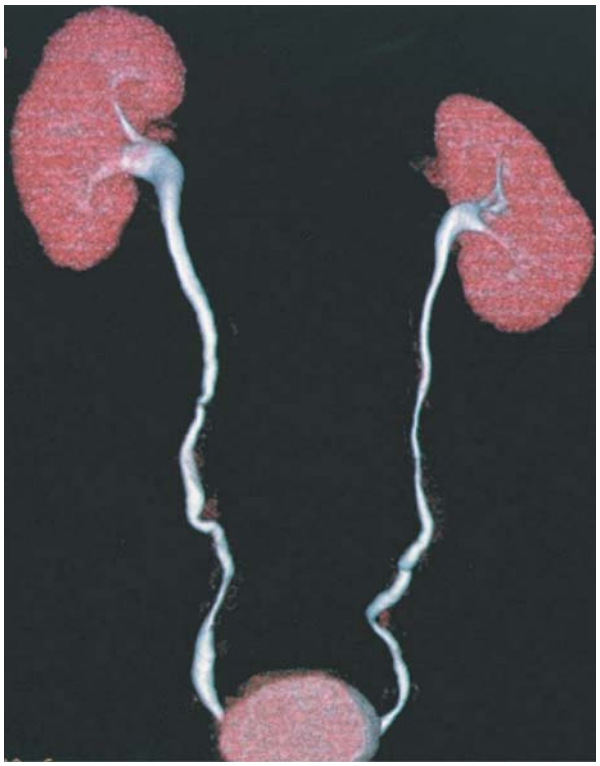

Figure 5-20 Noncontrast CT of bladder and kidney. Computer-reformatted, volume-rendered CT urogram obtained from axial CT acquisition.

Density of Common Substances Determined by Computed Tomography

Substance	HU
Air	–1000
Fat	–120
Water	0
Muscle	+40
Bone	+400 or more

Table 5-4 CT determination of density of common substances. Hounsfield unit (HU) scale is a measurement of relative densities compared with distilled water.

Contrast-Enhanced and Noncontrast Computed Tomography

The CT examination of the kidneys can be performed with or without intravenous administration of contrast material. Noncontrast imaging allows the kidneys to be evaluated for the presence of calcium deposition and hemorrhage, which are obscured after contrast administration.

Noncontrast CT (CT urography, CTU) is the examination of choice in patients with suspected nephrolithiasis and has replaced the KUB and IVU in most situations.[20,21] The study consists of unenhanced images from the kidneys through the bladder for detection of calculi (Fig. 5-20). CTU has the advantage of being both highly sensitive (97% to 100%) and specific (94% to 96%) for diagnosis of urinary calculi.[19,22] Noncontrast CT can identify a possible obstructing calculus as well as the extent of parenchymal and perinephric involvement.

In cases other than stone evaluation, the kidneys are imaged after contrast administration. The kidneys are imaged in the corticomedullary phase for evaluation of the renal vasculature as well as in the nephrographic phase for evaluation of the renal parenchyma. The degree of enhancement can be assessed in both solid masses and complex cysts (see Fig. 60-10).

A compression device can be used as in IVU. Delayed images through the kidneys and bladder are performed for evaluation of the opacified and distended collecting system, ureters, and bladder.[23,24] After acquisition, the axial images can be reformatted into coronal or sagittal planes to optimize visualization of the entire collecting system. The CT study can be tailored to the individual clinical scenario. For example, the corticomedullary phase can be eliminated to decrease the radiation dose if there is no concern about a vascular abnormality or no need for presurgical planning. A diuretic or saline bolus can be administered after contrast to better distend the collecting system and ureters during the excretory phase.

The kidneys should be similar in size and show equivalent enhancement and excretion. During the corticomedullary phase, there is brisk enhancement of the cortex. The cortical mantle should be intact. Any disruption of the cortical enhancement requires further evaluation; it may be caused by acute pyelonephritis (see Fig. 5-19), scarring, mass lesions, or infarction (Fig. 5-21). During the excretory phase, the entire kidney and renal pelvis enhance. Delayed excretion and delay in pelvicalyceal appearance of contrast material may be found in obstruction (Fig. 5-22), but also in renal parenchymal disease such as acute tubular necrosis.

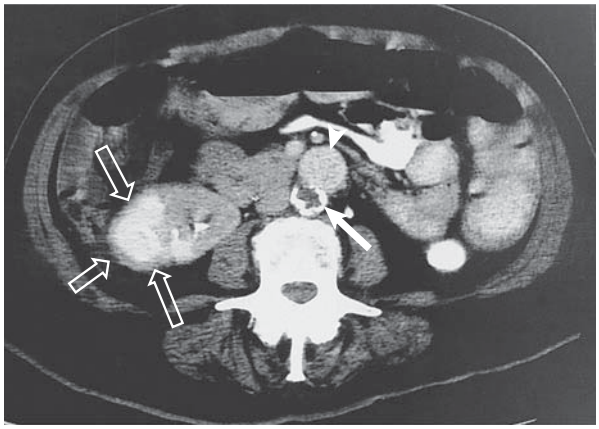

Figure 5-21 Renal infarction. CT scan showing an infarct *(open arrows)* involving half of the right kidney after aortic bypass surgery. The native aorta has a densely calcified wall *(arrow)*. The aortic graft is anterior to the native aorta *(arrowhead)*.

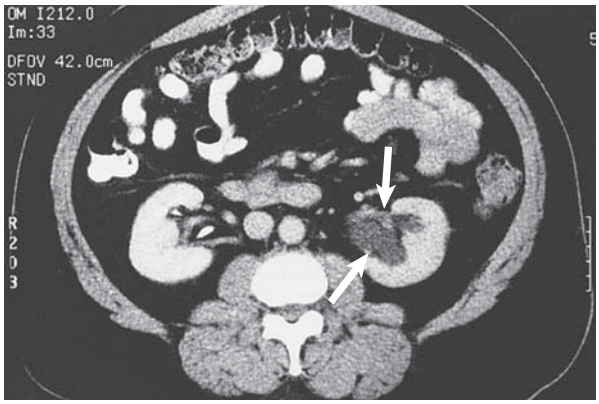

Figure 5-22 Delayed excretion in left kidney secondary to distal calculus. Contrast-enhanced CT scan shows dilated left renal pelvis *(arrows)*.

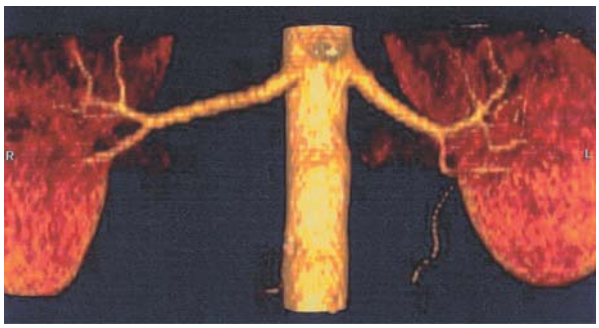

Figure 5-23 Normal renal arteries. Three-dimensional reformatted CT angiogram.

Computed Tomographic Angiography

Helical scanning facilitates CTA, which can produce images similar to conventional angiograms, but it is less invasive. A bolus of contrast material is administered, and the images are obtained at 0.5-mm to 3-mm consecutive intervals. The contrast bolus is timed for optimal enhancement of the aorta. The tightly focused and narrow CT beam allows higher resolution and better subsequent multiplanar reconstructions. The aorta and branch vessels are well demonstrated (Fig. 5-23). This technique is now widely used in living transplant donor evaluation (see Fig. 103-2), providing information not only on arterial and venous anatomy but also on size, number, and location of the kidneys as well as any ureteral anomalies of number or position.

In addition, CTA can be used to screen for atheromatous renal artery stenosis, with sensitivity of 96% and specificity of 99% for the detection of hemodynamically significant stenosis compared with digital subtraction angiography (DSA).[25] Furthermore, CTA allows visualization of both the arterial wall and lumen, which helps in planning renal artery revascularization procedures. Another advantage of CTA is the depiction of accessory renal arteries as well as nonrenal causes of hypertension, such as adrenal masses. CTA can be used to diagnose fibromuscular dysplasia but has a much lower sensitivity (87%) than DSA.[26]

Limitations of Computed Tomography

There are some limitations of CT. The cradle that the patient lies on usually has an upper weight limit of 100 to 200 kg (300 to 400 lb), but newer scanners can now accommodate up to 270 kg (600 lb). Obese patients often have suboptimal scans because of weight artifact and need higher radiation exposures to adjust for x-ray attenuation. Contrast-enhanced CT studies are contraindicated in patients with an allergy to radiographic contrast dye and in patients with impaired renal function. To minimize contrast-induced nephropathy, contrast should not be given to patients with GFR less than 30 ml/min without carefully assessing risks and benefits. Contrast should be used with caution in patients with GFR of 30 to 60 ml/min per 1.73 m^2. If contrast is administered, subjects should be hydrated with intravenous saline and/or bicarbonate solution; the additional value of prophylaxis with oral *N*-acetylcysteine continues to be debated (see Contrast-Induced Nephropathy).

Computed tomography is very sensitive to metal artifact and patient motion. Retroperitoneal clips and intramedullary rods will cause extensive streak artifact, which severely degrades the images. Patients who are unable to remain motionless will also have suboptimal or even nondiagnostic studies, and sometimes sedation or general anesthesia may be needed to obtain diagnostic scans, particularly in children. Intensive care unit and critically ill patients can be scanned by CT as long as they are stable enough to be transported to the CT suite. Ultrasound should be considered as an alternative to CT in the seriously ill patient who cannot be safely transported.

MAGNETIC RESONANCE IMAGING

Although it should only rarely be the first examination used to evaluate the kidneys, MRI is typically an adjunct to other imaging. The major advantage of MRI over other modalities is direct multiplanar imaging. CT is limited to slice acquisition in the axial plane of the abdomen, and coronal and sagittal planes are acquired only by reconstruction, which can lead to loss of information.

Tissues contain an abundance of hydrogen, the nuclei of which are positively charged protons. These protons spin on their axis, producing a magnetic field (magnetic moment). When a patient is placed in a strong magnetic field in an MRI scanner, some of the protons align themselves with the field. When a radiofrequency pulse is applied, some of the protons aligned with the field will absorb energy and reverse their direction. This absorbed energy is given off as a radiofrequency pulse as the protons relax (return to their original alignment), producing a voltage in the receiver coil. The coil is the hardware that covers the region of interest. For renal imaging, a body coil or torso coil is used. Relaxation is a 3D event giving rise to two parameters: T1 relaxation results in the recovery of magnetization in the longitudinal (spin-lattice) plane, whereas T2

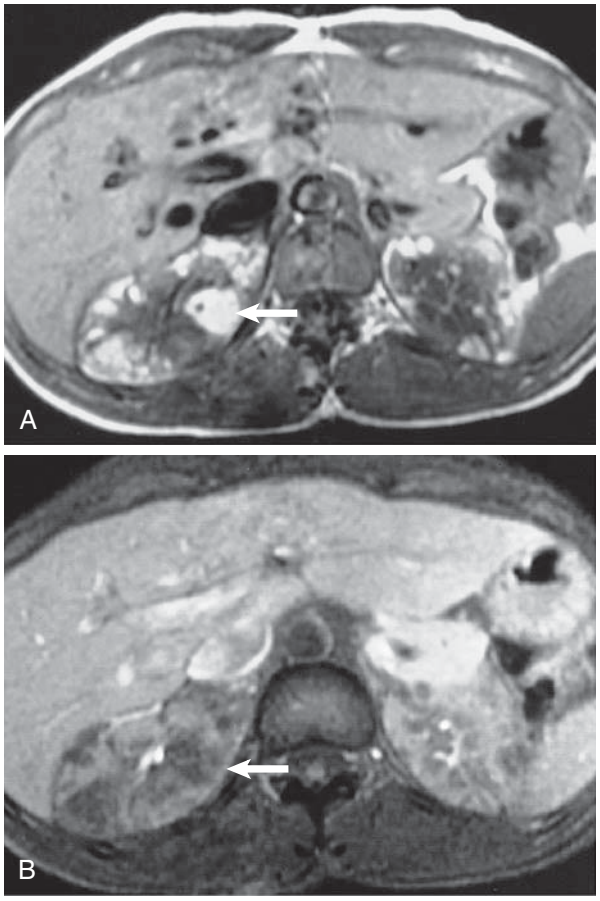

Figure 5-24 Tuberous sclerosis on MRI. Multiple renal angiomyolipomas are seen. **A,** T1-weighted MR image. The tumors are high in signal on T1 because of their fat; *arrow* shows the largest tumor. **B,** T1-weighted MR image with fat suppression. The fat within the tumors is now low in signal *(arrow)*.

results from the loss of transverse (spin-spin) magnetization. A rapid-sequence variant of T2 in common use is fast spin echo (FSE). Hydrogen ions move at slightly different rates in the different tissues. This difference is used to select imaging parameters that can suppress or aid in the detection of fat and water. Fluid, such as urine, is dark or low in signal on T1-weighted sequences and bright or high in signal on FSE sequences. Fat is bright on T1 and not as bright on FSE sequences (Fig. 5-24). The sequences and imaging planes selected must be tailored to the individual MR study. Diffusion-weighted imaging evaluates the freedom of water molecules to diffuse in tissues; restriction of diffusion is imaged as bright areas on the scan and is seen in infection, neoplasia, inflammation, and ischemia.

Standard MR images usually include T1, T2, or FSE sequences and often additional contrast-enhanced T1 images. The imaging plane varies according to the clinical concerns. Usually, at least one sequence is performed in the axial plane. Sagittal and coronal images cover the entire length of the kidney and can make some subtle renal parenchymal abnormalities more conspicuous (Fig. 5-25).

On T1-weighted sequences, the normal renal cortex is higher in signal than the medulla, producing a distinct corticomedullary differentiation, which becomes indistinct in parenchymal renal disease. It is analogous to the echogenic kidney seen on ultrasound. On FSE sequences, the corticomedullary distinction is not as sharp but should still be present.

Contrast-Enhanced Magnetic Resonance Imaging

As with CT, intravenous contrast material can be administered to allow further characterization of renal lesions. Gadolinium is a *paramagnetic* contrast agent frequently used in MRI and is much less nephrotoxic than iodinated contrast material.[27] Adverse reactions to gadolinium are discussed later (see Magnetic Resonance Contrast Agents). Paramagnetic contrast agents are currently being evaluated for measurement of glomerular function.

After injection of gadolinium, the vessels appear high in signal, or white, on T1-weighted sequences. Multiple images can be obtained in a single breath-held acquisition. This technique is useful for lesion characterization in patients who cannot receive iodinated contrast material. As with contrast-enhanced CT, the kidneys initially show symmetric cortical enhancement, which progresses to excretion. A delay in enhancement can be seen with renal artery stenosis.

Magnetic Resonance Urography

There are two techniques for performing magnetic resonance urography (MRU).[28,29] The first technique is sometimes called *static* MRU. Because urine contains abundant water, it will demonstrate high signal on a T2-weighted image. Therefore, a heavily T2-weighted sequence accentuates the static fluid in the collecting system and ureters, which stands out against the darker background soft tissues. Static MRU can be performed rapidly, which is a benefit in imaging of children. A disadvantage is that any fluid in the abdomen or pelvis, such as fluid collections or fluid in small bowel, will demonstrate similar bright signal that can obscure superimposed structures. Also, the collecting system and ureters need to be distended for acquisition of good MR images.

The second technique, often referred to as *excretory* MRU, is similar to CTU. Intravenous administration of gadolinium is followed by T1-weighted imaging. This technique allows some assessment of renal function because the contrast is filtered by the kidney and excreted into the urine (see Fig. 60-10). The opacified collecting system and ureters are well seen, and a diuretic can be administered to further dilate the renal pelvis and ureters if necessary. A limitation of MRU is in the detection of calculi because calcification is poorly visualized by MRI.

Because CTU and MRU are comparable examinations in identifying the cause and anatomic location of urinary obstruction, the choice of modality is a matter of local preference. CTU is the better choice in the evaluation of urinary tract calculi. In patients with renal impairment caused by obstruction, MRU is superior to CTU in identifying noncalculous causes of obstruction, whereas CTU is superior in identifying calculous causes of obstruction.[30,31] CTU is also more widely available, faster, and less expensive than MRU. MRU is better suited in patients with allergy to iodinated contrast agents and sometimes in children when radiation is an issue. MRU is also useful in depicting the anatomy in patients with urinary diversion to bowel conduits.

Magnetic Resonance Angiography

Although MRA can be performed with or without intravenous contrast, contrast provides better images. The aorta and branch vessels are beautifully demonstrated (Fig. 5-26). By adjustment of timing and type of sequences, the abdominal venous structures can be visualized (Fig. 5-27). MRA is performed to evaluate the renal arteries for stenosis and is less invasive than catheter angiography (Fig. 5-28).

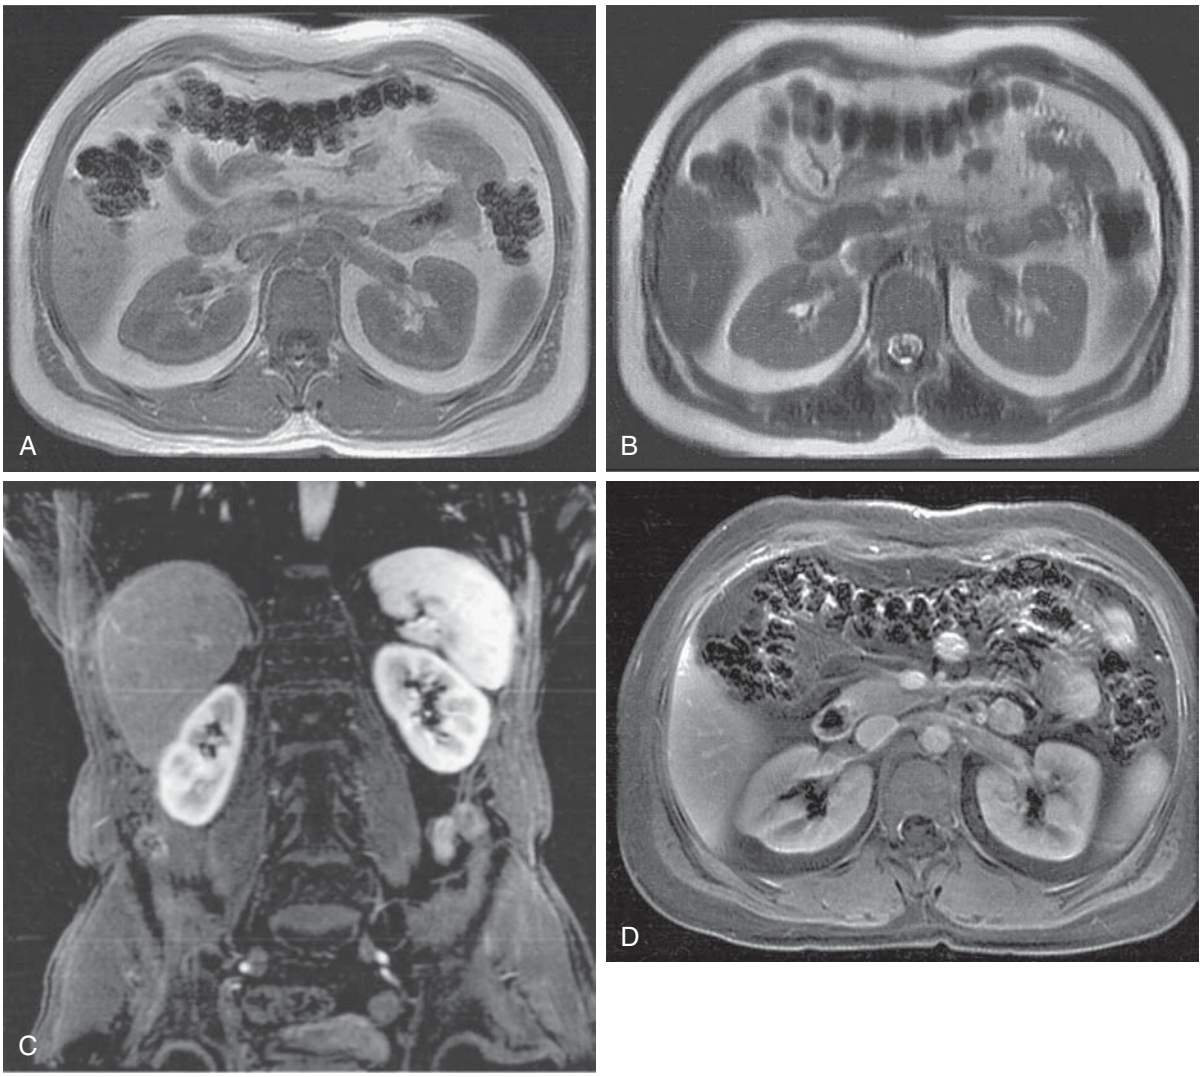

Figure 5-25 Normal MR images through kidneys. A, T1-weighted MR image. Note the distinct corticomedullary differentiation. **B,** Fast spin-echo MR image. Urine in the collecting tubules causes the high signal within the renal pelvis on this sequence. **C,** Coronal T1-weighted, fat-suppressed MR image after contrast administration. **D,** Axial T1-weighted, fat-suppressed image after contrast administration.

Technical advances, including faster sequences, now give sensitivity of 97% and specificity of 93% compared with DSA for contrast-enhanced MRA in the detection of renal artery stenosis.[32] MRA without gadolinium has a lower sensitivity (53% to 100%) and specificity (65% to 97%) for detection of renal artery stenosis.[33] MRA has limited power to assess accessory renal arteries and therefore is not an ideal study to evaluate fibromuscular dysplasia. It has become the primary screening modality in patients with hypertension, declining renal function, or allergy to iodinated contrast agents.[34] Where MRA is unavailable, Doppler ultrasound can be used.

Disadvantages of Magnetic Resonance Imaging

As with CT, MRI has some disadvantages. The table and gantry are confining, so claustrophobic patients may be unable to cooperate. Patients with some types of internal metallic hardware, such as pacemakers or cerebral aneurysm clips, cannot undergo MRI. Determination of in-stent stenosis is impossible as metallic artifact from renal artery stents completely obscures the lumen. Even with the new, fast imaging techniques, patients need to be able to cooperate with breath-holding instructions to minimize motion-related artifacts. MRI with gadolinium has until recently been contraindicated in patients with GFR below 30 ml/min/1.73 m^2 because of the risk of nephrogenic systemic fibrosis[35] (see later, Magnetic Resonance Contrast Agents).

MRI can be used in intensive care unit and critically ill patients only if they are stable enough to be transported to the MRI suite and have no implanted metallic devices. Ventilated patients can undergo MRI; however, specific MRI-compatible, nonferromagnetic ventilators and other life support devices must be used. Because of the confined nature of the MRI gantry, visualization and monitoring of the patient during the scan are compromised.

Incidental Findings

With the growth of cross-sectional imaging, incidental renal lesions are being found with increasing frequency. Almost 70% of renal cell carcinomas are discovered incidentally on imaging studies performed for other reasons. There is an age-dependent incidence of

Figure 5-26 Magnetic resonance angiography. Coronal 3D MR angiogram after contrast administration shows normal renal arteries.

Figure 5-27 Magnetic resonance venography.

renal cysts, from about 5% in patients younger than 30 to almost one third of those older than 60.[36] The differentiation of solid and cystic lesions is the first mandate because as many as two thirds of solid lesions are found to be malignant.[37] MRI is ideally suited for lesion evaluation and is often better than ultrasound, particularly for

Figure 5-28 Dysplasia on MR angiography. Coronal 3D MR angiogram shows fibromuscular dysplasia of the proximal right renal artery.

complex cystic lesions. Parameters being characterized include solid versus cystic, overall lesion complexity, lesion enhancement, involvement of renal vasculature and collecting system, and extension into perirenal tissues and organs. Diffusion-weighted MRI sequences are also being studied as a means of further differentiating benign and malignant solid lesions.

MEASUREMENT OF GLOMERULAR FILTRATION RATE

Renal blood flow and split renal function can be evaluated by CT and MRI.[38-40] The attenuation of the accumulated contrast material within the kidney is directly proportional to the GFR. Taking into account the renal volume, the function of each kidney can be determined. Although both modalities yield similar information, MRI is used more in children and in patients with allergy to contrast agents. This technique has not yet gained full acceptance, and renal scintigraphy remains a widely used method for determination of renal function, as discussed later.

ANGIOGRAPHY

Angiography is now most often performed for therapeutic intervention, such as embolotherapy or angioplasty and stenting, preceded by diagnostic angiography to evaluate the renal arteries for possible stenosis (Fig. 5-29). With improved resolution and scanning techniques, CTA and MRA have replaced conventional angiography, even for detection of accessory renal arteries, which are often small and bilateral but a possible cause of hypertension. However, angiography remains the gold standard (reference) test for the diagnosis of renal artery stenosis and fibromuscular dysplasia. There also remains a role for diagnostic angiography in the evaluation of medium- and large-vessel vasculitis and detection of renal infarction.

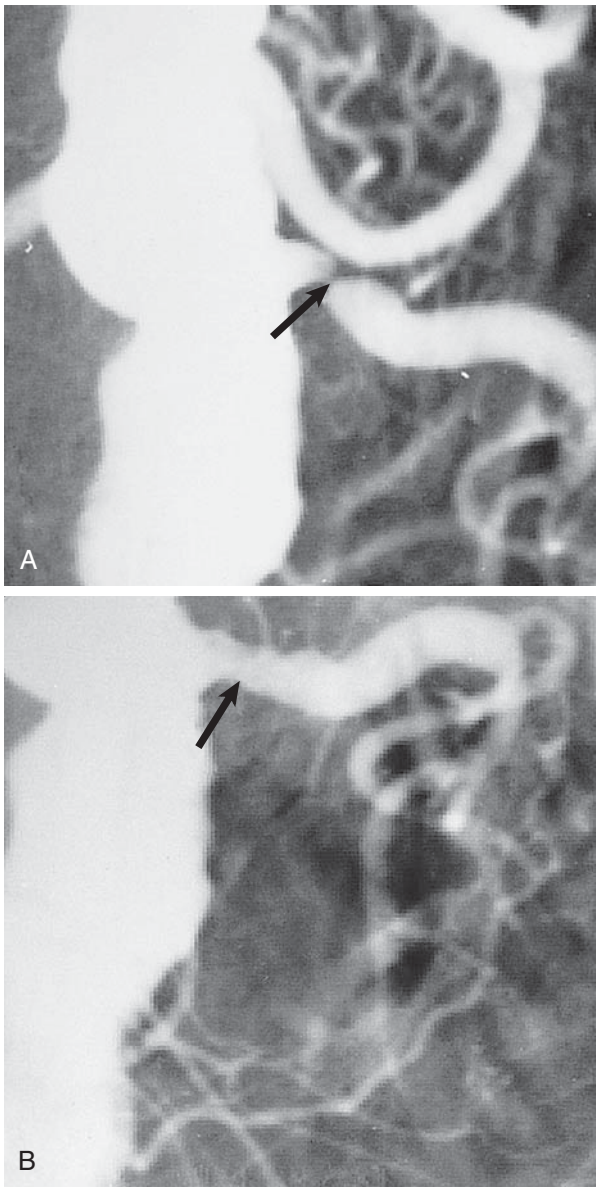

Figure 5-29 Left renal artery stenosis and angioplasty. A, Aortogram demonstrating a tight left renal artery stenosis *(arrow)*. **B,** Postangioplasty image with marked improvement of the stenosis *(arrow)*. *(Courtesy Dr. Harold Mitty.)*

The conventional angiogram is performed through arterial puncture, followed by catheter placement in the aorta. An abdominal aortogram is obtained to identify the renal arteries. Selective renal artery catheterization can be performed as necessary. Contrast is administered intra-arterially, and the images are obtained with conventional film or more often with DSA. Conventional angiography images are superior but require higher doses of contrast material and more radiation exposure. DSA uses computer reconstruction and manipulation to generate the images, with the advantage that previously administered and excreted contrast material and bones can be digitally removed to better visualize the renal vasculature. As well as with the risk of contrast-induced nephropathy, angiography is associated with a risk of cholesterol embolization (see Chapter 66). Pathologic evidence of cholesterol embolization is common, but clinically significant symptoms occur infrequently (1% to 2%).[41]

Choice of Radionuclide in Renal Imaging

Imaging Target	Radiotracer
Glomerular filtration rate	^{99m}Tc-DTPA
Glomerular filtration rate with renal impairment	^{99m}Tc-MAG3, ^{131}I-OIH
Effective renal plasma flow	^{99m}Tc-MAG3, ^{131}I-OIH
Renal scarring	^{99m}Tc-DMSA, ^{99}Tc-GH
Renal pseudotumor	^{99m}Tc-DMSA
Upper renal tract obstruction	^{99m}Tc-DTPA
Upper renal tract obstruction with renal impairment	^{99m}Tc-MAG3

Table 5-5 Choice of radionuclide in renal imaging.

RENAL VENOGRAPHY

Catheter venography was once used for evaluation of renal vein and gonadal vein thrombosis and for renal vein sampling to measure renin, but has largely been replaced with Doppler ultrasound, followed by contrast-enhanced CT or MRI (see Fig. 5-27).

NUCLEAR MEDICINE

Nuclear scintigraphy evaluates function as well as the anatomy seen with other diagnostic imaging modalities. Radiotracers are designed to accumulate in tissues or organs on the basis of underlying functions unique to that organ. The gamma camera captures the photons from a radiotracer within the patient and generates an image. Single-photon emission computed tomography (SPECT) is a specialized type of imaging whereby the emitted photons are measured at multiple angles, similar to CT, and multiplanar or even 3D images can be created. Three categories of radiotracers that differ in mode of renal clearance are used in renal imaging: glomerular filtration, tubular secretion, and tubular retention agents (Table 5-5).

Scintigraphy remains superior to the other imaging modalities in the evaluation of renal flow. It is the study of choice in the evaluation of renal transplants and for the evaluation of functional obstruction, especially when ultrasound evidence is equivocal. Scintigraphy is also widely used to measure GFR, although CT or MRI are preferred in some centers.

Nuclear scintigraphy also provides an accurate assessment of renal function, as in estimating the reduction in renal function after nephron-sparing surgery. Although CT, MRI, and contrast-enhanced ultrasound are being assessed for the evaluation of renal function, scintigraphy remains the preferred modality. Both CTA and MRA have replaced nuclear scintigraphy in the evaluation of renal artery stenosis and in evaluation of benign renal masses, such as a column of Bertin. Nuclear medicine is still used to assess the functional significance of renal artery stenosis independent of anatomy.

Glomerular Filtration Agents

Glomerular filtration agents are cleared by the glomerulus and can be used to measure GFR. Technetium Tc 99m–labeled diethylenetriaminepentaacetic acid (^{99m}Tc-DTPA) is the most common glomerular agent used for imaging and can also be used for GFR

calculation. In patients with poor renal function, renal imaging with tubular secretion agents such as mercaptoacetyltriglycine (^{99m}Tc-labeled MAG3) is superior to DTPA.[42,43]

Tubular Secretion Agents

Technetium-99m MAG3 is handled primarily by tubular secretion and can be used to estimate effective renal plasma flow. The clearance rate for ^{99m}Tc-MAG3 is 340 ml/min.[44]

Tubular Retention Agents

Tubular retention agents include ^{99m}Tc-labeled dimercaptosuccinate (DMSA) and less often ^{99m}Tc-labeled glucoheptonate (GH). These agents provide excellent cortical imaging and can be used in suspected renal scarring or infarction, in pyelonephritis, and for clarification of renal pseudotumors. These agents bind with high affinity to the sulfhydryl groups of the proximal tubules.

Renogram

A renogram (or renal scintigram) is generated by scintigraphy and provides information about blood flow, renal uptake, and excretion. Time-activity graphs are produced that plot blood flow of the radiotracer into each kidney relative to the aorta. Peak cortical enhancement and pelvicalyceal clearance of the tracer are also plotted. DTPA or MAG3 can be used to generate the renogram. The relative radiotracer uptake can be measured and can provide split or differential information about renal function (Fig. 5-30).

The blood pool or flow images are obtained after bolus injection of the radiotracers. Images are obtained with the gamma camera every few seconds for the first minute. The second component of the renogram evaluates renal function by measuring radiotracer uptake and excretion by the kidney. In normal patients, the peak renal cortical concentration occurs between 3 and 5 minutes after injection of tracer. Delayed transit of the isotope secondary to renal dysfunction (e.g., acute tubular necrosis or rejection) or obstructive uropathy will alter the curve of the renogram.

In cases of suspected obstructive uropathy, a diuresis renogram can be obtained. A loop diuretic is injected intravenously when radiotracer activity is present in the renal pelvis; a computer-generated washout curve is obtained. In patients with true obstruction, activity will remain in the renal pelvis, whereas it will quickly wash out in patients without an obstruction (Fig. 5-31; see also Fig. 60-12).

Cortical Imaging

Renal cortex imaging is performed with tubular retention agents, usually ^{99m}Tc-DMSA. Information about renal size, location, and contour can be obtained (Fig. 5-32). The cortical study is used most frequently for evaluation of renal scarring, particularly in children with reflux or chronic infections (see Chapter 63). It was formerly used for clarification of renal pseudotumors, such as a suspected column of Bertin, but this is now done with CT and MRI. Split renal function can also be determined from cortical imaging. Pinhole imaging (pinhole collimator magnifies the kidney to provide more anatomic detail than with planar imaging) and more recently SPECT have been found useful for detection of cortical defects caused by inflammation or scarring. Cortical imaging may be better than ultrasound in the evaluation of the young patient with urinary tract infection.[45] An infection, scar, or space-occupying lesion (tumor or cyst) will create a cortical defect, and correlation of the cortical defect

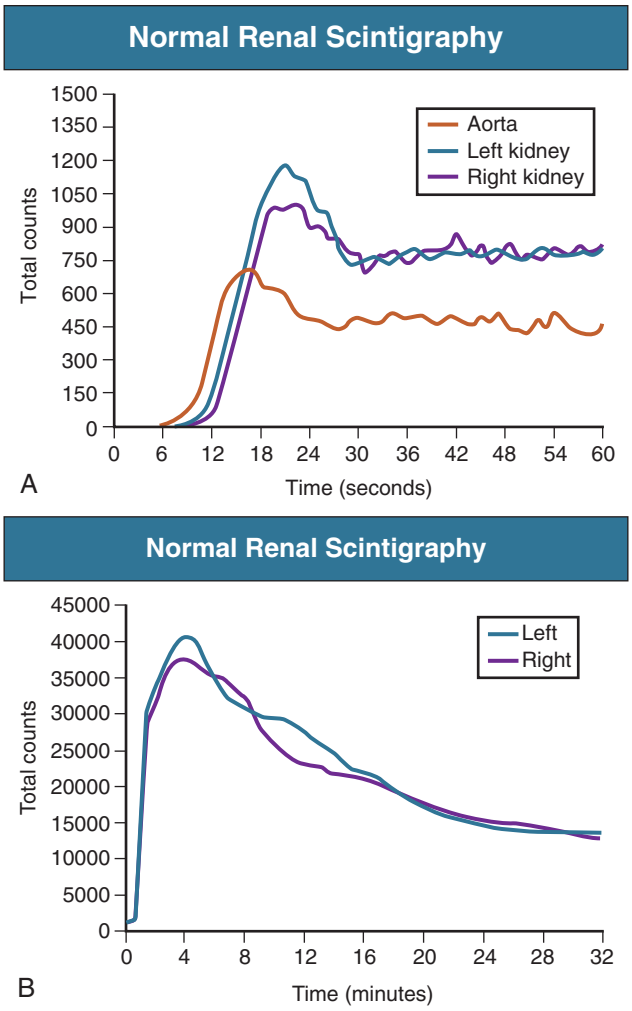

Figure 5-30 Normal ^{99m}Tc-labeled DTPA study: time-activity curves. **A,** Early (0-1 minute), showing renal blood flow. **B,** Later (0-30 minutes), showing renal uptake and excretion of tracer. *(Courtesy Dr. Chun Kim.)*

site with other cross-sectional imaging should be performed to differentiate these entities.

Vesicoureteral Reflux

In children with suspected vesicoureteral reflux, a standard cystogram is obtained. If reflux is shown, follow-up is subsequently performed with radioisotope cystography, which exposes the child to a lower radiation dose and can be used to quantitate the bladder capacity when reflux occurs. The study is performed after instillation of technetium pertechnetate through a catheter into the bladder. Images are obtained during voiding.

Renal Transplant

Renal transplants are easily evaluated with scintigraphy. ^{99m}Tc-MAG3 is cleared through tubular secretion, which is maintained in most kidneys to a better degree than glomerular filtration in renal failure. Because many transplant recipients have declining renal function, ^{99m}Tc-MAG3 is the first-choice nuclide.

As with the normal kidneys, information about blood flow and function can be determined. Postoperative complications involving the artery, vein, or ureter are also well delineated. Nuclear imaging can help define acute tubular necrosis versus rejection in transplant patients with declining renal function. Ultrasound with Doppler evaluation of resistive index is often a complementary investigation, and choice of imaging modality in part depends on local expertise and preference.

POSITRON EMISSION TOMOGRAPHY

Positron emission tomography scanning uses radioactive positron emitters, most often ^{18}F-labeled fluorodeoxyglucose (FDG). The FDG is intravenously injected and distributes in the body according to metabolic activity. Any process, such as a tumor or infection, that causes increased metabolic activity will result in an area of increased uptake on the scan. These areas of abnormality need to be differentiated from normally hypermetabolic tissues, such as brain, liver, bone marrow, and to some extent heart and bowel (Fig. 5-33). Because FDG is cleared through the kidneys and excreted in the urine, PET scanning has a limited role in renal imaging but is useful in the staging and follow-up of metastatic renal cancer.[46,47]

Figure 5-33 Normal PET scan. Note normal radiotracer uptake in brain, heart, intestines, and liver with normal excretion in kidneys.

MOLECULAR IMAGING

With molecular imaging, radiology is moving from the identification of generic anatomy and nonspecific enhancement patterns to assessment of specific molecular differences in tissues and disease processes. Nuclear imaging presently is molecular based but still nonspecific (e.g., FDG-PET, renal DTPA). The newer focus of molecular imaging studies dynamic processes such as metabolic activity, cell proliferation, apoptosis, receptor status, and antigen modulation. Typically, this involves imaging of biochemical and physiologic processes. Techniques are being developed with optical scanning, MRI, and ultrasound as well as with radionuclides.

Applications are established in clinical practice, particularly in oncology (e.g., CD20 imaging in lymphoma), and work is under way for renal-specific molecular imaging. For example, MR renal cell imaging may soon be available to help differentiate acute tubular necrosis from renal rejection and renal cell cancer from benign tumors.

RADIOLOGIC CONTRAST AGENTS

X-ray Contrast Agents

Contrast agents continue to have a role in many imaging techniques. A triiodinated benzene ring forms the chemical basis for CT intravascular contrast agents. Conventional contrast agents have high osmolality, about five times greater than plasma osmolality. They give excellent renal opacification, but this contributes to their toxicity. Modifications to the benzene ring have led to newer contrast agents, including low-osmolar and more recently iso-osmolar nonionic agents, which are less nephrotoxic.

Intravascular iodinated contrast material rapidly passes through the capillary pores into the interstitial, extracellular space and into the renal tubules through glomerular filtration.[48] In patients with normal renal function, the kidneys eliminate almost all the contrast agent. Extrarenal routes of excretion include the liver and bowel wall and account for less than 1% of elimination, but this can increase when renal function is compromised. The half-time in patients with normal renal function is 1 to 2 hours, compared with 2 to 4 hours in dialysis patients.[49]

The overall incidence of contrast reactions for iodinated agents is 3.1% to 4.7%.[50-52] Twenty percent of patients who have a contrast reaction will experience a reaction on reexposure that may be similar or worse. Contrast reactions can be anaphylactoid or chemotoxic reactions. The anaphylactoid reactions mimic an allergic response, whereas the chemotoxic reactions are believed to be mediated by direct toxic effects of the contrast material. The exact mechanism of contrast reaction is not known but is likely to be multifactorial. Formation of antigen-antibody complexes, complement activation, protein binding, and histamine release have all been cited as possible mechanisms.

Reactions may be minor, intermediate, or severe. Minor reactions include heat sensation, nausea, and mild urticaria. Intermediate reactions include vasovagal reaction, bronchospasm, and generalized urticaria. Severe reactions include profound hypotension, pulmonary edema, and cardiac arrest. The use of low-osmolar or iso-osmolar contrast agents reduces the incidence of minor and intermediate contrast reactions. The reported incidence of death related to high-osmolar contrast agents is 1 in 40,000. Immediate treatment of reactions should be directed toward the symptoms. In patients with a history of contrast allergy, pretreatment on reexposure is usually recommended. Various protocols are used but typically include antihistamines and corticosteroids.

Contrast-Induced Nephropathy

Acute kidney injury (AKI) associated with the administration of contrast material has been reported as the third most common cause of in-hospital AKI.[52] Patients with normal renal function rarely develop contrast-induced renal failure. In patients with GFR less than 45 ml/min, iodinated contrast agents should be used with caution because the risk for contrast-induced nephropathy is increased.[53] Nephrotoxicity ranges in severity from a nonoliguric transient fall in GFR to severe renal failure requiring dialysis. The combination of preexisting renal impairment and diabetes is the major risk factor. Other risk factors are diabetes, cardiovascular disease, use of diuretics, advanced age (>75 years), multiple myeloma in dehydrated patients, hypertension, uricosuria, and high-dose contrast. Both ionic and nonionic contrast media can induce nephrotoxicity, although nonionic contrast is significantly less nephrotoxic. In end-stage renal disease, contrast administration may result in fluid overload because of thirst induced by the osmotic load.

The two major theories for the pathogenesis of contrast-induced nephropathy are renal vasoconstriction, perhaps mediated by alterations in nitric oxide, and direct nephrotoxicity of the contrast agent. Most underlying cellular events occur within the first 60 minutes after administration of the contrast agent, with the greatest risk in the first 10 minutes.

There is some evidence that suggests that patients with diabetes and heart failure have altered nitric oxide metabolism, which may account for their increased risk for contrast-induced nephrotoxicity. Tubular injury produces oxygen free radicals, possibly from the vasoconstriction. In animal studies, reduction in antioxidant enzymes associated with hypovolemia contributes to the injury.[54] Hydration with normal saline or sodium bicarbonate is the mainstay of prevention; no substantial evidence shows that sodium bicarbonate offers any advantage over saline.[55] Oral *N*-acetylcysteine, a thiol-containing antioxidant, is often given in conjunction with hydration but has not proved to be consistently protective.[56] In most patients the renal failure is transient, and the patients recover without incident.

An important differential diagnosis for contrast-induced nephropathy in patients with vascular disease undergoing catheter angiography is cholesterol embolization (see Chapters 66 and 69).

In patients with GFR less than 60 ml/min, low-osmolar or iso-osmolar contrast agents should be used and the doses reduced. Repetitive, closely performed contrast studies should be avoided. In high-risk patients, alternative imaging studies, ultrasound, MRI, or noncontrast CT should always be considered. The prevention and management of contrast-induced nephropathy is further discussed in Chapter 73.

Magnetic Resonance Contrast Agents

The two classes of MRI contrast agents are diffusion and nondiffusion agents. Diffusion agents, with appropriate timing of imaging sequences, can delineate vessels as well as parenchymal tissues. Nondiffusion agents remain in the bloodstream and are primarily useful for MRA. All the contrast agents are based on the paramagnetic properties of gadolinium. Gadolinium itself is highly toxic and is given only when it is tightly chelated (e.g., Gd-DOTA, Gd-DTPA).

Minor reactions such as headache and nausea occur in 3% to 5% of patients; but life-threatening reactions and nephrotoxic reactions are rare. In patients with renal impairment, a rare severe reaction, nephrogenic systemic fibrosis, has been described (see Chapter 88), and therefore the use of gadolinium agents is contraindicated in patients with severe renal impairment. The most recent guidelines confirm that MRI using high-risk gadolinium-containing contrast agents is contraindicated in patients with AKI and in those with CKD stages 4 and 5 (i.e., GFR <30 ml/min/1.73 m^2).[35] However, lower-risk cyclic gadolinium–containing contrast agents allow contrast MRI to be undertaken with caution in patients with CKD stages 4 and 5, with a minimum interval of 7 days between repeat studies.

CHAPTER 6

Renal Biopsy

Peter S. Topham and Yipu Chen

DEFINITION

Percutaneous renal biopsy was first described in the early 1950s by Iversen and Brun[1] and Alwall.[2] These early biopsies were performed with the patient in the sitting position by use of a suction needle and intravenous urography for guidance. An adequate tissue diagnosis was achieved in less than 40% of these early cases. In 1954, Kark and Muehrcke[3] described a modified technique using the Franklin-modified Vim-Silverman needle, with the patient in a prone position and an exploring needle used to localize the kidney before insertion of the biopsy needle. These modifications yielded a tissue diagnosis in 96% of cases, and no major complications were reported. Since then, the basic renal biopsy procedure has remained largely unchanged, although the use of real-time ultrasound and refinement of biopsy needle design have offered significant improvements. Renal biopsy is now able to provide a tissue diagnosis in more than 95% of patients, with a life-threatening complication rate of less than 0.1%.

INDICATIONS FOR RENAL BIOPSY

Ideally, analysis of a renal biopsy sample should identify a specific diagnosis, reflect the level of disease activity, and provide information to allow informed decisions about planned treatment. Although not always able to fulfill these criteria, the renal biopsy remains a valuable clinical tool and is of particular benefit in the clinical situations discussed next (Box 6-1).

Nephrotic Syndrome

Routine clinical and serologic examination of patients with nephrotic syndrome usually allows the clinician to determine whether a systemic disorder is present. In adults and in adolescents beyond puberty without systemic disease, there is no reliable way to predict the glomerular pathologic process with confidence by noninvasive criteria alone; therefore a renal biopsy should be performed. In children age 1 year up to puberty, a presumptive diagnosis of minimal change disease (MCD) can be made. Renal biopsy is reserved for nephrotic children with atypical features, including microscopic hematuria, reduced serum complement levels, renal impairment, and failure to respond to corticosteroids.

Acute Kidney Injury

In most patients with acute kidney injury or AKI on a background of chronic kidney disease (CKD), the cause can be determined without a renal biopsy. Obstruction, reduced renal perfusion, and acute tubular necrosis (ATN) can usually be identified from other lines of investigation. In a minority of patients, however, a confident diagnosis cannot be made, and a renal biopsy should be performed on an urgent basis so that appropriate treatment can be started before irreversible renal injury develops. This is particularly true in patients with AKI accompanied by active urine sediment or with suspected drug-induced or infection-induced acute interstitial nephritis.

Systemic Disease Associated with Renal Dysfunction

Patients with diabetes mellitus and renal dysfunction do not usually require biopsy if the clinical setting is associated with diabetic nephropathy, as in isolated proteinuria, diabetes of long duration, or evidence of other microvascular complications. Renal biopsy should be performed, however, if the presentation is atypical, such as proteinuria associated with glomerular hematuria (acanthocytes), absence of retinopathy or neuropathy (in patients with type 1 diabetes), onset of proteinuria less than 5 years from documented onset of diabetes, uncharacteristic change in renal function or renal disease of acute onset, and presence of immunologic abnormalities.

Serologic testing for antineutrophil cytoplasmic antibody (ANCA) and for anti–glomerular basement membrane antibodies has allowed a confident diagnosis of renal small-vessel vasculitis or Goodpasture disease without invasive measures in most patients. Nonetheless, a renal biopsy should still be performed to confirm the diagnosis and to clarify the extent of active inflammation versus chronic fibrosis and thus the potential for recovery. This information may be important in helping to decide whether to initiate or continue immunosuppressive therapy, particularly in patients who may tolerate immunosuppression poorly.

Lupus nephritis can usually be diagnosed by noninvasive criteria such as autoantibodies, urine protein excretion, renal function, and urine sediment abnormalities. Some experts argue that this information can be used to gauge the severity of renal involvement and to inform decisions about initial immunosuppressive treatment. However, a renal biopsy will clarify the underlying pathologic lesion, level of acute activity, and extent of chronic fibrosis, thereby providing robust guidance for evidence-based therapy.

The diagnosis of viral infection–related nephropathy (e.g., hepatitis B virus–associated membranous nephropathy) is suggested by the presence of the expected glomerular lesion in association with evidence of active viral infection. However, the identification of virus-specific protein or DNA or RNA in the renal biopsy tissue by immunopathologic and molecular pathologic techniques (e.g., *in situ* hybridization) can ensure the diagnosis.

Other systemic diseases, such as amyloidosis, sarcoidosis, and myeloma, can be diagnosed with renal biopsy. However, because these diagnoses can often be made by other investigative approaches,

Indications for Renal Biopsy

Nephrotic Syndrome

Routinely indicated in adults

In prepubertal children, indicated only if clinical features atypical of minimal change disease

Acute Kidney Injury

Indicated if obstruction, reduced renal perfusion, and acute tubular necrosis have been ruled out

Systemic Disease with Renal Dysfunction

Indicated in patients with small-vessel vasculitis, anti–glomerular basement membrane disease, and systemic lupus

Indicated in patients with diabetes only if atypical features present

Non-nephrotic Proteinuria

May be indicated if proteinuria >1 g/24 h

Isolated Microscopic Hematuria

Indicated only in unusual circumstances

Unexplained Chronic Kidney Disease

May be diagnostic (e.g., identify IgA nephropathy even in "end-stage kidney")

Familial Renal Disease

Biopsy of one affected member may give diagnosis and minimize further investigation of family members

Renal Transplant Dysfunction

Indicated if ureteral obstruction, urinary sepsis, renal artery stenosis, and toxic calcineurin inhibitor levels are not present

Box 6-1 Indications for renal biopsy

a renal biopsy is indicated only if the diagnosis remains uncertain or if knowledge of renal involvement would change management.

Renal Transplant Dysfunction

Renal allograft dysfunction in the absence of ureteral obstruction, urinary sepsis, renal artery stenosis, or toxic levels of calcineurin inhibitors requires a renal biopsy to determine the cause. In the early post-transplantation period, this is most useful in differentiating acute rejection from ATN and the increasingly prevalent BK virus nephropathy. Later, renal biopsy can differentiate late acute rejection from chronic allograft nephropathy, recurrent or *de novo* glomerulonephritis (GN), and calcineurin inhibitor toxicity. The accessible location of the renal transplant in the iliac fossa facilitates biopsy of the allograft and allows repeated biopsies when indicated. This has encouraged many units to adopt a policy of *protocol* (surveillance) biopsies to detect subclinical acute rejection and renal scarring and to guide the choice of immunosuppressive therapy (see Chapter 104).

Non-nephrotic Proteinuria

The value of renal biopsy in patients with non-nephrotic proteinuria is debatable. All conditions that result in nephrotic syndrome can cause non-nephrotic proteinuria, except for MCD. However, the benefit of specific treatment with corticosteroids and other immunosuppressive agents in these patients probably does not justify the risk of significant drug-related side effects. In patients with proteinuria of more than 1 g/day, generic treatment with strict blood pressure control and angiotensin-converting enzyme (ACE) inhibitors and angiotensin receptor blockers (ARBs) alone or in combination reduces proteinuria and reduces the risk for development of progressive renal dysfunction (see Chapter 80). Nonetheless, although the renal biopsy may not lead to an immediate change in management, it can be justified in these circumstances because it will provide prognostic information, may identify a disease for which a different therapeutic approach is indicated, and may provide clinically important information about the future risk of disease recurrence after renal transplantation.

Isolated Microhematuria

Patients with microhematuria should initially be evaluated to identify structural lesions such as renal stones or renal and urothelial malignant neoplasms if they are older than 40 years. The absence of a structural lesion suggests that the hematuria may have a glomerular source. Biopsy studies have identified glomerular lesions in up to 75% of biopsies.[4] In all series, IgA nephropathy has been the most common lesion, followed by thin basement membrane nephropathy. In the absence of nephrotic proteinuria, renal impairment, or hypertension, the prognosis for patients with these conditions is excellent, and because specific therapies are not available, renal biopsy is not necessary and patients require only follow-up. Biopsy should be performed only if the result would provide reassurance to the patient, avoid repeated urologic investigations, or provide specific information, as in the evaluation of potential living kidney donors, in familial hematuria, or for life insurance and employment purposes.

Unexplained Chronic Kidney Disease

Renal biopsy can be informative in the patient with unexplained chronic renal impairment and normal-sized kidneys, because in contrast to AKI, it is often difficult to determine the underlying cause with clinical criteria alone. Studies have shown that in these patients with CKD, the biopsy will demonstrate disease that was not predicted in almost half.[5] However, if both kidneys are small (<9 cm on ultrasound), the risks of biopsy are increased, and the diagnostic information may be limited by extensive glomerulosclerosis and tubulointerstitial fibrosis. In this setting, however, immunofluorescence studies may still be informative. For example, glomerular IgA deposition may be identified despite advanced structural damage.

Familial Renal Disease

A renal biopsy can be helpful in the investigation of patients with a family history of renal disease. A biopsy performed in one affected family member may secure the diagnosis for the whole family and avoid the need for repeat investigation. Conversely, a renal biopsy may unexpectedly identify disease that has an inherited basis, thereby stimulating evaluation of other family members.

Role of Repeat Renal Biopsy

In some patients, a repeat biopsy may be indicated. For example, the pathologic changes in lupus nephritis may evolve, necessitating treatment adjustment. Also, corticosteroid-resistant/dependent MCD or frequently relapsing MCD may actually represent a missed diagnosis of focal segmental glomerulosclerosis (FSGS), which may be detected on repeat biopsy. Some nephrologists believe that repeat biopsy in patients who have had aggressive immunosuppressive therapy of crescentic GN can help determine the most appropriate next line of therapy.

VALUE OF RENAL BIOPSY

Biopsy Adequacy

In the assessment of a renal biopsy, the number of glomeruli in the sample is the major determinant of whether the biopsy will be diagnostically informative.

For a focal disease such as FSGS, the diagnosis could be made on a biopsy specimen containing a single glomerulus that contains a typical sclerosing lesion. However, the probability that FSGS is not present in a patient with nephrotic syndrome and minimal changes on the biopsy specimen depends on the actual proportion of abnormal glomeruli in the kidney and the number of glomeruli obtained in the biopsy specimen. For example, if 20% of glomeruli in the kidney have sclerosing lesions and five glomeruli are sampled, there is a 35% chance that all the glomeruli in the biopsy specimen will be normal and that the biopsy will miss the diagnosis. By contrast, in the same kidney, if 10 or 20 glomeruli are sampled, the chance of obtaining all normal glomeruli is reduced to 10% and less than 1%, respectively, and the biopsy is more discriminating. This argument assumes that any segmental lesions present in the biopsy specimen are actually identified; this requires the biopsy specimen to be sectioned at multiple levels.

Unless all glomeruli are affected equally, the probability that the observed involvement in the biopsy specimen accurately reflects true involvement in the kidney depends not only on the number of glomeruli sampled but also on the proportion of affected glomeruli. For example, in a biopsy specimen containing 10 glomeruli, of which three are abnormal (30%), there is a 95% probability that the actual glomerular involvement is between 7% and 65%. In the same kidney, if the biopsy specimen contained 30 glomeruli with 30% being abnormal, the 95% confidence intervals are narrowed to 15% and 50%.

Therefore the interpretation of the biopsy needs to take into account the number of glomeruli obtained. A typical biopsy sample will contain 10 to 15 glomeruli and will be diagnostically useful. Nonetheless, it must be appreciated that because of the sampling issue, a biopsy sample of this size will occasionally be unable to diagnose focal diseases and at best will provide imprecise guidance on the extent of glomerular involvement.

An adequate biopsy should also provide samples for immunohistology and electron microscopy (EM). Immunohistology is provided by either immunofluorescence on frozen material or immunoperoxidase on fixed tissue, according to local protocols and expertise. It is helpful for the biopsy cores to be viewed under an operating microscope immediately after being taken to ensure that they contain cortex and that when the cores are divided, the immunohistology and EM samples both contain glomeruli.

If the material obtained for a complete pathologic evaluation is insufficient, a discussion with the pathologist should address how best to proceed before the tissue is placed in fixative, so that the material can be processed in a way that will provide maximum information for the specific clinical scenario. For example, if the patient has heavy proteinuria, most information will be gained from EM because it is able to demonstrate podocyte foot process effacement, focal sclerosis, electron-dense deposits of immune complexes, and the organized deposits of amyloid.

If a sample is supplied for immunofluorescence microscopy but contains no glomeruli, it may be possible to reprocess the paraffin-embedded sample to identify immune deposits by immunoperoxidase or immunofluorescence techniques.

Is Renal Biopsy a Necessary Investigation?

The role of the renal biopsy has been much debated. Early studies suggested that renal biopsy provided diagnostic clarity in the majority of patients, but that this information did not alter management, with the exception of those with heavy proteinuria or systemic disease. More recent prospective studies have suggested that the renal biopsy identifies a diagnosis different from that predicted on clinical grounds in 50% to 60% of patients and leads to a treatment change in 20% to 50%.[6] This is particularly apparent in patients with heavy proteinuria or AKI, more than 80% of whom have biopsy findings that alter their management.[7]

PREBIOPSY EVALUATION

The prebiopsy evaluation identifies issues that may compromise the safety and success of the procedure (Fig. 6-1). It will determine

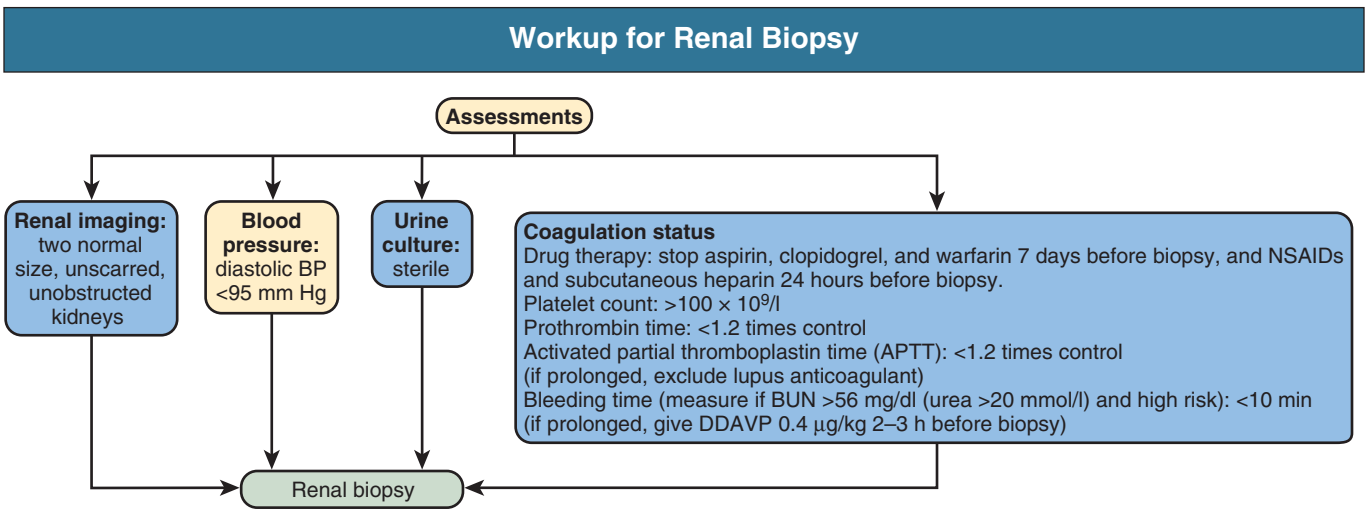

Figure 6-1 Workup for renal biopsy. *NSAID,* Nonsteroidal anti-inflammatory drug; *BUN,* blood urea nitrogen; *DDAVP,* desmopressin.

whether the patient has two normal-sized unobstructed kidneys, sterile urine, controlled blood pressure, and no bleeding diathesis. A thorough history should be taken to identify evidence of a bleeding diathesis, such as previous prolonged surgical bleeding, spontaneous bleeding, family history of bleeding, and ingestion of medication that increases bleeding risk, including antiplatelet agents and warfarin.

An ultrasound scan should be performed to assess kidney size and to identify significant anatomic abnormalities, such as solitary kidney, polycystic or simple cystic kidneys, malpositioned kidneys, horseshoe kidneys, small kidneys, and hydronephrosis.

The value of the *bleeding time* in patients undergoing renal biopsy is controversial. The predictive value of the bleeding time for postrenal biopsy bleeding has never been prospectively tested. Retrospective studies, however, demonstrated a threefold to fivefold increase in bleeding complications after renal biopsy in patients with prolonged bleeding time. Prospective studies of percutaneous liver biopsy patients showed a fivefold increase in bleeding complications in those with uncorrected bleeding times.[8] A consensus document concluded that the bleeding time is a poor predictor of postsurgical bleeding, but it does correlate with clinical bleeding episodes in uremic patients.[9]

Several approaches to the management of bleeding risk have been adopted. First, all subjects undergoing biopsy should discontinue any agent that can prolong bleeding, including aspirin (7 days before biopsy), clopidogrel (7 days), warfarin (7 days), nonsteroidal anti-inflammatory drugs (NSAIDs; 24 hours), and subcutaneous heparin (24 hours). Many centers measure the prebiopsy bleeding time and administer 1-desamino-8-D-arginine vasopressin (desmopressin, DDAVP; 0.4 µg/kg intravenously 2 to 3 hours before biopsy) if the bleeding time is prolonged beyond 10 minutes. Another method no longer measures the bleeding time but routinely administers DDAVP to patients with significant renal impairment (blood urea nitrogen level >56 mg/dl [urea >20 mmol/l] or serum creatinine concentration >3 mg/dl [250 µmol/l]). Platelet transfusion can also be used to reverse clopidogrel-induced platelet dysfunction when the renal biopsy is urgent.

The routine use of desmopressin in low-risk patients (estimated GFR > 60 ml/min; blood pressure <140/90 mm Hg; normal coagulation parameters) has been shown to reduce the risk of hematoma formation after biopsy compared with placebo (13.7% vs. 30.5%, respectively).[10] The hematomas were clinically silent, however, and no patient in either group had macrohematuria or required a transfusion. The study was also unable to determine the risks related to DDAVP (thrombosis or hyponatremia). Therefore use of DDAVP prophylaxis in all patients undergoing renal biopsy cannot be recommended.

The use of thromboelastography (TEG) has been described in the patient undergoing renal transplant biopsy.[11] TEG provides an overall measure of the coagulation, platelet, and fibrinolytic systems in one assay and thus may be more predictive of clinical bleeding. In this study, most bleeding episodes were associated with normal clotting test results, but TEG was the only assay associated with an increased risk of postbiopsy bleeding. The role of TEG in the patient undergoing native kidney biopsy requires further evaluation.

Contraindications to Renal Biopsy

The contraindications to percutaneous renal biopsy are listed in Table 6-1. The major contraindication is a bleeding diathesis. If the disorder cannot be corrected and the biopsy is deemed indispensable, alternative approaches can be used, such as open biopsy, laparoscopic biopsy, or transvenous (usually transjugular) biopsy.

Contraindications to Renal Biopsy

Kidney Status	Patient Status
Multiple cysts	Uncontrolled bleeding diathesis
Solitary kidney	Uncontrolled blood pressure
Acute pyelonephritis	Uremia
Perinephric abscess	Obesity
Renal neoplasm	Uncooperative patient

Table 6-1 Contraindications to renal biopsy. Most contraindications are relative rather than absolute. Clinical circumstances that necessitate urgent renal biopsy may be overridden, except for uncontrolled bleeding diathesis.

Inability of the patient to comply with instructions during renal biopsy is another major contraindication. Sedation or, in extreme cases, general anesthesia may be necessary.

Hypertension (>160/95 mm Hg), hypotension, perinephric abscess, pyelonephritis, hydronephrosis, severe anemia, large renal tumors, and cysts are relative contraindications to renal biopsy. When possible, these should be corrected before the biopsy is undertaken.

The presence of a solitary functioning kidney has been considered a contraindication to percutaneous biopsy, and some argue that the risk of biopsy is reduced by direct visualization at open biopsy. However, the postbiopsy nephrectomy rate of 1/2000 to 1/5000 is comparable to the mortality rate associated with the general anesthetic required for an open procedure. Therefore, in the absence of risk factors for bleeding, percutaneous biopsy of a solitary functioning kidney can be justified.

RENAL BIOPSY TECHNIQUE

Percutaneous Renal Biopsy

Native Renal Biopsy

At our centers, the kidney biopsy is performed by nephrologists with continuous (real-time) ultrasound guidance and disposable automated biopsy needles. We use 16-gauge needles as a compromise between the greater tissue yield of larger needles and the trend toward fewer bleeding complications of smaller needles. For most patients, premedication or sedation is not required. The patient is prone, and a pillow is placed under the abdomen at the level of the umbilicus to straighten the lumbar spine and to splint the kidneys. Figure 6-2 shows the anatomic relationships of the left kidney. Ultrasound is used to localize the lower pole of the kidney where the biopsy will be performed (usually the left kidney). An indelible pen mark is used to indicate the point of entry of the biopsy needle. The skin is sterilized with povidone-iodine (Betadine) or chlorhexidine solution. A sterile fenestrated sheet is placed over the area to maintain a sterile field. Local anesthetic (2% lidocaine [lignocaine]) is infiltrated into the skin at the point previously marked.

While the anesthetic takes effect, the ultrasound probe is covered in a sterile sheath. Sterile ultrasound jelly is applied to the skin, and under ultrasound guidance, a 10-cm, 21-gauge needle is guided to the renal capsule and further local anesthetic infiltrated into the perirenal tissues, then along the track of the needle on withdrawal. A stab incision is made through the dermis to ease passage of the biopsy needle. This is passed under ultrasound guidance to the kidney capsule (Fig. 6-3). As the needle approaches the capsule, the patient is instructed to take a breath until the kidney is moved to a position such that the lower pole rests just under the biopsy needle, and then to stop breathing. The biopsy needle tip is advanced to the renal capsule, and the trigger mechanism is released, firing the

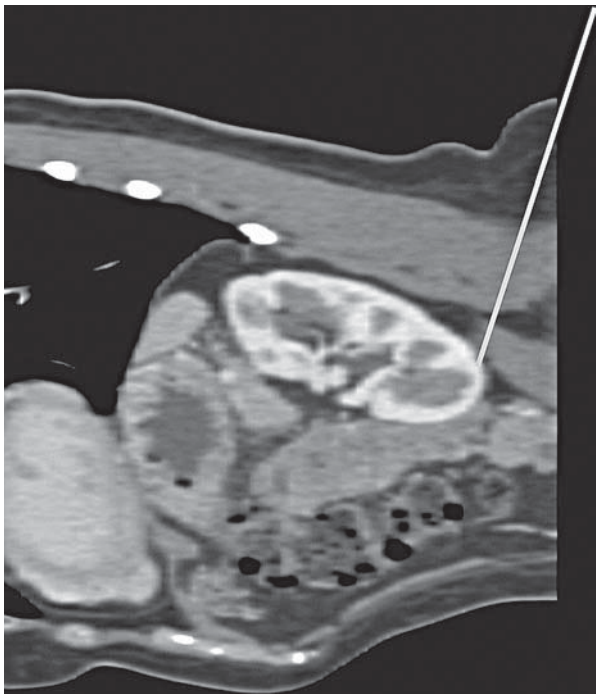

Figure 6-2 Computed tomography through the left kidney. The angle of approach of the needle is demonstrated. Note the relative adjacency of the lower pole of the kidney to other structures, particularly the large bowel.

Figure 6-3 Renal biopsy procedure. The biopsy needle is introduced at an angle of approximately 70 degrees to the skin and is guided by continuous ultrasound. The operator is shown wearing a surgical gown. This is not strictly necessary; sterile gloves and maintenance of a sterile field are sufficient.

needle into the kidney (Fig. 6-4). The needle is immediately withdrawn, the patient is asked to resume breathing, and the contents of the needle are examined (Fig. 6-5). We examined the tissue core under an operating microscope to ensure that renal cortex has been obtained (Fig. 6-6). A second pass of the needle is usually necessary to obtain additional tissue for immunohistology and EM. If insufficient tissue is obtained, further passes of the needle are made. In our experience, however, passing the needle more than four times is associated with a modest increase in the postbiopsy complication rate.

Once sufficient renal tissue has been obtained, the skin incision is dressed and the patient rolled directly into bed for observation.

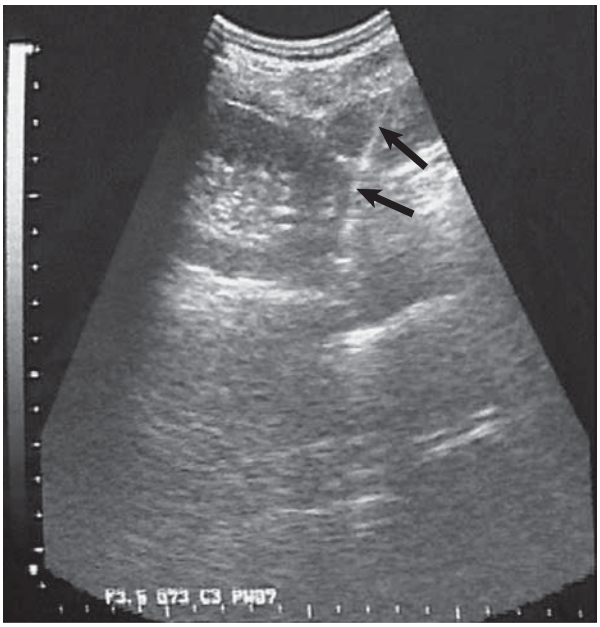

Figure 6-4 Renal biopsy imaging. Ultrasound scan shows the needle entering the lower pole of the left kidney. *Arrows* indicate the needle track, which appears as a fuzzy white line.

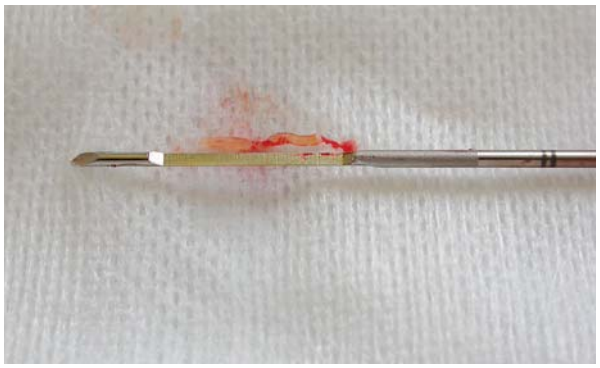

Figure 6-5 Renal biopsy sample. A core of renal tissue is demonstrated in the sampling notch of the biopsy needle.

No single fixative has been developed that allows good-quality light microscopy, immunofluorescence, and EM to be performed on the same sample. Therefore, the renal tissue is often divided into three samples and placed in formalin for light microscopy, normal saline for subsequent snap-freezing in liquid nitrogen for immunofluorescence, and glutaraldehyde for EM. Some centers are able to produce satisfactory light microscopy, immunohistochemistry, and EM on formalin-fixed biopsy material, although this depends on the expertise of individual laboratories.

The percutaneous renal biopsy technique has several variations. Whereas the majority of biopsies are guided by ultrasound, some operators choose to use it only to localize the kidney and to determine the depth and angle of approach of the needle, then performing the biopsy without further ultrasound guidance. The success and complication rates appear to be no different from those seen with continuous ultrasound guidance. For technically challenging biopsies, computed tomography can be used to guide the biopsy needle.

For obese patients and patients with respiratory conditions who find the prone position difficult, the supine anterolateral approach has recently been described.[12] Patients lie supine with the flank on the side to be sampled elevated by 30 degrees with towels under the

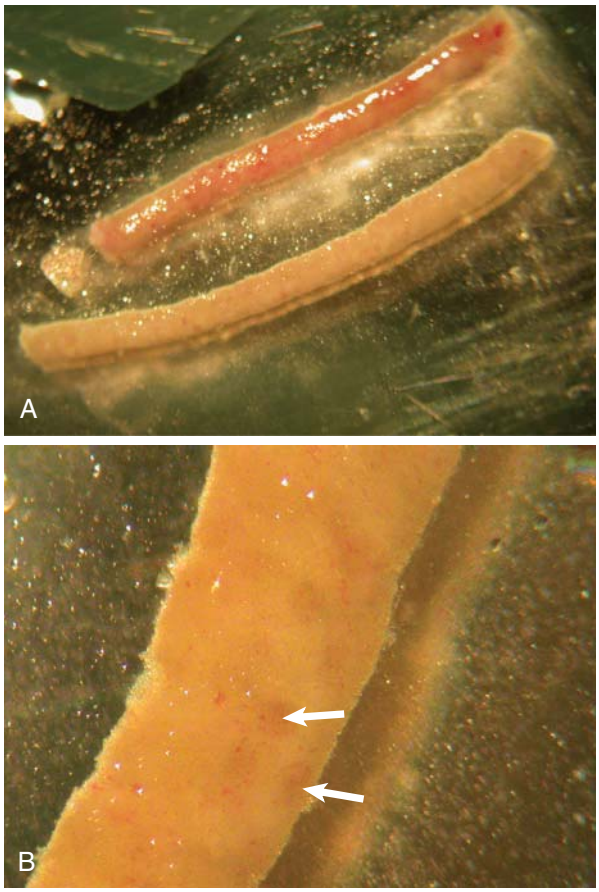

Figure 6-6 Renal biopsy micrographs. Appearance of renal biopsy material under the operating microscope. **A,** Low-power view shows two good-sized cores. **B,** Higher-magnification view shows the typical appearance of glomeruli *(arrows)*.

shoulder and buttocks. The biopsy needle is inserted through the Petit (inferior lumbar) triangle, bounded by the latissimus dorsi muscle, 12th rib, and iliac crest. This technique provides good access to the lower pole of the kidney, is better tolerated than the prone position by these patients, and has a diagnostic yield and safety profile comparable to the standard technique for native renal biopsy.

Renal Transplant Biopsy

Biopsy of the transplant kidney is facilitated by the proximity of the kidney to the anterior abdominal wall and the lack of movement on respiration. It is performed under real-time ultrasound guidance with use of an automated biopsy needle. In most patients, the renal transplant biopsy is performed to identify the cause of acute allograft dysfunction. In these circumstances, the goal is to identify acute rejection, and therefore the diagnosis can be made on a formalin-fixed sample alone for light microscopy. If vascular rejection is suspected, a snap-frozen sample for C4d immunostaining should also be obtained (although some laboratories are able to detect C4d on formalin-fixed material). If recurrent or *de novo* GN is suspected in patients with chronic allograft dysfunction, additional samples for EM and immunohistology should be collected.

Postbiopsy Monitoring

After the biopsy, the patient is placed supine and subjected to strict bed rest for 6 to 8 hours. The blood pressure is monitored frequently, the urine examined for visible hematuria, and the skin puncture site examined for excessive bleeding. If there is no evidence of bleeding after 6 hours, the patient is sat up in bed and subsequently allowed to move. If visible hematuria develops, bed rest is continued until the bleeding settles.

Conventionally, patients have been observed for complications in the hospital for 24 hours after biopsy. However, outpatient (day-case) renal biopsy with same-day discharge after 6 to 8 hours of observation has become increasingly popular for both native and renal transplant biopsies. Largely driven by financial and resource implications of overnight hospital admission, this has been justified by the perception that the significant complications of renal biopsy will become apparent during this shortened period of observation. This view has been challenged by a study of 750 native renal biopsies, which showed that only 67% of major complications, defined as those that either required a blood transfusion or an invasive procedure or resulted in urinary tract obstruction, septicemia, or death, were apparent by 8 hours after biopsy.[13] These authors concluded that the widespread application of an early discharge policy after renal biopsy is not in the patient's best interest, and that a 24-hour observation period is preferable.

In Leicester, approximately half of renal biopsies are outpatient procedures. The patient population is selected to avoid those with the highest risk of complications, including impaired renal function (estimated GFR <30 ml/min), small kidneys, and uncontrolled hypertension. In addition, we require that the patient not be alone at home for at least one night after the biopsy. This selection policy has proved to be safe. Of 429 outpatient biopsies performed in our unit, 6% developed a self-limited postbiopsy complication within 6 hours that required a short hospital admission. Five patients returned after same-day discharge with biopsy-related complications, one with visible hematuria at 24 hours and four with loin pain between 3 and 5 days after biopsy. All patients recovered with conservative management. We believe that outpatient renal biopsy is acceptably safe when a low-risk patient group is selected.

A study investigated whether ultrasound 1 hour after biopsy is able to predict bleeding complications.[14] The absence of hematoma was predictive of an uncomplicated course, but the identification of hematoma was not reliably predictive of a significant biopsy complication; identification of hematoma at 1 hour had a 95% negative predictive value and 43% positive predictive value. The role of this imaging in the wider clinical setting remains to be determined given the additional expense of routine postbiopsy ultrasound.

Alternatives to the Percutaneous Approach

When the percutaneous approach is contraindicated, other approaches to renal biopsy have been described. The choice of technique depends on the safety, morbidity, recovery period, and adequacy of the technique, but mainly on the local expertise available.

Transvenous (Transjugular or Transfemoral) Renal Biopsy

Transvenous sampling of the kidney is theoretically safer than the percutaneous approach because the needle passes from the venous system into the renal parenchyma and is directed away from large blood vessels. In addition, any bleeding that occurs should be directed back into the venous system, and if capsular perforation develops, significant bleeding points can be immediately identified and controlled by coil embolization. Others argue that coil embolization of the punctured vein is unhelpful because significant bleeding into a perirenal hematoma or the urine indicates an arterial breach that requires selective angiography and arterial embolization.

Transvenous renal biopsy cannot be regarded as routine because it involves specialist skills and additional time and expense compared with the percutaneous approach. The main indication for this approach is an uncontrollable bleeding diathesis. It has also been advocated for patients receiving artificial ventilation in the intensive care unit; the need to obtain tissue from more than one organ, including the kidney, liver, or heart; large-volume ascites that precludes the prone position; uncontrolled hypertension; morbid obesity; severe respiratory insufficiency; solitary kidney; failed percutaneous approach; and coma.

The patient lies supine, and the right internal jugular vein is cannulated. A guidewire is passed into the inferior vena cava (IVC), and a catheter is passed over the guidewire and selectively into the right renal vein, which is shorter and enters the IVC at a more favorable angle than the left renal vein. A sheath is passed over the catheter to a suitable peripheral location in the kidney with the aid of contrast enhancement. Finally, the biopsy device (usually a side-cut biopsy needle system) is passed through the sheath and samples are taken. Contrast is then injected into the biopsy track to identify capsular perforation, and embolization coils are inserted if brisk bleeding is identified.

The quality of renal tissue obtained by transjugular biopsy is variable, although studies report diagnostic yields of more than 90%.[15] The complication rate appears comparable to that seen with percutaneous renal biopsy, which is reassuring given that these are high-risk patients.

Open Renal Biopsy

Open renal biopsy has been established as a safe alternative to percutaneous biopsy when uncorrectable contraindications exist. In a series of 934 patients, tissue adequacy was 100% with no major complications.[16] This is an effective approach with minimal postprocedure complications, but the risk of general anesthesia and the delayed recovery time have prevented its widespread adoption. Open biopsy may still be performed, however, when a renal biopsy is required in patients who are otherwise undergoing abdominal surgery.

Laparoscopic Renal Biopsy

Laparoscopic renal biopsy requires general anesthesia and two laparoscopic ports in the posterior and anterior axillary lines to gain access to the retroperitoneal space. Laparoscopic biopsy forceps are used to obtain cortical biopsy samples, and the biopsy sites are coagulated with laser and packed to prevent hemorrhage. In the largest study of laparoscopic renal biopsy, adequate tissue was obtained in 96% of 74 patients.[17] Significant bleeding occurred in three patients, the colon was injured in one, and a biopsy was performed inadvertently on the spleen and liver, respectively, in two others. Inadvertent biopsy was subsequently averted by the use of intraoperative ultrasound to define the anatomy in difficult cases.

COMPLICATIONS OF RENAL BIOPSY

The complication rates compiled from large series of renal biopsies are shown in Table 6-2.

Complications of Renal Biopsy

Complication	Percentage
Visible hematuria	3.5%
Need for blood transfusion	0.9%
Need for intervention to control bleeding	0.7% (0.6% angiographic; 0.1% surgical)
Death	0.02%

Table 6-2 Complications in 9474 native kidney biopsies. *(Data from reference 19.)*

Pain

Patients should be informed about the inevitable dull ache around the needle entry site when the local anesthetic wears off after renal biopsy. Simple analgesia with acetaminophen (paracetamol) or acetaminophen-codeine combinations usually suffices. More severe pain in the loin or abdomen on the side of the biopsy suggests significant perirenal hemorrhage. Opiates may be necessary for pain relief, with appropriate investigation to clarify the severity of the bleed. Patients with visible hematuria may develop clot colic and describe the typical severe pain associated with ureteral obstruction.

Hemorrhage

A degree of perirenal bleeding accompanies every renal biopsy. The mean decrease in hemoglobin after a biopsy is approximately 1 g/dl.[18] Significant perirenal hematomas are almost invariably associated with severe loin pain. Both visible hematuria and painful hematoma are seen in 3% to 4% of patients after biopsy. The initial management is strict bed rest and maintenance of normal coagulation indices. If bleeding is brisk and associated with hypotension or prolonged and fails to settle with bed rest, renal angiography should be performed to identify the source of bleeding. Coil embolization can be performed during the same procedure, and this has largely eliminated the need for open surgical intervention and nephrectomy.

Arteriovenous Fistula

Most postbiopsy arteriovenous fistulas are detected by Doppler ultrasound or contrast-enhanced computed tomography and, when looked for specifically, can be found in as many as 18% of patients. Because most are clinically silent and more than 95% resolve spontaneously within 2 years, fistulas should not be routinely sought. In a small minority of patients, arteriovenous fistulas can lead to visible hematuria (typically recurrent, dark red, and often with blood clots), hypertension, and renal impairment, which requires embolization.

Other Complications

A variety of rare complications of renal biopsy have been reported, including biopsy performed on other organs (liver, spleen, pancreas, bowel, gallbladder), pneumothorax, hemothorax, calyceal-peritoneal fistula, dispersion of carcinoma, and *Page kidney* (compression of kidney by perirenal hematoma leading to renin-mediated hypertension).

Death

Death resulting directly from renal biopsy has become much less common according to recent biopsy series compared with earlier reports. Most deaths are the result of uncontrolled hemorrhage in high-risk patients, particularly those with severe renal impairment.

SECTION III

Fluid and Electrolyte Disorders

CHAPTER 7

Disorders of Extracellular Volume

Elwaleed A. Elhassan and Robert W. Schrier

EXTRACELLULAR FLUID COMPARTMENT

Water is the predominant constituent of the human body. In healthy individuals, it makes up 60% of a man's body weight and 50% of a woman's body weight. Body water is distributed in two compartments: the intracellular fluid (ICF) compartment, containing 55% to 65% of body water, and the extracellular fluid (ECF) compartment, containing the remaining 35% to 45%. The ECF is further subdivided into two spaces: the *interstitial* space accounts for about three fourths of ECF, and the *intravascular* space represents the remaining fourth (Table 7-1).

Total body water diffuses freely between the intracellular space and the extracellular spaces in response to solute concentration gradients. Therefore the amount of water in different compartments depends entirely on the quantity of solute in that compartment. The major solute in the ECF is sodium ion (Na^+), and the major intracellular solute is potassium ion (K^+). The maintenance of this distribution is fulfilled by active transport through the Na^+,K^+–adenosine triphosphate (ATP)–dependent pumps on the cell membrane, and this determines the relative volume of different compartments. Because sodium is the predominant extracellular solute, the ECF is determined primarily by the sodium content of the body and the mechanisms responsible for its maintenance. The amount of sodium is therefore tightly regulated by modulation of renal retention and renal excretion in situations of deficient and excess ECF, respectively.

Fluid movement between the intravascular and interstitial spaces of the ECF occurs across the capillary wall and is governed by Starling forces, namely, the capillary hydrostatic pressure and colloid osmotic pressure. The transcapillary hydrostatic pressure gradient exceeds the corresponding oncotic pressure gradient, thereby favoring movement of plasma ultrafiltrate into the extravascular compartment. The return of fluid into the intravascular compartment occurs through lymphatic flow.

Maintaining the ECF volume determines the adequacy of the circulation and in turn the adequacy of delivery of oxygen, nutrients, and other substances needed for organ functions as well as removal of waste products. This is achieved despite day-to-day variations in the intake of sodium and water, with the ECF volume varying by only 1% to 2%.

The term *effective arterial blood volume* is used to describe the blood volume detected by the sensitive arterial baroreceptors in the arterial circulation. The effective arterial blood volume (EABV) can change independently of the total ECF volume. EABV can explain the sodium and water retention in different clinical situations (see later discussion).

REGULATION OF EXTRACELLULAR FLUID HOMEOSTASIS

Circulatory stability depends on a meticulous degree of ECF homeostasis. The operative homeostatic mechanisms include an *afferent* sensing limb, comprising several volume and stretch detectors distributed throughout the vascular bed, and an *efferent* effector limb. Adjustments in the effector mechanisms occur in response to afferent stimuli by sensing-limb detectors, to modify circulatory parameters. Disorders of either sensing mechanisms or effector mechanisms can lead to failure of adjustment of sodium handling by the kidney, with resultant hypertension or edema formation in the patient with positive sodium balance, or hypotension and hypovolemia in the patient with negative sodium balance.

Afferent (Sensor) Limb

Afferent limb (sensing) sites include low-pressure cardiopulmonary receptors (atrial, ventricular, and pulmonary stretch receptors), high-pressure arterial baroreceptors (carotid, aortic arch, and renal sensors), central nervous system (CNS) receptors, and hepatic receptors (Table 7-2). The cardiac atria possess the distensibility and the compliance needed to monitor changes in intrathoracic venous volume. An increase in left atrial pressure suppresses the release of antidiuretic hormone (ADH), also called arginine vasopressin (AVP). Atrial distention and a sodium load cause release into the circulation of atrial natriuretic peptide (ANP), a polypeptide normally stored in secretory granules within atrial myocytes. The closely related brain natriuretic peptide (BNP) is stored primarily in ventricular myocardium and is released when ventricular diastolic pressure rises. The atrial-renal reflexes enhance renal sodium and water excretion on sensing of a distended left atrium.

The sensitive arterial stretch receptors in the carotid artery, aortic arch, and glomerular afferent arteriole respond to a decrease in arterial pressure. Information from these nerve endings is carried by the vagal and glossopharyngeal nerves to vasomotor centers in the medulla and brainstem. In the normal situation, the prevailing discharge from these receptors exerts a tonic restraining effect on the heart and circulation by inhibiting the sympathetic outflow and augmenting parasympathetic activity. In addition, changes in transmural pressure across the arterial vessels and the atria also influence the secretion of AVP and renin and the release of ANP. Activation of the arterial receptors signals the kidney to retain sodium and water by increases in the sympathetic activity and by increases in vasopressin release. Stimulation of the sympathetic nervous system also enhances the renin-angiotensin-aldosterone system (RAAS). A rise in arterial

Total Body Water for 70 kg Man (60% or 42 Liters)

Table 7-1 Composition of body fluid compartments. The table indicates the relative size of the compartments and their approximate absolute volume (in liters) in a 70-kg adult. Electrolyte concentrations are shown in milimoles per liter.

Major Mechanisms in Extracellular Fluid Homeostasis	
Afferent (Sensing)	**Efferent (Effector)**
Cardiopulmonary receptors	Renal-angiotensin-aldosterone system (RAAS)
Atrial	Prostaglandins
Ventricular	Arginine vasopressin (AVP)
Pulmonary	Natriuretic peptides
High-pressure baroreceptors	Atrial (ANP)
Carotid	Brain (BNP)
Aortic	C-type (CNP)
Renal	Other hormones
Glomerular afferent	Nitric oxide (NO)
Juxtaglomerular apparatus	Endothelin
Central nervous system receptors	Kallikrein-kinin system
Hepatic receptors	

Table 7-2 Homeostatic mechanisms in extracellular fluid (ECF) volume. Adjustments in the effector mechanisms occur in response to afferent stimuli by sensing limb detectors.

pressure elicits the opposite response, resulting in decreased catecholamine release and natriuresis.

Renal sensing mechanisms include the juxtaglomerular apparatus, which is involved in the generation and release of renin from the kidney. Renin secretion is inversely related to perfusion pressure and directly related to intrarenal tissue pressure. Solute delivery to the macula densa is also an important determinant of renin release because of the tubuloglomerular feedback (TGF) mechanism; an increase in chloride passage through the macula densa results in inhibition of renin release, whereas a decrease in concentration results in enhanced secretion of renin. Renal nerve stimulation through activation of β-adrenergic receptors of the juxtaglomerular apparatus cells directly stimulates renin release. Other receptors reside in the CNS and hepatic circulation but have been less well defined.

Efferent (Effector) Limb

The stimulation of the effector limb of the ECF volume homeostasis leads to activation of effector mechanisms (Table 7-2). These effector mechanisms aim predominantly at modulation of renal sodium and water excretion to preserve circulatory stability.

Sympathetic Nervous System

Sympathetic nerves that originate in the prevertebral celiac and paravertebral ganglia innervate cells of the afferent and efferent arterioles, juxtaglomerular apparatus, and renal tubule. Sympathetic nerves alter renal sodium and water handling by direct and indirect mechanisms.[2] Increased nerve stimulation indirectly stimulates proximal tubular sodium reabsorption by altering preglomerular and postglomerular arteriolar tone, thereby influencing filtration fraction. Renal nerves directly stimulate proximal tubular fluid reabsorption through receptors on the basolateral membrane of the proximal convoluted tubule cells. These effects on sodium handling are further amplified by the ability of the sympathetic nerves to stimulate renin release, which leads to the formation of angiotensin II (Ang II) and aldosterone.

Renin-Angiotensin-Aldosterone System

Renin formation by the juxtaglomerular apparatus increases in response to the aforementioned ECF homeostatic afferent limb stimuli. Renin converts angiotensinogen to angiotensin I, which is then converted to Ang II by the action of angiotensin-converting enzyme (ACE); Ang II can subsequently affect circulatory stability and volume homeostasis. It is an effective vasoconstrictor and modulator of renal sodium handling mechanisms at multiple nephron sites. Ang II preferentially increases the efferent arteriolar tone and thus affects the glomerular filtration rate (GFR) and filtration fraction by altering Starling forces across the glomerulus, which leads to enhanced proximal sodium and water retention. Ang II also augments sympathetic neurotransmission and enhances the TGF mechanism. In addition to these indirect mechanisms, Ang II directly enhances proximal tubular volume reabsorption by activating apical membrane sodium-hydrogen (Na^+-H^+) exchangers. In addition to a nephron effect, Ang II enhances sodium absorption by stimulating the adrenal gland to secrete aldosterone, which in turn increases sodium reabsorption in the cortical collecting tubule.

Prostaglandins

Prostaglandins are proteins derived from arachidonic acid that modulate renal blood flow and sodium handling. Important renal prostaglandins include PGI_2, which mediates baroreceptor (but not beta-adrenergic) stimulation of renin release. PGE_2 is stimulated by Ang II and has vasodilatory properties. Increased level of Ang II, AVP, and catecholamines stimulates synthesis of prostaglandins, which in turn act to dilate the renal vasculature, to inhibit sodium and water reabsorption, and further to stimulate renin release. By doing so, renal prostaglandins serve to dampen and counterbalance the physiologic effects of the hormones that elicit their production and so maintain renal function. Inhibition of prostaglandins by nonsteroidal anti-inflammatory drugs (NSAIDs) leads to magnification of the effect of vasoconstricting hormones and unchecked sodium and water retention.

Arginine Vasopressin

The polypeptide AVP is synthesized in supraoptic and paraventricular nuclei of the hypothalamus and is secreted by the posterior pituitary gland. Besides osmotic control of AVP release, there is also a nonosmotic regulatory pathway sensitive to EABV.[3] AVP release is suppressed in response to ECF volume overload sensed by increased afferent impulses from arterial baroreceptors and atrial receptors, whereas decreased ECF volume has the opposite effect. AVP release leads to antidiuresis and, in high doses, to systemic vasoconstriction through the V_1 receptors.[4] The antidiuretic action of AVP results from the effect on the principal cell of the collecting duct through activation of the V_2 receptor. AVP increases the synthesis and

provokes the insertion of aquaporin 2 water channels into the luminal membrane, thereby allowing water to be reabsorbed down the favorable osmotic gradient. AVP may also lead to enhanced Na^+ reabsorption and K^+ secretion. AVP appears to have synergistic effects with aldosterone on sodium transport in the cortical collecting duct.[5] AVP stimulates potassium secretion by the distal nephron, and this serves to preserve potassium balance during ECF depletion, when circulating levels of vasopressin are high and tubular delivery of sodium and fluid is reduced.

Natriuretic Peptides

Atrial natriuretic peptide is a polypeptide hormone that stimulates diuresis, natriuresis, and vasorelaxation. ANP is primarily synthesized in the cardiac atria and released in response to a rise in atrial distention. ANP augments sodium and water excretion by increasing the GFR, possibly by dilating the afferent arteriole and constricting the efferent arteriole. Furthermore, it inhibits sodium reabsorption in the cortical collecting tubule and inner medullary collecting duct, reduces renin and aldosterone secretion, and opposes the vasoconstrictive effects of Ang II. BNP is another natriuretic hormone that is produced in the cardiac ventricles. It induces natriuretic, endocrine, and hemodynamic responses similar to those induced by ANP.[6] Circulating levels of ANP and BNP are elevated in congestive heart failure (CHF) and in cirrhosis with ascites, but not to levels sufficient to prevent edema formation. In addition, in those edematous states, there is resistance to the actions of natriuretic peptides.

C-type natriuretic peptide (CNP) is produced by endothelial cells, where it is believed to play a role in the local regulation of vascular tone and blood flow. However, its physiologic significance in the regulation of sodium and water balance in humans is not well defined.

Other Hormones

Other hormones that contribute to renal sodium handling and ECF volume homeostasis include nitric oxide (NO), endothelin, and the kallikrein-kinin system. NO is an endothelium-derived mediator that has been shown to participate in the natriuretic responses to increases in blood pressure or ECF volume expansion, so-called pressure natriuresis. Endothelins are natriuretic factors, and kinins are potent vasodilator peptides; their physiologic roles are not yet fully defined.

EXTRACELLULAR FLUID VOLUME CONTRACTION

Contraction of ECF volume refers to a decrease in ECF volume caused by sodium or water loss exceeding intake. Losses may be renal or extrarenal through the gastrointestinal tract, skin, and lungs or by sequestration in potential spaces in the body (e.g., abdomen, muscle) that are not in hemodynamic equilibrium with the ECF (Table 7-3). The reduction in ECF volume occurs simultaneously from both the interstitial and the intravascular compartment and is determined by whether the volume loss is primarily solute-free water or a combination of sodium and water. The loss of solute-free water has a lesser effect on intravascular volume because of the smaller amount of water present in the ECF compared with the ICF and the free movement of water between fluid compartments.

Major Causes of Extracellular Fluid Volume Depletion

Renal	Extrarenal
Diuretic use	Gastrointestinal losses
Tubular disorders	Vomiting
Genetic	Gastrointestinal suctioning
Bartter and Gitelman syndromes	Diarrhea
Pseudohypoaldosteronism type 1	Ileostomy/colostomy secretions
Acquired tubular disorders	Dermal losses
Acute kidney injury	Sweat
Recovery phase of oliguric kidney injury	Exudative skin disease
Release of urinary tract obstruction	Third-space sequestration
Hormonal and metabolic disturbances	Ascites
Mineralocorticoid deficiency or resistance	Pleural effusion, hydrothorax
Primary adrenal insufficiency (Addison disease)	Intestinal obstruction
Hyporeninemic hypoaldosteronism	Retroperitoneal collection
Diabetes mellitus	Hemorrhage
Chronic interstitial renal diseases	Internal
Solute diuresis	External
Renal water loss	
Diabetes insipidus	

Table 7-3 Major causes of extracellular fluid volume depletion

Extrarenal Causes

Gastrointestinal Losses

Approximately 3 to 6 liters of fluids and digestive juices are secreted daily throughout the gastrointestinal tract, and most of this fluid is reabsorbed. Vomiting or nasogastric suction may cause volume loss that is usually accompanied by metabolic alkalosis, whereas diarrhea may result in volume depletion that is accompanied by metabolic acidosis.

Dermal Losses

Sweat is typically hypotonic, leading to more water loss than salt loss. Sweat production can be excessive in high ambient temperature or with prolonged exercise in hot, humid climates and may lead to volume depletion. Loss of the skin barrier with superficial burns and exudative skin lesions may lead to significant ECF volume depletion.

Third-Space Sequestration

Body fluid accumulation in potential spaces that are not in hemodynamic equilibrium with the ECF compartment can cause volume depletion. This pathologic accumulation, often called third-space sequestration, includes ascites, hydrothorax, and intestinal obstruction, with fluid collecting in the peritoneal cavity, pleural space, and intestines, respectively, and leading to significant ECF volume loss. Severe pancreatitis may result in retroperitoneal fluid collections.

Hemorrhage

Hemorrhage occurring internally (e.g., from bleeding esophageal varices) or externally (e.g., trauma) may lead to significant volume loss.

Renal Losses

In the normal individual, about 25,000 mmol of sodium is filtered every day, and a small amount of that quantity is excreted in the urine. The small quantities of sodium excreted in urine relative to the filtered load depend on intact tubular reabsorptive mechanisms to adjust urinary sodium excretion according to the degree needed to maintain ECF homeostasis. Impairment in the integrity of these sodium reabsorptive mechanisms can result in significant sodium deficit and volume depletion.

Diuretic Use

Most of the widely used diuretic medications inhibit specific sites for sodium reabsorption at different segments of the nephron. Diuretics may cause renal sodium wasting, volume contraction, and metabolic acid-base disturbances if abused or inappropriately prescribed. Ingestion of osmotic diuretics results in obligatory renal sodium and water loss, as discussed in detail later.

Genetic and Acquired Tubular Disorders

Tubular sodium reabsorption may be disrupted in several genetic disorders that include Bartter syndrome and Gitelman syndrome (see Chapter 49). These autosomal recessive disorders are caused by mutations of sodium transporters that are targets of diuretics or other transporters that are their essential cellular partners. Both syndromes result in sodium wasting, volume contraction, and hypokalemic metabolic alkalosis.[7] The tubular defect in Bartter syndrome resembles that of chronic ingestion of loop diuretics. Five variants result from a defect in any of several genes that direct the functioning of transporters in the thick ascending limb of Henle loop. Gitelman syndrome, which is more common in adults, is caused by a defect of sodium chloride (NaCl, salt) reabsorption in the distal tubule. It resembles chronic thiazide diuretic ingestion. Pseudohypoaldosteronism type 1 (PHA1) is a rare inherited disorder characterized by renal sodium wasting and hyperkalemic metabolic acidosis. Acquired tubular disorders that may be accompanied by salt wasting include acute kidney injury (AKI), during the recovery phase of oliguric AKI or urinary obstruction (see Chapters 60 and 71).

Hormonal and Metabolic Disturbances

Mineralocorticoid deficiency and resistance states often lead to sodium wasting. This may occur in the setting of primary adrenal insufficiency (Addison disease) and PHA1. Salt wasting can also be seen in chronic tubular and interstitial renal diseases. Severe hyperglycemia or high levels of blood urea during release of urinary tract obstruction can lead to obligatory renal sodium and water loss secondary to glucosuria or urea diuresis, respectively.

Renal Water Loss

Diabetes insipidus (DI) represents a spectrum of diseases resulting from AVP deficiency, causing *central* DI, or tubular resistance, causing *nephrogenic* DI, to the actions of AVP. The most common causes of polyuria from nephrogenic DI in adults are chronic lithium ingestion, hypercalcemia, and less frequently, hypokalemia (see Chapter 8). In these disorders the tubular reabsorption of solute-free water is impaired. This generally results in a lesser effect on ECF volume because, in contrast to sodium, there is a relatively smaller amount of the total body water in the ECF compartment compared with the ICF compartment.

Clinical Manifestations

The spectrum of the clinical manifestations of volume contraction depends on the amount and rate of ECF volume loss as well as on the vascular and renal responses to that loss. An adequate history and physical examination are crucial to elucidate the cause of hypovolemia. Symptoms are usually nonspecific and can range from mild postural symptoms, thirst, muscle cramps, and weakness to drowsiness and disturbed mentation with profound volume loss. Physical examination may reveal tachycardia, cold clammy skin, postural or recumbent hypotension, and reduced urine output, depending on the degree of volume loss (Box 7-1). Reduced jugular venous pressure (JVP) noted at the base of the neck is a useful parameter of volume depletion and may roughly estimate the central venous pressure (CVP). However, an elevated CVP does not exclude hypovolemia in patients with underlying cardiac failure or pulmonary hypertension. The lack of symptoms or discernible physical findings does not preclude volume depletion in an appropriate clinical setting, and hemodynamic monitoring and administration of a fluid challenge may be necessary.

Clinical Evaluation of Extracellular Fluid Volume Depletion

Mild to Moderate Volume Loss

- Thirst
- Delay in capillary refill
- Postural dizziness, weakness
- Dry mucous membranes and axillae
- Cool clammy extremities and collapsed peripheral veins
- Tachypnea
- Tachycardia with pulse rate >100 beats/min, or postural pulse increment of 30 beats/min or more
- Postural hypotension (systolic blood pressure decrease >20 mm Hg on standing)
- Low jugular venous pulse
- Oliguria

Severe Volume Loss and Hypovolemic Shock

- Depressed mental status (or loss of consciousness)
- Peripheral cyanosis
- Reduced skin turgor (in young patients)
- Marked tachycardia, low pulse volume
- Supine hypotension (systolic blood pressure <100 mm Hg)

Box 7-1 Clinical evaluation of extracellular fluid volume depletion

Laboratory Tests

Laboratory parameters may assist in defining the underlying causes of volume depletion. Hemoconcentration and increased serum albumin concentration may be seen early with hypovolemia, but anemia or hypoalbuminemia caused by a concomitant disease may confound interpretation of these laboratory values. In healthy individuals, the blood urea nitrogen (BUN)–serum creatinine ratio is approximately 10 mg/dl (40 mmol/l). In volume-contracted states, this ratio may significantly increase because of an associated differential increase in urea reabsorption in the collecting duct. Several clinical conditions affect this ratio. Upper gastrointestinal hemorrhage and administration of corticosteroids increase urea production, and hence the BUN/creatinine ratio increases. Malnutrition and underlying liver disease diminish urea production, and thus the ratio is less helpful to support volume depletion in such clinical settings.

Urine osmolality and specific gravity may be elevated in hypovolemic states but may be altered by an underlying renal disease that leads to renal sodium wasting, concomitant intake of diuretics, or a solute diuresis. Hypovolemia normally promotes avid renal sodium reabsorption, resulting in low urine sodium concentration and low fractional excretion of sodium. Urine chloride follows a similar pattern because sodium and chloride are generally reabsorbed together. Volume depletion with metabolic alkalosis (e.g., with vomiting) is an exception because of the need to excrete the excess bicarbonate in conjunction with sodium to maintain electroneutrality; in this case, urine chloride concentration is a better index of sodium

avidity. The fractional excretion of sodium (FE_{Na}) is calculated by the following formula:

$$FE_{Na} = [U_{Na} \times P_{creat} / U_{creat} \times P_{Na}] \times 100$$

where U_{Na} and U_{creat} are urinary sodium and creatinine concentrations, respectively, and P_{Na} and P_{creat} are serum sodium and creatinine concentrations, respectively. Elevated FE_{Na} is most helpful in the diagnosis of AKI; FE_{Na} less than 1% is consistent with volume depletion.

Therapy for Extracellular Volume Contraction

The goal of treatment for ECF volume depletion is to replace the fluid deficit and ongoing losses, in general with a fluid that resembles the lost fluid. The first step is estimating the magnitude of volume loss using such tools as clinical parameters for mild to moderate versus severe volume loss (Box 7-1), which can also be assessed by invasive monitoring when necessary. The initial replacement volume is then determined and delivered with an administration rate that is tailored to the patient, as subsequently judged by frequent monitoring of clinical parameters. Mild volume contraction can usually be corrected through the oral route. In patients with hypovolemic shock and evidence of life-threatening circulatory collapse or organ dysfunction, intravenous (IV) fluid must be administered as rapidly as possible until clinical parameters improve. In most patients, however, a slow, more careful approach is warranted, particularly in elderly patients and those with an underlying cardiac condition, to avoid overcorrection with subsequent pulmonary or peripheral edema.

Crystalloid solutions with sodium as the principal cation are effective because they distribute primarily in the ECF. One third of an infusate of isotonic saline remains inside and expands the intravascular compartment, whereas two thirds distributes into the interstitial compartment. Colloid-containing solutions include human albumin (5% and 25%) and hetastarch (6% hydroxyethyl starch, HES). Because of large molecular size, these solutions remain within the vascular compartment, provided the transcapillary barrier is intact and not disrupted by capillary leak states, such as often occurs with multiorgan failure or systemic inflammatory response syndrome. The solutions augment the plasma oncotic pressure and thus expand the plasma volume by counteracting the capillary hydraulic pressure.

Colloid-containing solutions have not shown an advantage in the treatment of hypovolemic states. A meta-analysis of 55 studies showed no outcome difference between critically ill patients who received albumin and those who received crystalloids.[8] A large, multicenter trial that randomized medical and surgical critical patients to receive fluid resuscitation with 4% albumin or normal saline showed similar mortality, measured morbidity parameters, and hospitalization rates in the two groups.[9] Conversely, a recent study randomly assigned intensive care unit patients with severe sepsis to fluid resuscitation with either 6% hetastarch or Ringer acetate.[10] Patients who received hetastarch had increased mortality risk and were more likely to require renal replacement therapy, raising concerns about its safety in such patients. Consequently, artificial colloids should be avoided in patients with severe sepsis or at risk of developing AKI.[11]

Isotonic saline is usually the preferred initial choice in volume-depleted patients with normal serum [Na^+] and most of those with low serum [Na^+]. Furthermore, isotonic saline is the preferred fluid to restore ECF volume in hypovolemic patients with hypernatremia. Once euvolemia is established, further fluid therapy should be delivered to gradually correct tonicity in the form of hypotonic (0.45%) saline. Administration of large volumes of isotonic saline may result in the development of hyperchloremic metabolic acidosis; lactated-Ringer solution can be substituted if that takes place. Hypokalemia may be present initially or may subsequently ensue. It should be corrected by adding appropriate amounts of potassium chloride to replacement solutions.

Hypovolemic shock may be accompanied by lactic acidosis resulting from tissue hypoperfusion. Fluid resuscitation restores tissue oxygenation and will decrease the production of lactate. Correction of acidosis with sodium bicarbonate ($NaHCO_3$) has the potential for increasing tonicity, expanding volume, worsening intracellular acidosis from increased carbon dioxide production, and not improving hemodynamics compared with isotonic saline. Use of $NaHCO_3$ for correction of cardiac contractility coexisting with lactic acidosis has not been well documented by clinical studies. Therefore, $NaHCO_3$ to manage lactic acidosis in the setting of volume depletion is not recommended (unless arterial pH <7.1).

EXTRACELLULAR FLUID VOLUME EXPANSION

Expansion of ECF volume refers to excess fluid accumulation in the ECF compartment, usually resulting from sodium and water retention by the kidneys. Generalized edema results from an apparent increase in the interstitial fluid volume, most often in response to cardiac failure, cirrhosis with ascites, and nephrotic syndrome. Weight gain of several liters usually precedes clinically apparent edema. Localized excess fluid may accumulate in the peritoneal and pleural cavities, leading to ascites and pleural effusion, respectively.

Pathogenesis

Renal sodium and water retention secondary to arterial underfilling leads to an alteration in capillary hemodynamics that favors fluid movement from the intravascular compartment into the interstitium. In general, these two processes account for edema formation.

Capillary Hemodynamic Disturbances

According to the Starling equation, the exchange of fluid between the plasma and the interstitium is determined by the hydrostatic and oncotic pressures in each compartment. Interstitial fluid excess results from a decrease in plasma oncotic pressure or an increase in capillary hydrostatic pressure. In other words, edema is a result of an increase in fluid movement from the intravascular compartment to the interstitial space or a decrease in fluid movement from the interstitial space to the intravascular compartment, or both. Thus, the degree of interstitial fluid accumulation as determined by rate of fluid removal by the lymphatic vessels is a determinant of edema.

The capillary hydrostatic pressure is relatively insensitive to alterations in arterial pressure. The stability of the capillary pressure is a result of variations in the precapillary sphincter, which governs how much arterial pressure is transmitted to the capillary, a locally controlled response called *autoregulation*. In contrast, the venous end is not similarly well regulated. Therefore, when the blood volume expands, as in CHF and renal disease, capillary hydrostatic pressure increases, and edema ensues. Venous obstruction works by the same mechanism to cause edema, as exemplified at least partially by ascites formation in liver cirrhosis and by acute pulmonary edema after sudden impairment in cardiac function (e.g., myocardial infarction). In hepatic cirrhosis and nephrotic syndrome, another factor in edema formation is reduction in plasma oncotic pressure, with a tendency for fluid transudation into the interstitial space. The balance of the Starling forces acting on the capillary favors the net filtration

into the interstitium because capillary hydrostatic pressure exceeds the plasma colloid pressure in several tissues throughout the length of the capillary. In these tissues, a substantial amount of filtered fluid is returned to the circulation through lymphatic channels, which serve as a protective mechanism for minimizing edema formation.

Renal Sodium Retention

The mechanism for maintenance of ECF volume expansion and edema formation is renal sodium retention, which can be primary or secondary in response to reduction in EABV (Table 7-4).

Primary Renal Sodium Retention A primary defect in renal sodium excretion can occur with both acute and chronic renal failure and with glomerular disease. Patients with AKI have a limited ability to excrete sodium and water. Advanced chronic kidney disease may lead to sodium and water retention by GFR reduction secondary to a decrease in functioning nephrons. Primary renal sodium retention characterizes some forms of glomerulonephritis and occurs through incompletely understood mechanisms in the presence of a relatively suppressed renin-angiotensin system (RAS), but frequently with decreased GFR.

States of mineralocorticoid excess or enhanced mineralocorticoid activity are associated with a phase of sodium retention. However, because of the phenomenon of *mineralocorticoid escape,* the clinical manifestation is generally hypertension rather than hypervolemia. In normal individuals, administration of a high-dose mineralocorticoid initially increases renal sodium retention so that ECF volume is increased. However, renal sodium retention then ceases, spontaneous diuresis ensues, sodium balance is reestablished, and there is no detectable edema. This escape from mineralocorticoid-mediated sodium retention explains why edema is not a characteristic feature of primary hyperaldosteronism. The pathophysiologic mechanism of mineralocorticoid escape involves an increase in GFR and reduction of proximal tubular sodium and water reabsorption. This leads to an increase in sodium and water delivery to the distal nephron site of aldosterone action, which overrides the sodium reabsorption of aldosterone. Other mechanisms believed to account for this phenomenon involve decreased expression of distal tubular thiazide-sensitive NaCl cotransporters,[12] increased secretion of ANP induced by hypervolemia,[13] and pressure natriuresis. *Pressure natriuresis* refers to the phenomenon whereby increasing renal perfusion pressure (caused in part by systemic hypertension) enhances sodium excretion. These mechanisms act by decreasing tubular reabsorption at sites other than the aldosterone-sensitive cortical collecting duct.

Major Causes of Extracellular Volume Fluid Expansion

Primary Renal Sodium Retention	Secondary Renal Sodium Retention*
Acute kidney injury	Cardiac failure
Advanced chronic kidney disease	Cirrhosis
Glomerular diseases	Nephrotic syndrome
	Idiopathic edema
	Drug-induced edema
	Pregnancy

Table 7-4 Major causes of extracellular fluid volume expansion. *Secondary to reduced effective arterial blood volume depletion (arterial underfilling).

Renal Sodium Retention as Compensatory Response to Effective Arterial Volume Depletion

Pathophysiology of Arterial Underfilling Estimates of blood volume distribution indicate that 85% of blood circulates on the low-pressure venous side of the circulation, whereas an estimated 15% of blood is circulating in the high-pressure arterial circulation. Thus, an increase in total blood volume could occur, even when there is underfilling of the arterial circulation, if the increase in total blood volume is primarily caused by expansion of the venous compartment. Underfilling of the arterial circulation could result from a decrease in cardiac output, as occurs in low-output cardiac failure, or from systemic arterial vasodilation, which occurs early in cirrhosis as a result of decreased systemic vascular resistance (SVR) in the splanchnic circulation.[14] This hypothesis proposes that the events triggered by arterial underfilling as a result of either decreased cardiac output or systemic arterial vasodilation are compensatory responses necessary to restore arterial circulatory integrity (Fig. 7-1).

Renal Response to Arterial Underfilling If there is arterial underfilling, either due to a decrease in cardiac output or due to systemic

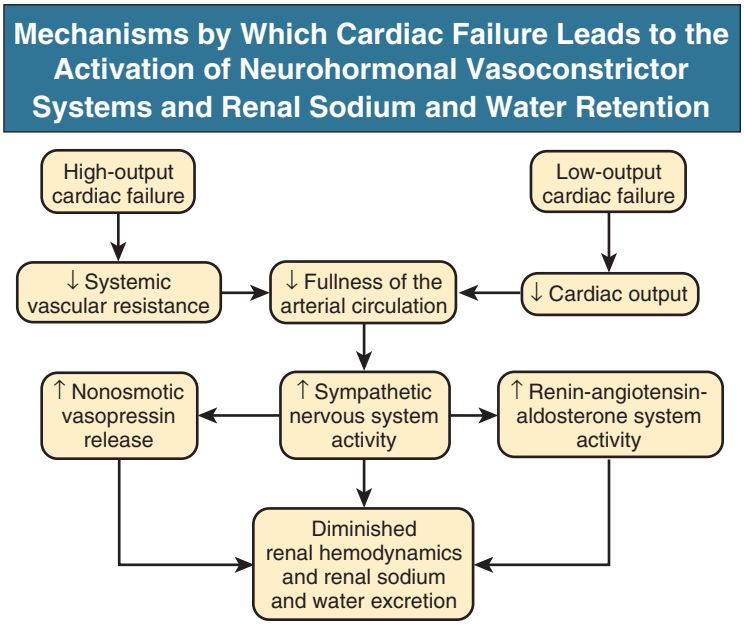

Figure 7-1 Mechanisms of cardiac failure. Cardiac failure results in activation of neurohormonal vasoconstrictor systems and retention of renal sodium and water. *(Modified from reference 48.)*

arterial vasodilation, the underfilling is sensed by the arterial stretch receptors. This leads to activation of the efferent limb of body fluid volume homeostasis. Specifically, a decrease in glossopharyngeal and vagal tone from the carotid and aortic receptors to the CNS leads to a rapid increase in sympathetic activity with associated activation of the RAAS axis and nonosmotic release of vasopressin. The resultant increase in SVR and renal sodium and water retention attenuates the arterial underfilling and associated diminished arterial perfusion. The purpose of these concerted actions is to maintain the arterial circulatory integrity and restore the perfusion to the vital organs, which is mandatory for survival.

Sodium and Water Retention in Cardiac Failure

The renal sodium and water retention that occurs in CHF involves several mediators.[15] Decreased cardiac output with arterial underfilling leads to reduced stretch of arterial baroreceptors. This results in increased sympathetic discharge from the CNS and resultant activation of the RAAS. Adrenergic stimulation and increased Ang II activate receptors on the proximal tubular epithelium that enhance sodium reabsorption. The renal vasoconstriction of the glomerular efferent arteriole by Ang II in CHF also alters net Starling forces in the peritubular capillary in a direction to enhance sodium reabsorption.[16] Thus, angiotensin and α-adrenergic stimulation increase sodium reabsorption in the proximal tubule by a direct effect on the proximal tubule epithelium and secondarily by renal vasoconstriction. This subsequently leads to decreased sodium delivery to the collecting duct, which is the major site of action of aldosterone and the natriuretic peptides. CHF patients experience renal resistance to natriuretic effects of atrial and ventricular peptides. The resultant decreased sodium delivery to the distal nephron impairs the normal escape mechanism from the sodium-retaining effect of aldosterone and impairs the effect of natriuretic peptides. These effects help explain why sodium retention and ECF expansion occur in CHF (Fig. 7-2). Accordingly, CHF patients have substantial natriuresis when spironolactone, a competitive mineralocorticoid receptor antagonist, is given in adequate doses to compete with increased endogenous aldosterone levels.[17]

Another outcome of the neurohumoral activation that occurs in cardiac failure is the baroreceptor-mediated nonosmotic release of AVP.[18] This nonosmotic AVP stimulation overrides the osmotic regulation of AVP and is the major factor leading to the hyponatremia associated with CHF.[19] AVP causes antidiuresis by activating V_2 receptors on the basolateral surface of the principal cells in the collecting duct.[20] Activation of these receptors initiates a cascade of intracellular signaling events by means of the adenylyl cyclase–cyclic adenosine monophosphate (cAMP) pathway, leading to an increase in aquaporin 2 (AQP2) water channel protein expression and its trafficking to the apical membrane of the collecting duct. This sequence of events leads to increased water reabsorption and can cause hyponatremia, which is an ominous prognostic indicator in patients with heart failure.[21] Concurrently, increased nonosmotic AVP release stimulates V_1 receptors on vascular smooth muscle cells and thereby may increase SVR. This adaptive vasoconstrictive response may become maladaptive and contribute to cardiac dysfunction in patients with severe heart failure.

The atrial-renal reflexes, which normally enhance renal sodium excretion, are impaired during CHF because renal sodium and water retention occurs despite elevated atrial pressure. Moreover, in contrast to normal subjects, plasma levels of ANP were found not to increase further during a saline load in patients with dilated cardiomyopathy and mild heart failure, and the natriuretic response was also blunted. The attenuation of these reflexes on the low-pressure side of the circulation not only is attributable to a blunting of the atrial-renal reflexes but also may be caused by counteracting arterial baroreceptor-renal reflexes. Autonomic dysfunction and blunted arterial baroreceptor sensitivity in CHF occur and are associated with increased circulating catecholamines and increased renal sympathetic activity. There is also evidence for parasympathetic withdrawal in CHF in addition to the increase in sympathetic drive.

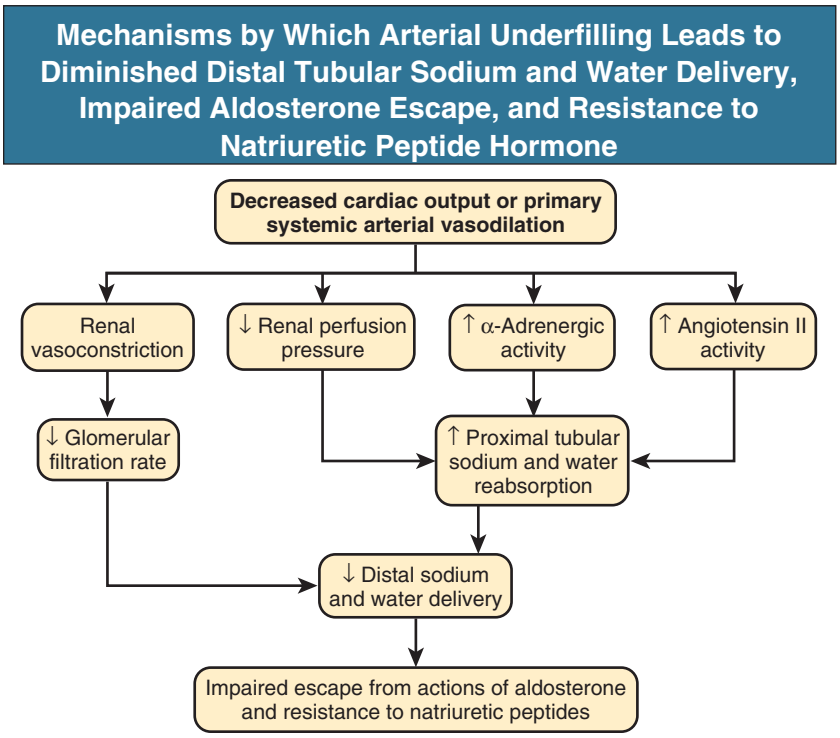

Figure 7-2 Mechanisms of arterial underfilling. Underfilling of arteries leads to reduced delivery of distal tubular sodium and water, impaired aldosterone escape, and resistance to natriuretic peptide hormone. *(Modified from reference 48.)*

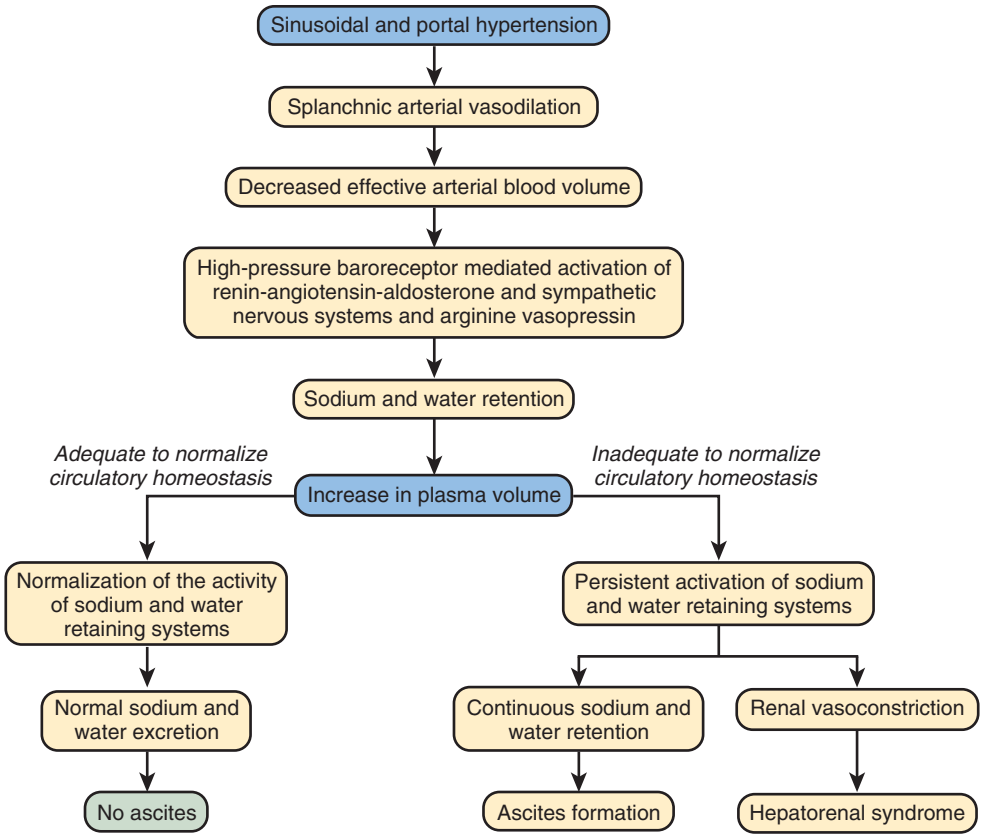

Figure 7-3 Liver cirrhosis. Pathogenesis of functional renal abnormalities and ascites formation. *(Modified from reference 27.)*

Sodium and Water Retention in Cirrhosis

Many pathogenetic aspects of sodium and water retention are similar in cirrhosis and CHF (Fig. 7-3). The arterial underfilling in cirrhosis, however, occurs secondary to splanchnic arterial vasodilation, with resultant water and sodium retention. The initial event in ascites formation in cirrhotic patients is likely sinusoidal and portal hypertension.[22] In cirrhotic patients, this is a consequence of distortion of hepatic architecture, increased hepatic vascular tone, or increased splenohepatic flow. Decreased intrahepatic bioavailability of NO and increased production of vasoconstrictors (angiotensin, endothelin) also are responsible for increased resistance in the hepatic vasculature.[23] Portal hypertension caused by increased sinusoidal pressure activates vasodilatory mechanisms in the splanchnic circulation.[24] These mechanisms, mediated at least partly by NO and carbon monoxide (CO) overproduction, lead to splanchnic and peripheral arteriolar vasodilation. In advanced stages of cirrhosis, arteriolar vasodilation causes underfilling of the systemic arterial vascular space. This event, through a decrease in EABV, leads to a fall in arterial pressure. Consequently, baroreceptor-mediated activation of the RAAS, sympathetic nervous system stimulation, and nonosmotic release of ADH occur to restore the blood volume homeostasis.[25] This involves compensatory vasoconstriction as well as renal sodium and water retention. However, splanchnic vasodilation also increases splanchnic lymph production, which exceeds the lymph transporting capacity, and thus lymph leakage into the peritoneal cavity occurs with ascites development.[26] Persistent renal sodium and water retention, along with increased splanchnic vascular permeability with lymph leakage into the peritoneal cavity, plays the major role in a sustained ascites formation.

Sodium and Water Retention in Nephrotic Syndrome

Unlike CHF and liver cirrhosis, in which the kidneys are structurally normal, the nephrotic syndrome is characterized by diseased kidneys that are often functionally impaired. Nephrotic patients typically have a higher arterial blood pressure, higher GFR, and less impairment of sodium and water excretion than patients with CHF and cirrhosis. Whereas edema is recognized as a major clinical manifestation of the nephrotic syndrome, its pathogenetic mechanism remains less clearly defined. Two possible explanations are the underfill and the overfill theories (Fig. 7-4). The underfill theory suggests that reduced plasma oncotic pressure from proteinuria increases fluid movement from the vascular to interstitial compartment. The resultant arterial underfilling culminates in activation of homeostatic mechanisms involving the sympathetic nervous system and the RAAS. The overfill theory, on the other hand, implicates primary renal sodium and water retention that translates into elevated total plasma volume, hypertension, and suppressed RAAS. Distinguishing between the two situations is important because it influences the approach to diuretic use in nephrotic patients.

The following observations support the underfill theory for edema formation. Plasma volume, systemic arterial blood pressure, and cardiac output are diminished in some nephrotic patients, especially in children with MCD (see Chapter 17), and can be corrected by plasma volume expansion with albumin infusion. The Starling forces governing the fluid movement across the capillary wall equal the difference of the hydrostatic pressure and the oncotic pressure gradients. The gradual decrease in the plasma albumin concentration and the plasma oncotic pressure is mitigated by the reduced entry of

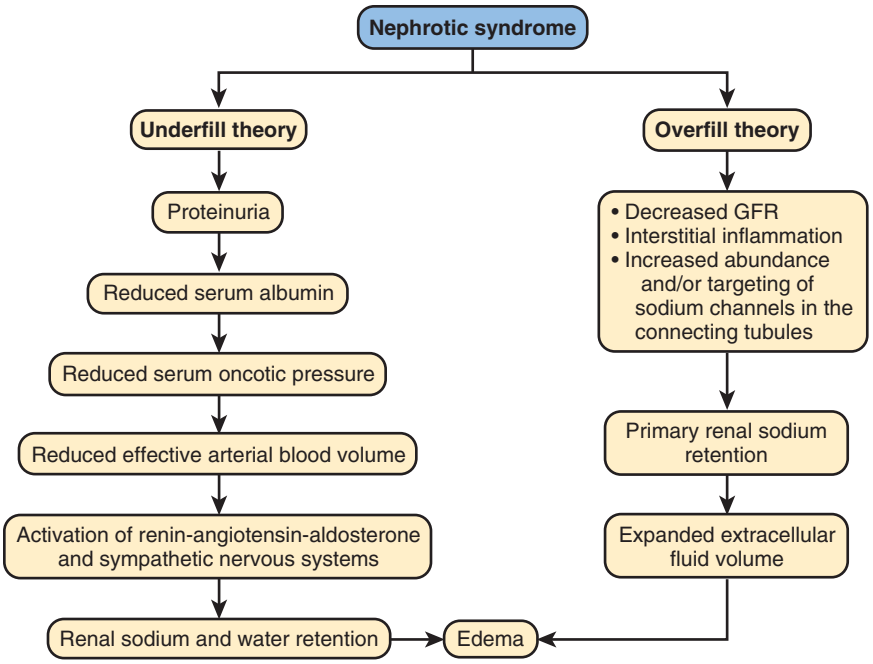

Figure 7-4 Nephrotic syndrome. Underfill and overfill theories in pathogenesis of edema in nephrotic syndrome.

albumin into the interstitial space and a concurrent decline in interstitial oncotic pressure. Consequently, less ECF volume expansion and edema formation is noted unless hypoalbuminemia is severe.[28] Thus, nephrotic patients who are underfilled and are predisposed to AKI despite generalized edema generally have serum albumin concentration of less than 2 g/dl (20 g/l).

Observations supporting the overfill theory include studies of adults with MCD who have increased blood volume and blood pressure. After remission induced by prednisone (or prednisolone), there are reductions in plasma volume and blood pressure decline, with an increase in plasma renin activity. However, evaluation of intravascular volume is somewhat unreliable because the afferent stimulus for edema formation appears to be a dynamic process, with different results at different phases of edema formation.[28] Also supporting primary renal sodium retention, experimental studies in animals with unilateral nephrotic syndrome demonstrate that sodium retention occurs secondary to increased reabsorption in the collecting tubules.[29] Increased abundance and apical targeting of epithelial sodium channel (ENaC) subunits in the connecting tubule and collecting duct play an important role in the pathogenesis of sodium retention in nephrotic syndrome in experimental animals.[30]

In summary, nephrotic patients with arterial underfilling are more likely to have MCD with severe hypoalbuminemia, preserved GFR, and low blood pressure or postural hypotension. Other glomerular diseases are more often associated with an overfill picture with volume expansion, raised blood pressure, and a decline in GFR. It has been postulated that interstitial inflammatory cells, a feature of some glomerular diseases other than MCD, may facilitate an increase in sodium retention and hypertension by releasing mediators that cause vasoconstriction.[31]

Drug-Induced Edema

Ingestion of several types of drugs may generate peripheral edema. Systemic vasodilators such as minoxidil and diazoxide induce arterial underfilling and subsequent sodium with water retention, through mechanisms similar to those in CHF or cirrhosis. Dihydropyridine calcium channel blockers may cause peripheral edema, which is related to redistribution of fluid from the vascular space into the interstitium, possibly induced by capillary afferent sphincter vasodilation in the absence of an appropriate microcirculatory myogenic reflex. This facilitates transmission of the systemic pressure to the capillary circulation.[32] Fluid retention and CHF exacerbation may be seen with thiazolidinedione therapy in patients with type 2 diabetes mellitus, involving activation of peroxisome proliferator–activated receptor γ (PPARγ) that leads to stimulation of sodium reabsorption by the sodium channels in collecting tubule cells.[33] NSAIDs can exacerbate volume expansion in CHF and cirrhotic patients by decreasing vasodilatory prostaglandins in the afferent arteriole of the glomerulus.

Idiopathic Edema

Idiopathic edema is a poorly defined syndrome characterized by intermittent edema secondary to sodium and water retention and most frequently noted on the upright position. Patients often complain of face and hand edema, leg swelling, and variable weight gain.[34] Idiopathic edema occurs most often in menstruating women. These patients also often misuse diuretics or laxatives, which may chronically stimulate the RAAS. The diagnosis of idiopathic edema is usually made by exclusion of other causes after history, physical examination, and investigation.

Sodium and Water Retention in Pregnancy

In the first trimester of normal pregnancy, systemic arterial vasodilation and a decrease in blood pressure occur in association with a compensatory increase in cardiac output.[35] After this state of arterial underfilling, RAAS activation with renal sodium and water retention occurs early in normal pregnancy. Decreased plasma osmolality, stimulated thirst, and persistent nonosmotic vasopressin release are other features of normal pregnancy. In contrast to disease states such as CHF and cirrhosis, pregnancy is associated with an increase in GFR and renal blood flow. The increased GFR, leading to higher filtered load and increased distal sodium delivery in pregnancy, no doubt contributes to the better escape from the sodium-retaining effect of aldosterone compared with CHF patients. This attenuates edema formation compared with other edematous disorders.

However, the cause of peripheral vasodilation in pregnancy is multifactorial. Estrogen upregulates endothelial NO synthase in pregnancy, and inhibitors of NO synthesis normalize the systemic and renal hemodynamics in rat pregnancy.[36] The placenta creates an arteriovenous fistula in the maternal circulation, which contributes to systemic vasodilation. High levels of vasodilating prostaglandins are another contributing factor.[37] Relaxin level increases early in gestation, which can also contribute to the circulatory changes in the kidney and other maternal organs during pregnancy.[38]

Clinical Manifestations

A thorough patient history and physical examination are important to identify the etiology of ECF volume expansion and edema. A known history of an underlying disease, such as coronary artery disease, hypertension, or liver cirrhosis, can pinpoint the underlying mechanism of edema formation. Patients with left-sided heart failure may present with exertional dyspnea, orthopnea, and paroxysmal nocturnal dyspnea. Patients with right-sided heart failure or biventricular failure may exhibit weight gain and lower limb swelling. Physical examination reveals increased JVP, pulmonary crackles, a third heart sound, or dependent peripheral edema that may be elicited in the ankles or sacrum.

Nephrotic patients classically present with periorbital edema because of their ability to lie flat during sleep. However, those with severe disease may exhibit marked generalized edema with anasarca. Cirrhotic patients present with ascites and lower limb edema caused by portal hypertension and hypoalbuminemia. Physical examination may reveal stigmata of chronic liver disease and splenomegaly.

Diagnostic and Therapeutic Approach to Extracellular Volume Expansion

Management of ECF volume expansion consists of recognizing and treating the underlying cause and attempting to achieve negative sodium balance by dietary sodium restriction and administration of diuretics. Before embarking on diuretic therapy in a congested patient, it is imperative to appreciate that ECF volume expansion may have occurred as a compensatory mechanism for arterial underfilling, as in CHF and cirrhosis. A judicious approach is therefore necessary to avoid a precipitous fall in cardiac output and tissue perfusion. Rapid removal of excess fluid is generally necessary only in life-threatening situations, such as pulmonary edema and hypervolemia-induced hypertension, whereas a more gradual approach is warranted in less compromised patients.

Moderate dietary sodium restriction (2 to 3 g/day; 86 to 130 mmol/day) should be encouraged. If salt substitutes are used, it is important to consider that these contain potassium chloride and thus should not be used for patients with advanced renal impairment or those concurrently taking potassium-sparing diuretics. Restriction of total fluid intake is usually necessary only for hyponatremic patients. Any concomitant medications that promote sodium restriction (e.g., NSAIDs) should be discontinued. Diuretics are the cornerstone of therapy to remove excess volume. Other measures can be used in patients with inadequate response or lack of response to diuretics. In those with liver cirrhosis, large-volume paracentesis with albumin infusion can be used to remove large volumes of ascitic fluid. Interventional maneuvers to shunt ascitic fluid to a central vein can also be considered in refractory ascites and may improve the GFR and sodium excretion. Extracorporeal fluid removal by ultrafiltration can be used in patients with acute decompensated heart failure accompanied by renal insufficiency or diuretic resistance. ACE inhibitors and angiotensin receptor blockers (ARBs) are adjunctive disease-modifying agents in patients with CHF or nephrotic syndrome. Additional aggressive therapies for cardiac failure include antiarrhythmic agents, positive inotropes, and mechanical devices, such as left ventricular assist device.

The treatment of suspected diuretic-induced edema, which is associated with persistent secondary hyperaldosteronism, is to withdraw diuretics for 3 to 4 weeks after informing the patient that edema may worsen initially. If the edema does not improve after 4 weeks, spironolactone can be instituted at 50 to 100 mg/day and increased to a maximum of 200 mg/day.

Diuretics

Principles of Action

Diuretics are the mainstay of therapy for edematous states, with five classes based on the predominant sites of diuretic action along the nephron (Fig. 7-5). Most diuretics reach their luminal transport sites through tubular fluid secretion. All diuretics except osmotic agents have a high degree of protein binding, which limits glomerular filtration, traps the drug in the vascular spaces, and allows it to be delivered to the proximal convoluted tubule for secretion.[39] Diuretics act by inhibiting sodium reabsorption with an accompanying anion, usually chloride. The resultant natriuresis decreases the ECF volume. Despite administration of a diuretic causing a sustained net deficit in total body sodium, the time course of natriuresis is limited because renal mechanisms attenuate the sodium excretion. This phenomenon is known as *diuretic braking,* and its mechanism includes activation of the sympathetic nervous system and RAAS, decreased systemic and renal arterial blood pressure, hypertrophy of the distal nephron cells with increased expression of epithelial transporters, and perhaps alterations in natriuretic hormones (e.g., ANP).[41]

Adverse Effects

Many common diuretics are derived from sulfanilamide and may therefore induce allergy in susceptible patients, manifested as hypersensitivity reactions, usually as a rash or rarely acute interstitial nephritis. The most serious adverse effects of diuretics are electrolyte disturbances. By blocking sodium reabsorption in the loop of Henle and the distal tubule, loop and thiazide diuretics cause natriuresis and increased distal sodium delivery. The resultant negative sodium balance activates the RAAS. The effect of aldosterone to enhance distal K^+ and H^+ excretion can lead to hypokalemia and metabolic alkalosis. Patients should therefore be monitored, and oral supplementation or addition of a potassium-sparing diuretic may need to be considered.

Loop diuretics impair tubular reabsorption by abolishing the transepithelial potential gradient and thus increase excretion of magnesium and calcium. Thiazide diuretics exert the same effect on magnesium, but unlike loop diuretics, thiazide diuretics decrease urinary calcium losses and are therefore preferred in the treatment of hypercalciuric states and in subjects with osteoporosis. Thiazide diuretics interfere with urine-diluting mechanisms by blocking sodium reabsorption at the distal convoluted tubule, an effect that may risk hyponatremia. Acutely, loop and thiazide diuretics increase the excretion of uric acid, whereas chronic administration results in reduced uric acid excretion. The chronic effect may be caused by enhanced transport in the proximal convoluted tubule secondary to volume depletion, leading to increased uric acid reabsorption, or competition between the diuretic and uric acid for secretion in the proximal tubule, leading to reduced uric acid secretion. Other adverse effects with large doses may include ototoxicity with loop diuretics, particularly with aminoglycoside coadministration, and gynecomastia, which may develop with spironolactone.

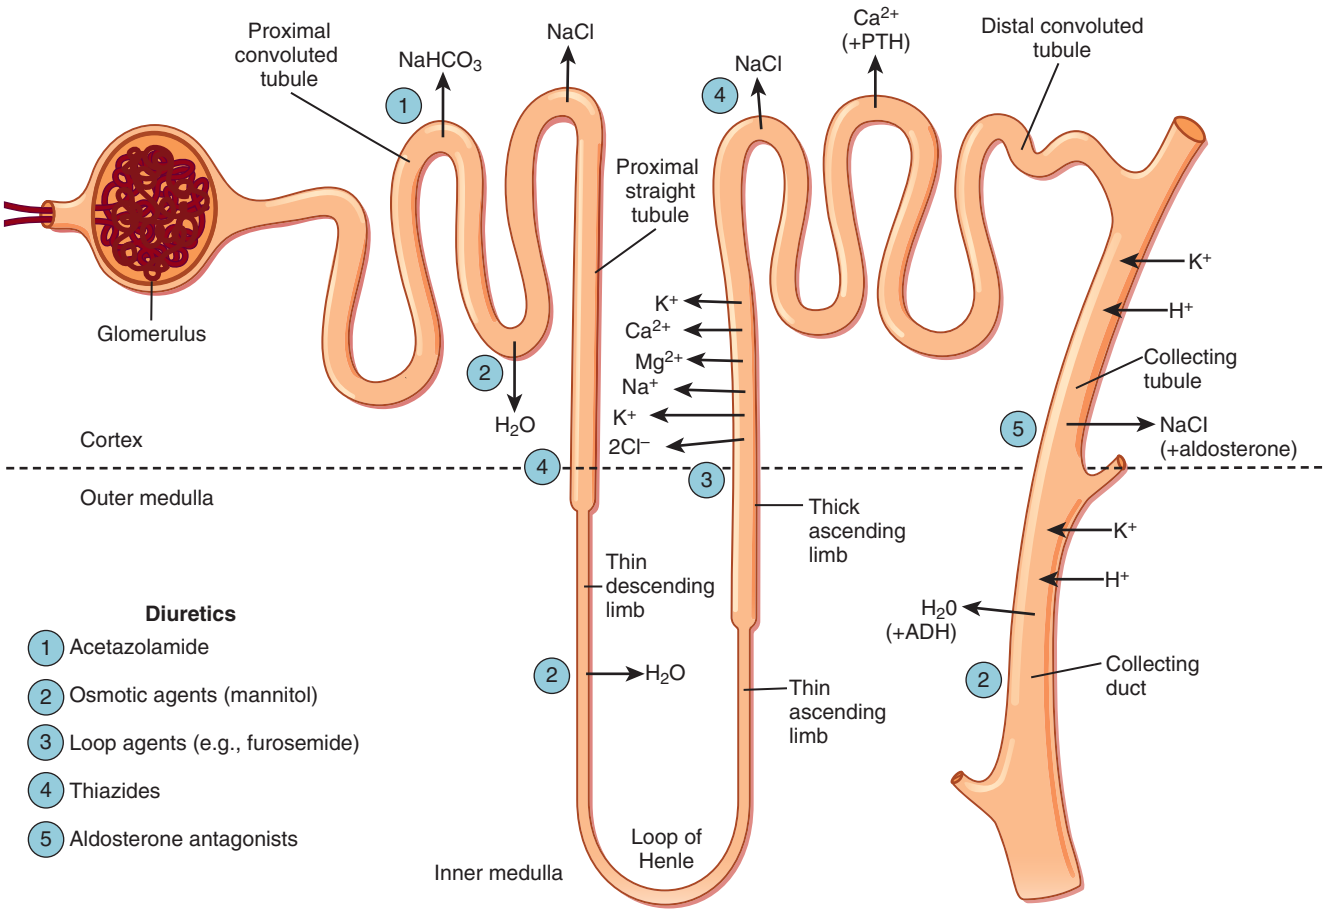

Figure 7-5 Tubule transport systems and sites of action of diuretics. *(Modified from reference 40.)*

Diuretic Tolerance and Resistance

Long-term loop diuretic *tolerance* refers to resistance of their action as a result of distal nephron segment hypertrophy and enhanced sodium reabsorption that follows increased exposure to solutes not absorbed proximally.[39] This problem can be addressed by combining loop and thiazide diuretics because the latter block the distal nephron sites responsible.

Diuretic *resistance* refers to edema that is or has become refractory to a given diuretic. Figure 7-6 outlines an algorithm for diuretic therapy in patients with edema caused by renal, hepatic, or cardiac disease. Diuretic resistance can result from several causes. Chronic kidney disease is associated with decreased tubular delivery and secretion of diuretics, which subsequently reduces drug concentration at the active site in the tubular lumen. In patients with nephrotic syndrome, the high protein content of tubular fluid was previously thought to increase protein binding of furosemide and other loop diuretics and therefore inhibit their action. However, more recent data suggest that urinary protein binding does not affect the response to furosemide.[42] As explained earlier, arterial underfilling in cirrhosis and CHF is associated with diminished nephron responsiveness to diuretics because of increased proximal tubular sodium reabsorption, leading to decreased delivery of sodium to the distal nephron segment sites of diuretic action. NSAIDs block prostaglandin-mediated increases in renal blood flow and increase the expression of Na^+-K^+-Cl^- cotransporters in the thick ascending limb (TAL).

Salt restriction is the key approach to lessening postdiuretic sodium retention. Secondary hyperaldosteronism also contributes to diuretic resistance. Further approaches to antagonize diuretic resistance include increasing the dose of loop diuretic, administering more frequent doses, and using combination therapy to block sequentially more than one site in the nephron, to cause a synergistic interaction between diuretics. It is reasonable to initiate aldosterone antagonist therapy before addition of a thiazide diuretic in patients with low or low-normal serum potassium level who are receiving only loop diuretic therapy, to enhance the diuresis and minimize the degree of potassium wasting. Highly resistant edematous patients may be treated with ultrafiltration.

Loop Diuretics

Loop diuretics such as furosemide, bumetanide, torsemide, and ethacrynic acid act by blocking the Na^+-K^+-Cl^- cotransporters at the apical surface of the TAL cells, thereby diminishing net reabsorption. Loop diuretics are the most potent of all diuretics because of the ability to inhibit the reabsorption of 25% of filtered sodium normally occurring at the TAL. Moreover, the nephron segment past the TAL does not possess the capacity to reabsorb completely the volume of fluid exiting the TAL. The oral bioavailability of furosemide varies between 10% and 100%; that of bumetanide and torsemide is comparatively higher. As a class, loop diuretics have a short elimination half-life, so the dosing interval needs to be short to maintain adequate levels in the lumen. Excessive prolongation of dosing interval may lead to avid sodium reabsorption by the nephron, which may result in postdiuretic sodium retention.

The intrinsic potency of a diuretic is defined by its dose-response curve, which is generally sigmoid. The steep dose-response is the reason that loop diuretics are often referred to as "threshold drugs."

Therapeutic Regimens for Loop Diuretics

	Renal Impairment				Preserved Renal Function					
	Moderate		*Severe*		*Nephrotic Syndrome*		*Cirrhosis*		*Congestive Heart Failure*	
	PO	***IV***	***PO***	***IV***	***PO***	***IV***	***PO***	***IV***	***PO***	***IV***
Furosemide	80-160	80	240	200	240	120	80-160	40-80	160-240	40-80
Bumetanide	2-3	2-3	8-10	8-10	3	3	1-2	1	2-3	2-3
Torsemide	50	50	100	100	50	5	10-20	10-20	50	20-50

Table 7-5 Therapeutic regimens for loop diuretics. *(Modified from reference 46.)*

This is exemplified by furosemide, which can initiate diuresis in a person with normal renal function with an IV dose of 10 mg, and a maximal effect is seen with 40 mg. A larger dose provides minimal or no extra benefit, and side effects may increase. Furthermore, the effective diuretic dose is higher in patients with CHF, advanced cirrhosis, and renal failure (Table 7-5). Patients who respond poorly to intermittent doses of a loop diuretic may receive continuous IV infusion, which hypothetically enhances the response by virtue of maintaining an effective amount of drug at the site of action.[43] The benefit of continuous infusion, however, was not confirmed in a Cochrane review, which concluded that available data are insufficient to assess the merits of each approach (bolus or continuous) despite greater

diuresis and a better safety profile of the continuous infusion.[44] Furthermore, a recent prospective randomized trial was performed to compare bolus versus continuous IV infusion of furosemide, as well as high-dose versus low-dose therapy. The study found no difference in the primary end points—the global assessment of symptoms over the course of 72 hours and the change in serum creatinine from baseline to 72 hours—for continuous versus bolus infusion. High-dose diuretics were more effective than low-dose diuretics, without clinically important negative effects on renal function.[45]

Although having typical pharmacologic characteristics of other loop diuretics, ethacrynic acid has greater ototoxic potential and therefore is reserved for patients allergic to other loop diuretics.

Distal Convoluted Tubule Diuretics

The distal convoluted tubule group includes thiazide diuretics such as chlorothiazide, hydrochlorothiazide, and chlorthalidone, in addition to metolazone and indapamide. These diuretics inhibit NaCl absorption in the distal tubule, where up to 5% of filtered sodium and chloride is reabsorbed, and are therefore less potent than loop diuretics. Thiazides have a relatively long half-life and can be administered once or twice daily. Metolazone has pharmacologic characteristics similar to those of thiazide diuretics and is more often used in conjunction with other classes of diuretics. Metolazone has a longer elimination half-life (~2 days), and thus more rapidly acting and predictable thiazide agents may be preferred.

Thiazides may be used alone to induce diuresis in patients with mild CHF but more often are used in combination to synergize the effect of loop diuretics by blocking multiple nephron segment sites. Because thiazide diuretics must reach the lumen to be effective, higher doses are required in patients with impaired renal function. Thiazides (possibly excluding metolazone and indapamide) are ineffective in patients with advanced renal impairment (GFR <30 to 40 ml/min). In these patients, thiazides can enhance the diuretic effect of loop diuretics if they are coadministered in sufficient doses to attain effective nephron lumen concentration. If used, such combination therapy should be initiated under close monitoring because of a pronounced risk of hypokalemia and excessive ECF depletion.

Collecting Duct Diuretics

Amiloride, triamterene, and the aldosterone antagonists spironolactone and eplerenone act on the collecting duct. Amiloride and triamterene act primarily in the cortical collecting tubule or the connecting tubule and cortical collecting duct by interfering with sodium reabsorption through the apical ENaC. These agents inhibit potassium secretion indirectly by dissipating the electronegative gradient normally created by sodium reabsorption that favors potassium secretion. Spironolactone and eplerenone are competitive antagonists of aldosterone and cause natriuresis and potassium retention. Potassium-sparing diuretics are considered weak diuretics because they block only about 3% of the filtered sodium load reaching their site of action and thus are most often used with other diuretics to augment diuresis or to preserve potassium. If combination therapy is used, careful monitoring is essential to prevent dangerous hyperkalemia. Vulnerable patients include those with underlying renal dysfunction, those with CHF, diabetic patients, and those concurrently taking ACE inhibitors, ARBs, NSAIDs, or β-blockers. Collecting duct diuretics are considered first-line agents in certain conditions, for example, spironolactone in patients with liver cirrhosis with ascites and amiloride in the treatment of Liddle syndrome. Liddle syndrome is a rare autosomal dominant condition characterized by a primary increase in collecting tubule sodium epithelial channel function, leading to hypertension and, in some patients, hypokalemia and metabolic alkalosis (see Chapter 49).

Proximal Tubule Diuretics

Acetazolamide acts by blocking the activity of the Na^+-H^+ exchanger, thus increasing sodium bicarbonate excretion. Acetazolamide is a weak diuretic because proximal sodium reabsorption is mediated by other pathways and also because the loop of Henle has a large reabsorptive capacity that captures most of the sodium and chloride escaping from the proximal tubule. Acetazolamide generates a hyperchloremic metabolic acidosis, particularly with prolonged use. It may also cause hypokalemia because of increased distal sodium delivery; it may cause hypophosphatemia, but the mechanism of this is not well understood. Rarely used as a single agent, acetazolamide is most frequently used with other diuretics, in treatment of metabolic alkalosis accompanied by edematous states, and in chronic obstructive pulmonary disease (COPD).

Osmotic Diuretics

Osmotic diuretics are substances that are freely filtered at the glomerulus but are poorly reabsorbed. Mannitol is the prototype of osmotic diuretics. Mannitol produces diuresis by increasing the osmotic pressure within the lumen of the proximal tubule and Henle loop. This causes enhanced water diuresis and to a lesser extent sodium and potassium excretion.[47] Patients with reduced cardiac output may develop pulmonary edema when given mannitol because of an initial intravascular hypertonic phase. Therefore, mannitol is not a preferred agent for treatment of edematous states but rather is used to treat cerebral edema induced by trauma or neoplasms and to reduce intraocular pressure. Mannitol is also used in the treatment of dialysis disequilibrium syndrome, increasing the serum osmolality and thus decreasing the rapid rate of solute removal by dialysis, thought to be responsible for the symptoms.

CHAPTER 8

Disorders of Water Metabolism

Tomas Berl and Chirag Parikh

PHYSIOLOGY OF WATER BALANCE

The maintenance of the tonicity of body fluids within a narrow physiologic range is made possible by homeostatic mechanisms that control the intake and excretion of water. Vasopressin, also known as arginine vasopressin (AVP) or antidiuretic hormone (ADH), governs the excretion of water by its effect on the renal collecting system. Osmoreceptors located in the hypothalamus control the secretion of vasopressin in response to changes in tonicity.

In the steady state, water intake matches water losses. Water intake is regulated by the need to maintain a physiologic serum osmolality of 285 to 290 mOsm/kg. Despite major fluctuations of solute and water intake, the total solute concentration (i.e., the tonicity) of body fluids is maintained virtually constant. The ability to dilute and to concentrate the urine allows wide flexibility in urine flow (see Chapter 2). During water loading, the diluting mechanisms permit excretion of 20 to 25 liters of urine daily, and during water deprivation, the urine volume may be as low as 0.5 l/day.[1,2]

VASOPRESSIN

Vasopressin plays a critical role in determining the concentration of urine. It is a 1099-d cyclic peptide and is synthesized and secreted by the specialized supraoptic and paraventricular magnocellular nuclei in the hypothalamus. Vasopressin has a short half-life of about 15 to 20 minutes and is rapidly metabolized in the liver and the kidney.

Osmotic Stimuli for Vasopressin Release

Substances restricted to the extracellular fluid (ECF), such as hypertonic saline and mannitol, decrease cell volume by acting as effective osmoles and enhancing osmotic water movement from the cell. This stimulates vasopressin release; in contrast, urea and glucose readily cross cell membranes and thus do not cause changes in cell volume. The "osmoreceptor" cells, located close to the supraoptic nuclei in the anterior hypothalamus, are sensitive to changes in plasma osmolality as small as 1% and bring about the release of vasopressin by a pathway that involves the activation of TRPV4 (transient receptor potential) channels. In humans, the osmotic threshold for vasopressin release is 280 to 290 mOsm/kg[2,3] (Fig. 8-1). This system is so efficient that plasma osmolality usually does not vary by more than 1% to 2% despite wide fluctuations in water intake.

Nonosmotic Stimuli for Vasopressin Release

There are several other nonosmotic stimuli for vasopressin secretion. Decreased effective circulating volume (e.g., heart failure, cirrhosis, vomiting) causes discharge from parasympathetic afferent nerves in the carotid sinus baroreceptors and increases vasopressin secretion. Other nonosmotic stimuli include nausea, postoperative pain, and pregnancy. Much higher vasopressin levels can be achieved with hypovolemia than with hyperosmolality, although a large (7%) decrease in blood volume is required before this response is elicited.

Mechanism of Vasopressin Action

Vasopressin binds three types of receptors coupled to G proteins: the V_{1a} (vascular and hepatic), V_{1b} (anterior pituitary), and V_2 renal receptors. The V_2 receptor is primarily localized in the collecting duct and leads to an increase in water permeability through aquaporin 2 (AQP2), which is a member of a family of cellular water transporters[4] (Fig. 8-2). AQP1 is localized in the apical and basolateral region of the proximal tubule epithelial cells and the descending limb of Henle loop and accounts for the high water permeability of these nephron segments. Because AQP1 is constitutively expressed, it is not subject to regulation by vasopressin. In contrast, AQP2 is found exclusively in apical plasma membranes and intracellular vesicles in the collecting duct principal cells. Vasopressin affects both the short-term and the long-term regulation of AQP2. The short-term regulation, also described as the "shuttle hypothesis," explains the rapid and reversible increase (within minutes) in collecting duct water permeability after vasopressin administration. This involves the insertion of water channels from subapical vesicles into the luminal membrane. Long-term regulation involves vasopressin-mediated increased transcription of genes involved in AQP2 production and occurs if circulating vasopressin levels are elevated for 24 hours or more. The maximal water permeability of the collecting duct epithelium is increased as a consequence of an increase in the total number of AQP2 channels per cell. This process is not readily reversible.

Aquaporins 3 and 4 are located on the basolateral membranes of the collecting duct (Fig. 8-2) and are probably involved in water exit from the cell. AQP3 is also urea permeable and, under the stimulus of vasopressin, increases the permeability of the collecting duct to urea, resulting in its movement into the interstitium. AQP4 is also found in the hypothalamus and is a candidate osmoreceptor for the control of vasopressin release.

THIRST AND WATER BALANCE

Hypertonicity is the most potent stimulus for thirst, with a change of only 2% to 3% in plasma osmolality producing a strong desire to drink. The osmotic threshold for thirst usually occurs at 290 to 295mOsm/kg H_2O and is above the threshold for vasopressin release (see Fig. 8-1). It closely approximates the level at which maximal concentration of urine is achieved. Hypovolemia, hypotension, and angiotensin II (Ang II) are also stimuli for thirst. Between the limits imposed by the osmotic thresholds for thirst and vasopressin release, plasma osmolality may be regulated more precisely by small,

osmoregulated adjustments in urine flow and water intake. The exact level at which balance occurs depends on various factors, such as insensible losses through skin and lungs, the gains incurred from drinking water and eating, and water generated from metabolism.

QUANTITATION OF RENAL WATER EXCRETION

Urine volume can be considered as having two components. The osmolar clearance (C_{osm}) is the volume needed to excrete solutes at the concentration of solutes in plasma. The free water clearance (C_{water}) is the volume of water that has been added to (positive C_{water}) or subtracted from (negative C_{water}) isotonic urine (C_{osm}) to create either hypotonic or hypertonic urine.

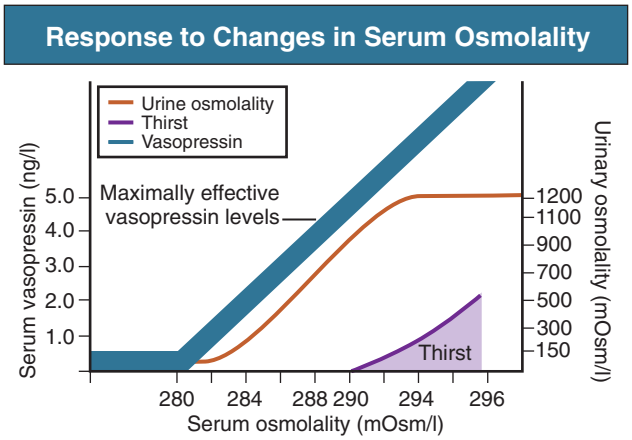

Figure 8-1 Mechanisms maintaining plasma osmolality. Thirst, vasopressin levels, and urinary osmolality in response to changes in serum osmolality. *(Modified from reference 2.)*

Urine volume flow (V) comprises the isotonic portion of urine (C_{osm}) plus the free water clearance (C_{water}).

$$V = C_{osm} + C_{water}$$

Therefore:

$$C_{water} = V - C_{osm}$$

The C_{osm}, solute clearance is determined by urine flow, urine osmolality, and plasma osmolality P_{osm} as follows:

$$C_{osm} = \left(\frac{U_{osm} \times V}{P_{osm}} \right)$$

Therefore:

$$C_{water} = V - \left(\frac{U_{osm} \times V}{P_{osm}} \right)$$
$$= V \left(1 - \frac{U_{osm}}{P_{osm}} \right)$$

This relationship reflects the following:

1. In hypotonic urine ($U_{osm} < P_{osm}$), C_{water} is positive.
2. In isotonic urine ($U_{osm} = P_{osm}$), C_{water} is zero.
3. In hypertonic urine ($U_{osm} > P_{osm}$), C_{water} is negative (i.e., water is retained).

If excretion of free water in a polyuric patient is unaccompanied by water intake, the patient will become hypernatremic. Conversely, failure to excrete free water with increased water intake can cause hyponatremia.

A limitation of the previous equation is that it fails to predict clinically important alterations in plasma tonicity and serum sodium concentration (serum [Na^+]) because it factors in urea. Urea is an important component of urinary osmolality; however, because it crosses cell membranes readily, urea does not establish a

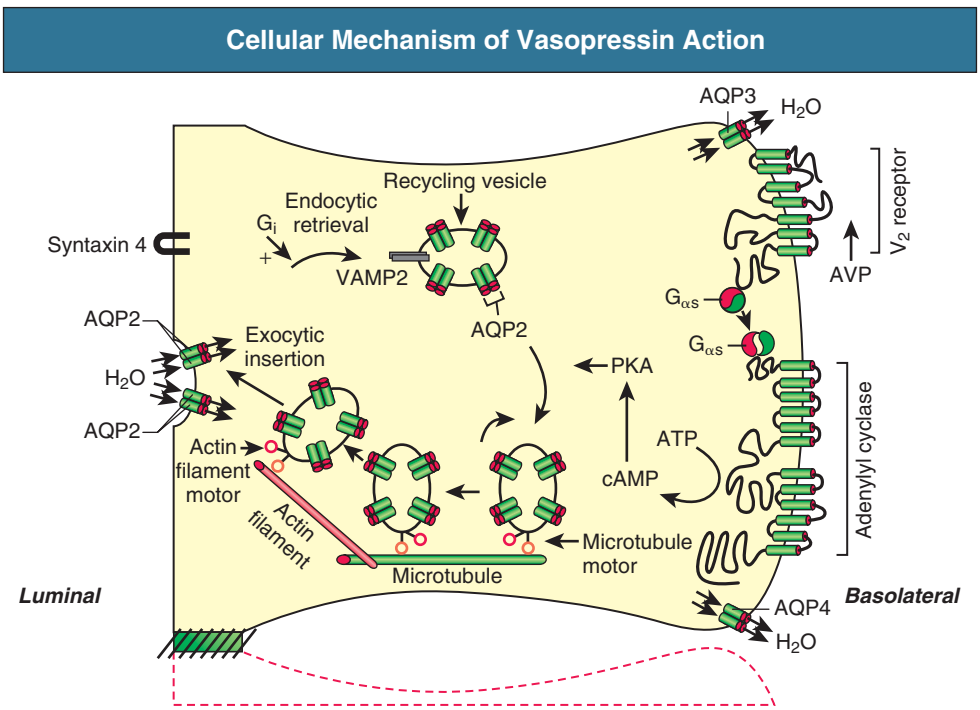

Figure 8-2 Cellular mechanism of vasopressin action. Vasopressin binds to V_2 receptors on the basolateral membrane and activates G proteins that initiate a cascade resulting in aquaporin 2 *(AQP2)* insertion in the luminal membrane. This then allows water uptake into the cell. *ATP,* Adenosine triphosphate; *AVP,* arginine vasopressin; *cAMP,* cyclic adenosine monophosphate; *PKA,* protein kinase A; *VAMP2,* vesicle-associated membrane protein 2. *(Modified from reference 3.)*

transcellular osmotic gradient and does not cause water movement between fluid compartments. Therefore, urea does not influence serum Na^+ concentration or the release of vasopressin. As a result, changes in serum $[Na^+]$ are better predicted by electrolyte free water clearance $[C_{water}(e)]$. The equation can be modified, replacing P_{osm} by plasma $[Na^+]$ (P_{Na}) and the urine osmolality by urine $[Na^+]$ and urine $[K^+]$, potassium concentration, $(U_{Na} + U_K)$:

$$C_{water}(e) = V\left(1 - \frac{U_{Na} + U_K}{P_{Na}}\right)$$

If $U_{Na} + U_K$ is less than P_{Na}, then $C_{water}(e)$ is positive and serum $[Na^+]$ increases. If $U_{Na} + U_K$ is greater than P_{Na}, then $C_{water}(e)$ is negative and serum $[Na^+]$ decreases. In the clinical setting, it is more appropriate to use the equation for electrolyte free clearance to predict if a patient's serum $[Na^+]$ will increase or decrease in the face of the prevailing water excretion. For example, in a patient with high urea excretion, the original equation would predict negative water excretion and a decrease in serum $[Na^+]$; but in fact, $[Na^+]$ increases, which is accurately predicted by the latter equation.

SERUM SODIUM CONCENTRATION, OSMOLALITY, AND TONICITY

The countercurrent mechanism of the kidneys, which allows urinary concentration and dilution, acts in concert with the hypothalamic osmoreceptors through vasopressin secretion to keep serum $[Na^+]$ and tonicity within a very narrow range[5] (Fig. 8-3). A defect in the urine-diluting capacity coupled with excess water intake leads to hyponatremia. A defect in urine-concentrating ability with inadequate water intake leads to hypernatremia.

Serum $[Na^+]$ along with its accompanying anions accounts for nearly all the osmotic activity of the plasma. Calculated serum osmolality is given by $2[Na^+]$ + BUN (mg/dl)/2.8 + glucose (mg/dl)/18, where BUN is blood urea nitrogen. The addition of other solutes to ECF results in an increase in measured osmolality (Table 8-1). Solutes that are permeable across cell membranes do not cause water movement and cause hypertonicity without cellular dehydration, as in uremia or ethanol intoxication. By contrast, in diabetic ketoacidosis with an increase in plasma glucose, which cannot move freely across cell membranes in the absence of insulin, water moves from the cells to the ECF, leading to cellular dehydration and lowering serum $[Na^+]$. This can be viewed as *translocational* because the decrease in serum $[Na^+]$ does not reflect change in total body water but rather the movement of water from intracellular to extracellular space. A correction whereby a decrease in serum $[Na^+]$ of 1.6 mmol/l for every 100 mg/dl (5.6 mmol/l) of glucose is used, but this may somewhat underestimate the impact of glucose to decrease serum $[Na^+]$.

Pseudohyponatremia occurs when the solid phase of plasma (usually 6% to 8%) is increased by large increments in either lipids or proteins (e.g., in hypertriglyceridemia and paraproteinemias). Serum osmolality is normal in pseudohyponatremia. This false result occurs because the usual method that measures the concentration of sodium uses whole plasma and not just the liquid phase, in which the concentration of sodium is 150 mmol/l. Many laboratories are now moving to direct ion-selective potentiometry, which will give the true aqueous sodium activity. In the absence of a direct-reading potentiometer, an estimate of plasma water can be obtained from the following well-validated formula[6]:

$$\text{Plasma water content (\%)} = 99.1 - (0.1 \times L) - (0.07 \times P)$$

where L and P refer to the total lipid and protein concentration (in g/l), respectively. For example, if the formula reveals that plasma water is 90% of the plasma sample rather than the normal 93% (which yields a serum sodium concentration of 140 mmol/l as 150 × 0.93 = 140), the concentration of measured sodium would be expected to decrease to 135 mmol/l (150 × 0.90).

ESTIMATION OF TOTAL BODY WATER

In normal individuals, total body water is approximately 60% of body weight (50% in women and obese individuals). With hyponatremia or hypernatremia, the change in total body water can be calculated from the serum $[Na^+]$ by the following formula:

$$\text{Water excess} = 0.6W \times \left(1 - \frac{[Na^+]_{obs}}{140}\right)$$

$$\text{Water deficit} = 0.6W \times \left(\frac{[Na^+]_{obs}}{140} - 1\right)$$

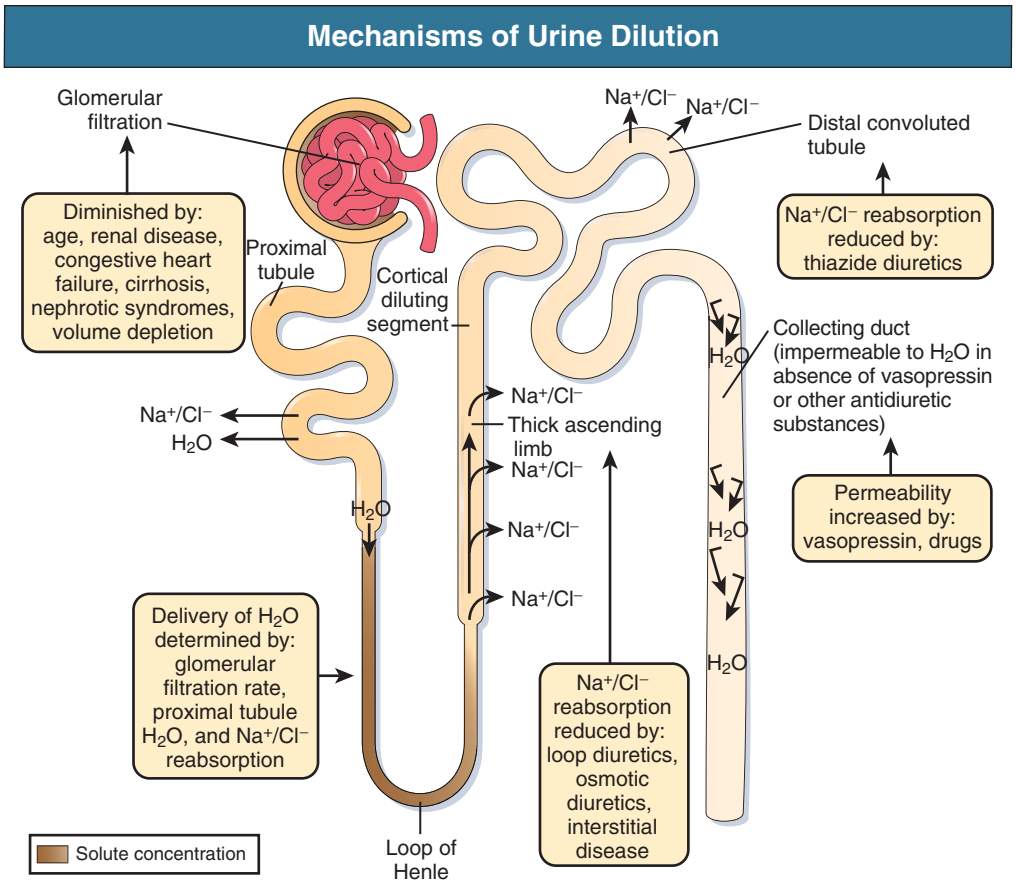

Figure 8-4 Mechanisms of urine dilution. Normal determinants of urinary dilution and disorders causing hyponatremia. *(Modified from reference 7.)*

where $[Na^+]_{obs}$ is observed sodium concentration (in mmol/l) and W is body weight (in kilograms). By use of this formula, a change of 10 mmol/l in the serum $[Na^+]$ in a 70-kg individual is equivalent to a change of 3 liters in free water.

HYPONATREMIC DISORDERS

Hyponatremia is defined as serum $[Na^+]$ of less than 135 mmol/l and equates with a low serum osmolarity once translocational hyponatremia and pseudohyponatremia are ruled out. True hyponatremia develops when normal urine-diluting mechanisms are disturbed[7] (Fig. 8-4). Hyponatremia may result from intrarenal factors, such as a diminished glomerular filtration rate (GFR) and an increase in proximal tubular fluid and Na^+ reabsorption, which decrease distal delivery of filtrate to the diluting segments of the nephron. Also, hyponatremia may result from a defect in Na^+-Cl^- transport out of the water-impermeable segments of the nephrons (thick ascending limb of Henle loop [TAL] or distal convoluted tubule). Most frequently, hyponatremia results from continued vasopressin secretion by nonosmotic mechanisms despite the presence of serum hypo-osmolality.

Etiology and Classification of Hyponatremia

Once pseudohyponatremia and translocational hyponatremia are ruled out and the patient is established as truly hypo-osmolar, the next step is to classify the patient as hypovolemic, euvolemic, or hypervolemic (Fig. 8-5).

Hypovolemia: Hyponatremia Associated with Decreased Total Body Sodium

A patient with hypovolemic hyponatremia has both a total body Na^+ and a water deficit, with the Na^+ deficit exceeding the water deficit. This occurs in patients with high gastrointestinal and renal losses of water and solute accompanied by free water or hypotonic fluid intake. The underlying mechanism is the nonosmotic release of vasopressin stimulated by volume contraction, which maintains vasopressin secretion despite the hypotonic state. Measurement of urine $[Na^+]$ is a useful tool in helping to diagnose these conditions (Fig. 8-5).

Gastrointestinal and Third-Space Sequestered Losses In the patient with diarrhea or vomiting, the kidney responds to volume contraction by conserving Na^+ and Cl^-. A similar pattern is observed in burn victims and patients with sequestration of fluids in third spaces, as in the peritoneal cavity with peritonitis or pancreatitis or in the bowel lumen with ileus. In all these patients, urine $[Na^+]$ is usually less than 10 mmol/l, and the urine is hyperosmolar. An exception to this is in patients with vomiting and metabolic alkalosis. Here, the increased bicarbonate ion (HCO_3^-) excretion obligates simultaneous cation excretion such that urine $[Na^+]$ may exceed 20 mmol/l despite severe volume depletion, but in this clinical setting the urine $[Cl^-]$ is lower than 10 mmol/l. Likewise, in chronic renal insufficiency, renal salt conservation is impaired and urine $[Na^+]$ may be high.

Diuretics Diuretic use is one of the most common causes of hypovolemic hyponatremia associated with a high urine $[Na^+]$. Loop diuretics inhibit Na^+-Cl^- reabsorption in the TAL. This interferes with the generation of a hypertonic medullary interstitium.

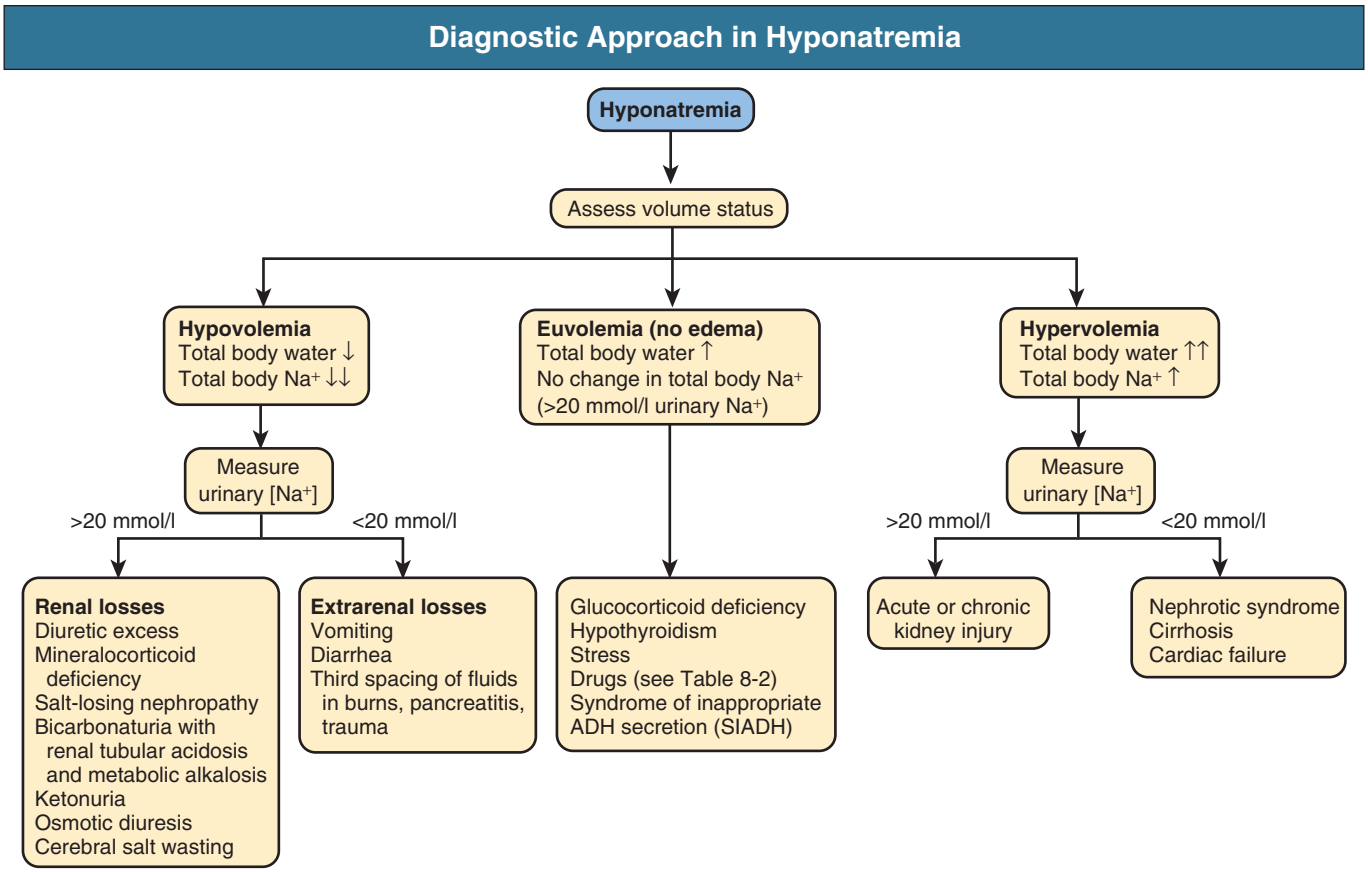

Figure 8-5 Algorithm for diagnostic assessment of the patient with hyponatremia. *(Modified from reference 5.)*

Therefore, even though volume contraction leads to increased vasopressin secretion, responsiveness to vasopressin is diminished and free water is excreted. In contrast, thiazide diuretics act in the distal tubule by interfering with urine dilution rather than with urine concentration, limiting free water excretion. Hyponatremia usually occurs within 14 days of initiation of therapy, although one third of patients present within 5 days. Underweight women and elderly patients appear to be most susceptible. Postulated mechanisms for diuretic-induced hyponatremia include the following:

- Hypovolemia-stimulated vasopressin release and decreased fluid delivery to the diluting segment
- Impaired water excretion through interference with maximal urinary dilution in the cortical diluting segment
- K^+ depletion, directly stimulating water intake by alterations in osmoreceptor sensitivity and increasing thirst

Water retention can mask the physical findings of hypovolemia, thereby making the patients with diuretic-induced hyponatremia appear euvolemic.

Salt-Losing Nephropathy A salt-losing state may occur in patients with advanced chronic renal impairment (GFR <15 ml/min), particularly from interstitial disease. It is characterized by hyponatremia and hypovolemia. In proximal type 2 renal tubular acidosis, there is renal Na^+ and K^+ wastage despite only moderate renal impairment, and bicarbonaturia obligates urine Na^+ excretion.

Mineralocorticoid Deficiency Mineralocorticoid deficiency is characterized by hyponatremia with ECF volume contraction, urine [Na^+] above 20 mmol/l, and high serum K^+, urea, and creatinine. Decreased ECF volume provides the nonosmotic stimulus for vasopressin release.

Osmotic Diuresis An osmotically active, non-reabsorbable solute obligates the renal excretion of Na^+ and results in volume depletion. In the face of continuing water intake, the diabetic patient with severe glycosuria, the patient with a urea diuresis after relief of urinary tract obstruction, and the patient with mannitol diuresis all undergo urinary losses of Na^+ and water, leading to hypovolemia and hyponatremia. Urine [Na^+] is typically above 20 mmol/l. The ketone bodies β-hydroxybutyrate and acetoacetate also obligate urinary electrolyte losses and aggravate the renal Na^+ wasting seen in diabetic ketoacidosis, starvation, and alcoholic ketoacidosis.

Cerebral Salt Wasting Cerebral salt wasting is a syndrome described primarily in patients with subarachnoid hemorrhage. The primary defect is salt wasting from the kidneys with subsequent volume contraction, which stimulates vasopressin release. The exact mechanism is not understood, but it is postulated that brain natriuretic peptide increases urine volume and Na^+ excretion. The diagnosis requires evidence of inappropriate sodium losses and reduced effective blood volume. These criteria are rarely fulfilled, suggesting that cerebral salt wasting is overdiagnosed.[8]

Hypervolemia: Hyponatremia Associated with Increased Total Body Sodium

In hypervolemia, if the total body water is increased more than total body Na^+ hyponatremia occurs, as in congestive heart failure (CHF), nephrotic syndrome, and cirrhosis, all of which are associated with impaired water excretion (see Fig. 8-5 and Chapter 7).

Congestive Heart Failure Edematous patients with CHF have reduced effective intravascular volume as a result of decreased systemic mean arterial pressure and cardiac output. This reduction is

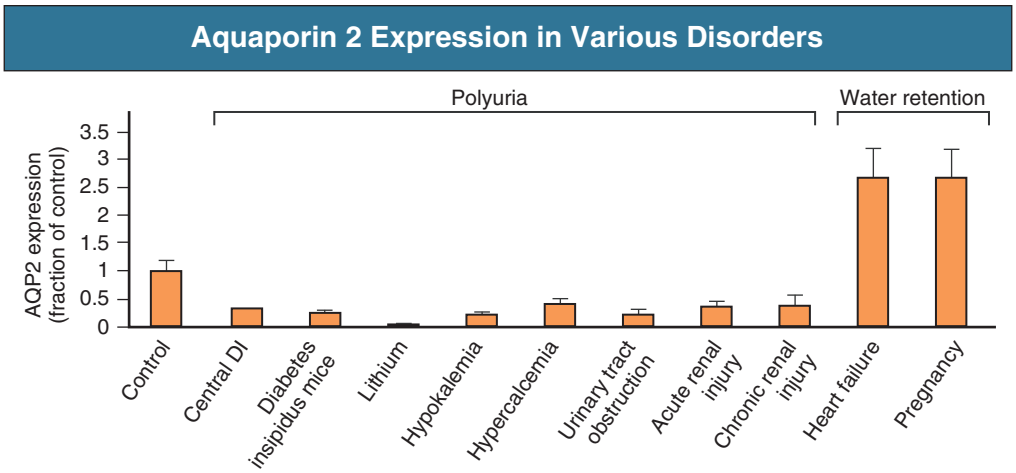

Figure 8-6 Changes in aquaporin 2 (AQP2) expression seen in association with different water balance disorders. Levels are expressed as a fraction (percentage) of control levels. AQP2 expression is reduced, sometimes dramatically, in a wide range of hereditary and acquired forms of diabetes insipidus *(DI)* characterized by different degrees of polyuria. Conversely, congestive heart failure and pregnancy are conditions associated with increased expression of AQP2 levels and excessive water retention. *(Modified from reference 9.)*

sensed by aortic and carotid baroreceptors activating nonosmotic pathways, and vasopressin is released. In addition, the relative "hypovolemic" state stimulates the renin-angiotensin axis and increases norepinephrine production, which in turn decreases GFR. The decrease in GFR leads to an increase in proximal tubular reabsorption and a decrease in water delivery to the distal tubule.

The neurohumorally mediated decrease in delivery of tubular fluid to the distal nephron and an increase in vasopressin secretion mediate hyponatremia by limiting Na^+-Cl^- and water excretion. In addition, low cardiac output and high Ang II levels are potent stimuli of thirst. There is also excessive intracellular targeting of AQP2 to the apical cell membrane of the collecting duct (Fig. 8-6).[9] These effects most likely result from high circulating levels of vasopressin.

As cardiac function improves with afterload reduction, plasma vasopressin decreases, with concomitant improvement in water excretion. The degree of hyponatremia has also been correlated with the severity of cardiac disease and with patient survival; serum [Na^+] of less than 125 mmol/l reflects severe CHF.

Hepatic Failure Patients with cirrhosis and hepatic insufficiency also have increased ECF volume (ascites, edema). Because of splanchnic venous dilation, these patients have increased plasma volume. Unlike patients with CHF, cirrhotic patients have an increased cardiac output because of multiple arteriovenous fistulas in their alimentary tract and skin. Vasodilation and arteriovenous fistulas lead to a decrease in mean arterial blood pressure. As the severity of cirrhosis increases, there are progressive increases in plasma renin, norepinephrine, vasopressin, and endothelin. There is also an associated decline in mean arterial pressure and serum [Na^+]. In experimental models of cirrhosis, there is increased expression of vasopressin-regulated AQP2 in collecting ducts.[4]

Nephrotic Syndrome In some patients with nephrotic syndrome, especially children with minimal change disease, hypoalbuminemia and lowered plasma oncotic pressure alter Starling forces, leading to intravascular volume contraction. Most patients with nephrotic syndrome appear to have a renal defect in sodium excretion resulting in increased effective circulating volume. In experimental models of nephrotic syndrome, expression of AQP2 and AQP3 in the renal collecting ducts is downregulated.[4]

Advanced Chronic Renal Impairment Patients with advanced renal impairment, either acute or chronic, have a profound increase in fractional excretion of Na^+ to maintain normal salt balance given the overall decreased number of functioning nephrons. Edema usually develops when the Na^+ ingested exceeds the kidneys' capacity to excrete this load. Likewise, if water intake exceeds threshold, there is positive water balance and hyponatremia. At a GFR of 5 ml/min, only 7.2 liters of filtrate is formed daily. Approximately 30%, or 2.2 liters, of this filtered fluid will reach the diluting segment of the nephron, which is therefore the maximum solute-free water that can be excreted daily.

Euvolemia: Hyponatremia Associated with Normal Total Body Sodium

Euvolemic hyponatremia is the most common dysnatremia in hospitalized patients. In these patients, no physical signs of increased total body Na^+ are detected.

Glucocorticoid Deficiency Glucocorticoid deficiency causes impaired water excretion in patients with primary and secondary adrenal insufficiency. Elevation of vasopressin accompanies the water excretion defect resulting from anterior pituitary and adrenocorticotropic hormone (ACTH, corticotropin) deficiency. This can be corrected by physiologic doses of corticosteroids. In addition, implicated vasopressin-independent factors are impaired renal hemodynamics and decreased distal fluid delivery to the diluting segments of the nephron.

Hypothyroidism Hyponatremia occurs in patients with severe hypothyroidism, who usually meet the clinical criteria for myxedema coma. A decrease in cardiac output leads to nonosmotic release of vasopressin. A reduction in the GFR leads to diminished free water excretion through decreased distal delivery to the distal nephron. The exact mechanisms are unclear. In patients with untreated myxedema, a vasopressin-independent mechanism is suggested by normal suppression of vasopressin after water loading, but in patients with advanced hypothyroidism, elevated vasopressin levels are reported in the basal state and after a water load. Hyponatremia is readily reversed by treatment with levothyroxine sodium (thyroxine).

Psychosis Patients with acute psychosis may develop hyponatremia. Some psychogenic drugs are associated with hyponatremia, but psychosis can cause hyponatremia independently. The pathophysiologic process involves an increased thirst perception, a mild defect in osmoregulation that causes vasopressin to be secreted at

lower osmolality, and an enhanced renal response to vasopressin. Individuals with self-induced water intoxication may also be more prone to development of rhabdomyolysis.[10]

Postoperative Hyponatremia Postoperative hyponatremia mainly is a result of excessive infusion of electrolyte-free water (hypotonic saline or 5% dextrose in water) and the presence of vasopressin, which prevents water excretion. Hyponatremia can also occur despite near-isotonic saline infusion within 24 hours of induction of anesthesia, mostly through the generation of electrolyte-free water by the kidneys in the presence of vasopressin.[11] In young women, hyponatremia is rarely accompanied by cerebral edema, leading to seizures and hypoxia with catastrophic neurologic events, particularly after gynecologic surgery. The mechanism has not been fully elucidated, and the patients at highest risk cannot be prospectively identified. Nevertheless, hypotonic fluids should be avoided after surgery, isotonic fluids minimized, and serum [Na^+] checked if hyponatremia is suspected.

Exercise-Induced Hyponatremia Hyponatremia is increasingly seen in long-distance runners. A study at a marathon race associated increased risk of hyponatremia with body mass index (BMI) less than 20 kg/m^2, running time exceeding 4 hours, and greatest weight gain.[12] A study in ultramarathon runners showed elevated vasopressin despite normal or low serum [Na^+].[13]

Drugs Causing Hyponatremia Drug-induced hyponatremia is becoming the most common cause of hyponatremia.[14] Thiazide diuretics are the most common cause, probably followed by selective serotonin reuptake inhibitors (SSRIs). Hyponatremia can be mediated by vasopressin analogues such as desmopressin (brand name DDAVP, 1-desamino-D-arginine vasopressin), drugs that enhance vasopressin release, and agents potentiating the action of vasopressin.[15] In other cases, the mechanism is unknown (Table 8-2). The increased use of desmopressin for nocturia in elderly patients and enuresis in young persons has resulted in a marked increase of reported cases of hyponatremia in these patients.[16] With the increasing use of intravenous immune globulin (IVIG) as a therapeutic modality in many disorders, cases of hyponatremia associated with its use have been described.[17] The mechanism of IVIG-associated hyponatremia is multifactorial, involving pseudohyponatremia as the protein concentration increases, translocation because of the sucrose in the solution, and true dilutional hyponatremia related to retention of water, particularly in those with associated acute kidney injury.[17]

Syndrome of Inappropriate Antidiuretic Hormone Secretion Despite being the most common cause of hyponatremia in hospitalized patients, the syndrome of inappropriate ADH secretion (SIADH) is a diagnosis of exclusion. A defect in osmoregulation causes vasopressin to be inappropriately stimulated, leading to urine concentration (Table 8-3). A few causes deserve special mention. Central nervous system (CNS) disturbances such as hemorrhage, tumors, infections, and trauma cause SIADH by excess vasopressin secretion. Small cell lung cancers, cancer of the duodenum and pancreas, and olfactory neuroblastoma cause ectopic production of vasopressin. Idiopathic cases of SIADH are unusual except in elderly patients, in whom hyponatremia is frequently multifactorial,[18] but in whom as

many as 10% have abnormal vasopressin secretion without known cause.

Several patterns of abnormal vasopressin release have emerged from studies of patients with clinical SIADH.[19] In one third of patients with SIADH, vasopressin release varies appropriately with serum [Na^+] but begins at a lower threshold of serum osmolality, implying a "resetting of the osmostat." Ingestion of free water then leads to water retention to maintain the serum [Na^+] at a new lower level, usually 125 to 130 mmol/l. In two thirds of patients, vasopressin release does not correlate with serum [Na^+], but a solute-free urine cannot be excreted. Therefore ingested water is retained, giving rise to moderate nonedematous volume expansion and dilutional hyponatremia. In about 10% of patients, vasopressin levels are not measurable, suggesting that the *syndrome of inappropriate antidiuresis* (SIAD) is a more accurate term.[19] Such patients may have a nephrogenic syndrome of antidiuresis, and a gain-of-function mutation in the vasopressin receptor may be a mechanism.[20]

The diagnostic criteria for SIADH are summarized in Box 8-1.[21] Plasma vasopressin may be in the "normal" range (up to 10 ng/l), but this is inappropriate given the hypo-osmolar state. In clinical practice, the measurement of plasma vasopressin is rarely needed because the urinary osmolality provides an excellent surrogate bioassay. Thus, a hypertonic urine (>300 mOsm/kg) provides strong evidence for the presence of vasopressin in the circulation because such urinary tonicities are unattainable in its absence. Likewise, a urinary osmolality lower than 100 mOsm/kg reflects the virtual absence of the hormone. Urinary osmolalities in the range of 100 to 300 mOsm/kg can occur in the presence or absence of vasopressin. A decrease in uric acid concentration is frequently encountered in the SIADH patient.

Clinical Manifestations of Hyponatremia

Most patients with a serum [Na^+] above 125 mmol/l are asymptomatic. Below 125 mmol/l, headache, yawning, lethargy, nausea, reversible ataxia, psychosis, seizures, and coma may occur as a result of cerebral edema. Rarely, hypotonicity leads to cerebral edema so severe that there is increased intracerebral pressure, tentorial herniation, respiratory depression, and death. Hyponatremia-induced cerebral edema usually occurs with rapid development of hyponatremia, typically in hospitalized postoperative patients receiving diuretics or hypotonic fluids. In patients with untreated severe hyponatremia, mortality is as high as 50%. Neurologic symptoms in a hyponatremic patient call for immediate attention and treatment.

Criteria for Syndrome of Inappropriate ADH Release

Essential Diagnostic Criteria

- Decreased extracellular fluid effective osmolality (270 mOsm/kg H_2O)
- Inappropriate urine concentration (>100 mOsm/kg H_2O)
- Clinical euvolemia
- Elevated urine Na^+ concentration under conditions of normal salt and water intake
- Absence of adrenal, thyroid, pituitary, or renal insufficiency or diuretic use

Supplemental Criteria

- Abnormal water-load test (inability to excrete at least 90% of a 20-ml/kg water load in 4 hours and/or failure to dilute urine osmolality to <100 mOsm/kg)
- Plasma vasopressin level inappropriately elevated relative to the plasma osmolality
- No significant correction of plasma Na^+ level with volume expansion, but improvement after fluid restriction

Box 8-1 Diagnostic criteria for syndrome of inappropriate antidiuretic hormone secretion (SIADH). *(Modified from reference 21.)*

Cerebral Edema

The development of cerebral edema largely depends on the cerebral adaptation to hypotonicity. Decreases in extracellular osmolality cause movement of water into cells, increasing intracellular volume and causing tissue edema. The water channel AQP4 appears to play a key role in the movement of water across the blood-brain barrier. Knockout mice for AQP4 are protected from hyponatremic brain swelling,[22] whereas animals overexpressing the water channel have exaggerated brain swelling.[23] Cellular edema within the fixed confines of the cranium causes an increase in intracranial pressure, leading to the neurologic syndrome. In most hyponatremic patients, mechanisms of volume regulation prevent cerebral edema.

Early in the course of hyponatremia, within 1 to 3 hours, a decrease in cerebral extracellular volume occurs by movement of fluid into the cerebrospinal fluid, which is then shunted back into the systemic circulation. Loss of extracellular solutes Na^+ and Cl^- occurs as early as 30 minutes after the onset of hyponatremia (Fig. 8-7). If hyponatremia persists for longer than 3 hours, the brain

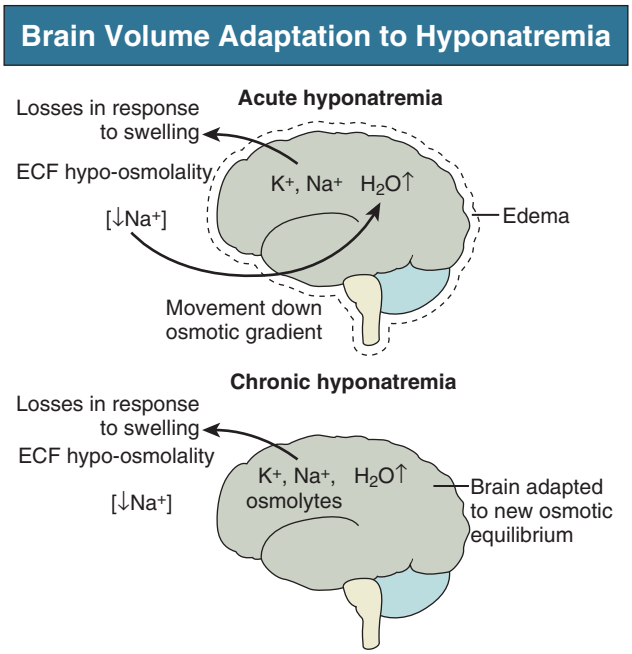

Figure 8-7 Brain volume adaptation to hyponatremia. During acute hyponatremia, water enters the brain to establish osmotic equilibrium with the ECF. As an acute adaptive change, NaCl exits from the brain interstitial space, followed by loss of potassium from cells several hours later. In chronic hyponatremia, the brain loses osmolytes, which lead to further water losses from the brain and an almost full restoration of brain water to levels marginally greater than baseline. *(Modified from reference 21.)*

Hyponatremic Patients at Risk for Neurologic Complications	
Acute Cerebral Edema	**Osmotic Demyelination Syndrome (Central Pontine Myelinolysis)**
Postoperative menstruating women	Liver transplant recipients
Elderly women taking thiazides	Alcoholic patients
Children	Malnourished patients
Patients with polydipsia secondary to psychiatric disorders	Hypokalemic patients
Hypoxemic patients	Burn victims
Marathon runners	Elderly women taking thiazides
	Hypoxemic patients
	Severe hyponatremia ($[Na^+]$ < 105 mmol/l)

Table 8-4 Neurologic risk in patients with hyponatremia. Patient groups at risk for acute cerebral edema and central pontine myelinolysis (osmotic demyelination). *(From reference 24.)*

adapts by losing cellular osmolytes, including K^+ and organic solutes, which tends to lower the osmolality of the brain, resulting in concomitant water losses. Thereafter, if hyponatremia persists, other organic osmolytes, such as phosphocreatine, myoinositol, and amino acids (e.g., glutamine, taurine), are lost, greatly decreasing cerebral swelling. As a result of these adaptations, some patients, particularly elderly, may have minimal symptoms despite severe hyponatremia ($[Na^+]$ <125 mmol/l).

Certain patients are at increased risk for development of acute cerebral edema in the course of hyponatremia[24] (Table 8-4). Hospitalized premenstrual women with hyponatremia are more symptomatic and more likely to have complications of therapy than postmenopausal women or men. This increased risk of cerebral edema is independent of the rate of development or the magnitude of hyponatremia. The best management of these patients is to avoid the administration of hypotonic fluids in the postoperative setting. Hyponatremia may occur in the postoperative state even if isotonic fluid is being used if urine $[Na^+]$ and $[K^+]$ exceed serum concentrations; the hyponatremia is mild and not associated with cerebral dysfunction.[11] Children are particularly vulnerable to the development of acute cerebral edema, perhaps because of a relatively high ratio of brain to skull volume.

Osmotic Demyelination

Another neurologic syndrome can occur in hyponatremic patients as a complication of correction of hyponatremia. Osmotic demyelination most often affects the central pons of the brainstem and is therefore also termed *central pontine myelinolysis.* It occurs at all ages; Table 8-4 lists patients most at risk. Osmotic demyelination syndrome is especially common after liver transplantation, with a reported incidence of 13% to 29% at autopsy. The risk of central pontine myelinolysis is related to the severity and chronicity of the hyponatremia. It rarely occurs with serum $[Na^+]$ above 120 mmol/l or acute onset of hyponatremia (<48 hours). The symptoms are biphasic. Initially, there is a generalized encephalopathy associated with rapid correction of serum $[Na^+]$. At 2 to 3 days after correction, the patient displays behavioral changes, cranial nerve palsies, and progressive weakness, culminating in quadriplegia and a locked-in syndrome. T2-weighted magnetic resonance imaging shows nonenhancing and hyperintense pontine and extrapontine lesions. These lesions may not appear until 2 weeks after development, so a diagnosis of myelinolysis should not be excluded if the imaging is initially normal.

The pathogenesis of osmotic demyelination syndrome is uncertain; one suggestion is that sodium-coupled amino acid transporters (e.g., SNAT2) are downregulated by hypotonicity, thereby delaying the return of osmolytes to the brain, rendering it more sensitive to the correction of hyponatremia.[16] Although serum $[Na^+]$ and $[K^+]$ return to normal in a few hours, osmotically active solutes in the brain require several days to reach normal levels. This temporary imbalance causes cerebral dehydration and can lead to a potential breakdown of the blood-brain barrier. Astrocytes appear to be an early target of the disease process, leading to their activation of microglial cells and the expression of proinflammatory cytokines.[25]

Whereas central pontine myelinolysis was originally considered to be uniformly fatal, evidence now shows that a substantial number of patients can have some neurologic recovery, even with severe symptoms at onset, and that milder forms of osmotic demyelination occur as well.[26]

Treatment of Hyponatremia

Symptoms and duration of hyponatremia determine treatment. Acutely hyponatremic patients (hyponatremia developing within 48 hours) are at great risk for development of permanent neurologic sequelae from cerebral edema if the hyponatremia remains uncorrected. Patients with chronic hyponatremia are at risk for osmotic demyelination if the hyponatremia is corrected too rapidly.

Acute Symptomatic Hyponatremia

Acute symptomatic hyponatremia almost always develops in hospitalized patients receiving hypotonic fluids, especially when associated with seizures or other neurologic manifestations (Fig. 8-8). Treatment should be prompt because the risk of acute cerebral edema far exceeds the risk of osmotic demyelination. Serum $[Na^+]$ should be ideally corrected by 2 mmol/l/h until symptoms resolve. It is not necessary to correct the serum $[Na^+]$ completely, although this appears to pose no risk. Correction may be achieved by administration of hypertonic saline (3% NaCl) at the rate of 1 to 2 ml/h/kg.[24,27] Administration of a loop diuretic enhances free water excretion and hastens the normalization of serum $[Na^+]$. If the patient presents with severe neurologic symptoms, such as seizures, obtundation, or coma, 3% NaCl may be infused at higher rates (4 to 6 ml/h/kg). Various formulas have been proposed to estimate an increase in serum $[Na^+]$ after administration of intravenous fluids,[19] but these tend to underestimate the rate of correction.[28] Therefore, during treatment with hypertonic saline, the patient should be monitored carefully for changes in neurologic and pulmonary status, and serum electrolytes should be checked frequently, about every 2 hours.

Chronic Symptomatic Hyponatremia

If the hyponatremia has taken more than 48 hours to evolve or if the duration is not known, correction should be undertaken with caution (Fig. 8-8). Controversy exists as to whether it is the rate of correction or the magnitude of correction of hyponatremia that predisposes to neurologic complications. In clinical practice, it is difficult to dissociate these two variables because a rapid correction rate is usually accompanied by a greater absolute magnitude of correction during a given time. Three important principles guide treatment, as follows[26]:

1. Because cerebral water is increased only by approximately 10% in severe chronic hyponatremia, the goal is to increase the serum Na^+ level by 10%, or about 10 mmol/l.
2. Do not exceed a correction rate of 1.0 to 1.5 mmol/l in any given hour.
3. The goal of treatment is 6 to 8 mmol/l, but do not increase serum sodium by more than 12 mmol/l/24 h.

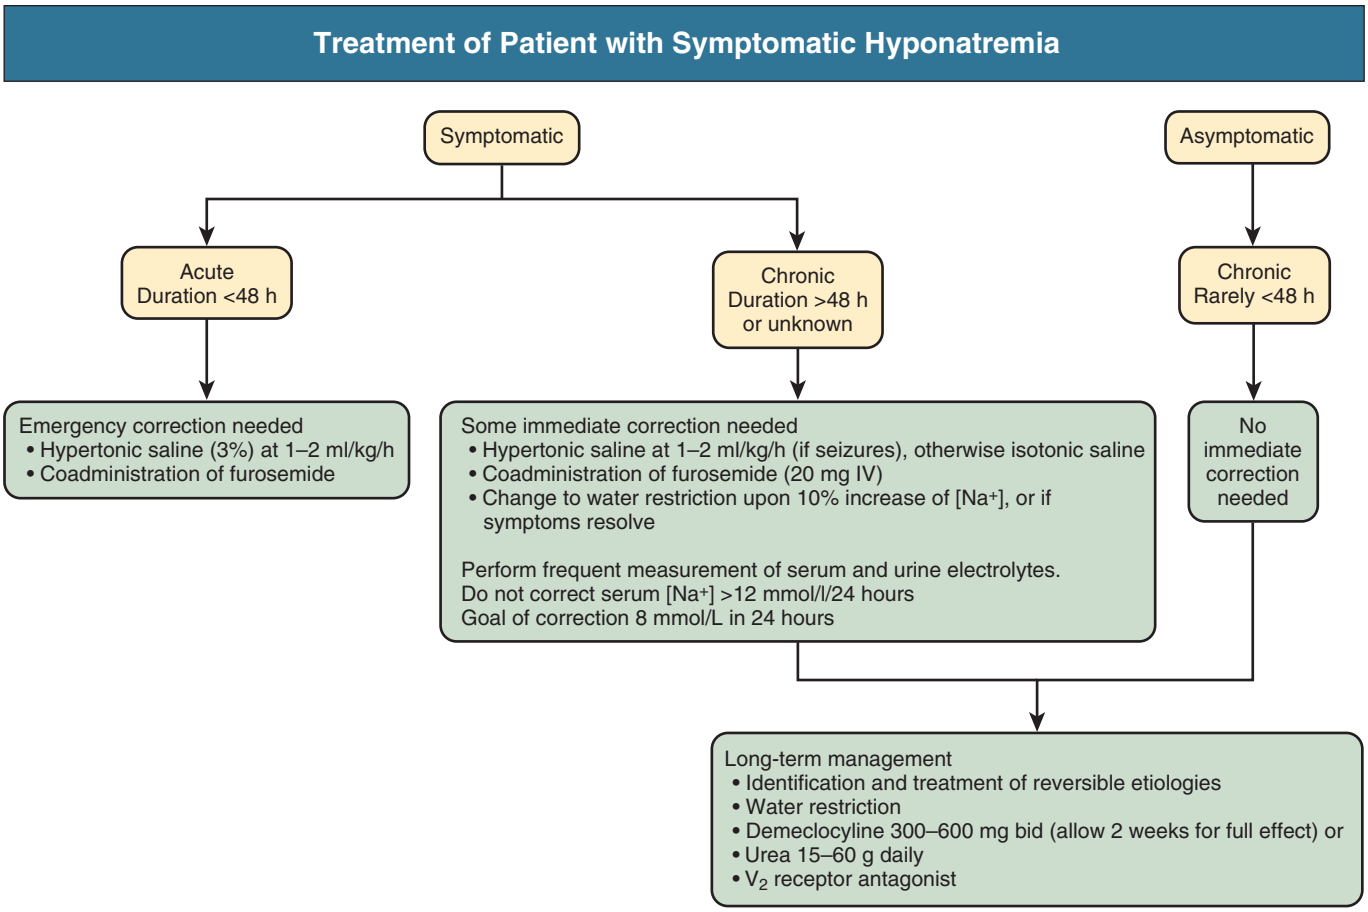

Figure 8-8 Algorithm for management of the patient with symptomatic (and "asymptomatic") hyponatremia. *(Modified from reference 24.)*

It is important to take into account the rate and electrolyte content of infused fluids and the rate of production and electrolyte content of urine. Once the desired increment in serum Na^+ concentration is obtained, treatment should consist of water restriction.

If correction has proceeded more rapidly than desired, usually because of excretion of hypotonic urine, the risk of osmotic demyelination may be decreased by relowering serum Na^+ concentration with intravenous or subcutaneous desmopressin or administration of 5% dextrose.[29]

Chronic "Asymptomatic" Hyponatremia

Although many patients with chronic hyponatremia appear to be asymptomatic, formal neurologic testing frequently reveals subtle impairments, including gait disturbances comparable to those seen in subjects with toxic levels of alcohol that reverse with correction of the hyponatremia. This results in an increased risk for falls and fractures.[30] This increased risk was observed even in patients with mild or asymptomatic hyponatremia (mean serum sodium, 131 mmol/l). Therefore, even "asymptomatic" patients should be treated in an attempt to restore serum sodium to near-normal levels, particularly if they display gait instability or have sustained a fall. These patients should also be evaluated for hypothyroidism, adrenal insufficiency, and SIADH and should have their medications reviewed.

Fluid Restriction Fluid restriction is the first-line therapy in patients with chronic asymptomatic hyponatremia (Table 8-5). This approach is usually successful if patients are compliant. It involves a calculation of the fluid restriction that will maintain a specific serum $[Na^+]$. The daily osmolar load (OL) and the minimal urinary osmolality $(U_{osm})_{min}$ determine a patient's maximal urine volume (V_{max}), as follows:

$$V_{max} = \frac{OL}{(U_{osm})_{min}}$$

The value of $(U_{osm})_{min}$ is a function of the severity of the diluting disorder. In the absence of circulating vasopressin, it can be as low as 50 mOsm. In a normal North American diet, the daily osmolar load is approximately 10 mOsm/kg (700 mOsm for 70-kg person). Assuming that a patient with SIADH has U_{osm} that cannot be lowered to less than 500 mOsm, the same osmolar load of 700 mOsm allows only 1.4 liters of urine to be excreted daily. Therefore if the patient drinks more than 1.4 l/day, the serum Na^+ concentration will decrease. Measurement of urine $[Na^+]$ and $[K^+]$ can indicate the degree of water restriction required in a given patient.[31] If the diluting defect is so severe that fluid restriction to less than 1 liter is necessary or if the patient's serum Na^+ concentration remains low (<130 mmol/l), an alternative approach to treatment, such as increasing solute excretion or pharmacologic inhibition of vasopressin, should be considered.

Maneuvers that Increase Solute Excretion If the patient remains unresponsive to fluid restriction, solute intake can be increased to facilitate an obligatory increase in excretion of solute

Treatment of Chronic Asymptomatic Hyponatremia				
Treatment	**Mechanism of Action**	**Dose**	**Advantages**	**Limitations**
Fluid restriction	Decreases availability of free water	Variable	Effective and inexpensive; not complicated	Noncompliance
Pharmacologic Inhibition of Vasopressin Action				
Lithium	Inhibits kidney's response to vasopressin	900-1200 mg/day	Unrestricted water intake	Polyuria, narrow therapeutic range, neurotoxicity
Demeclocycline	Inhibits kidney's response to vasopressin	300-600 mg twice daily	Effective; unrestricted water intake	Neurotoxicity, polyuria, photosensitivity, nephrotoxicity
V_2 receptor antagonist	Antagonizes vasopressin action	—	Addresses underlying mechanisms	Limited clinical experience
Increased Solute (Salt) Intake				
With furosemide	Increases free water clearance	Titrate to optimal dose; coadminister 2-3 g NaCl	Effective	Ototoxicity, K^+ depletion
With urea	Osmotic diuresis	30-60 g/day	Effective; unrestricted water intake	Polyuria, unpalatable, gastrointestinal symptoms

Table 8-5 Treatment of patients with chronic "asymptomatic" hyponatremia.

and free water.[32] This can be achieved by increasing oral salt and protein intake in the diet to increase the C_{osm} of the urine. Loop diuretics combined with high sodium intake (2 to 3 g of additional salt) are effective in the management of hyponatremia. A single diuretic dose (40 mg furosemide) is usually sufficient but should be doubled if the diuresis induced in the first 8 hours is less than 60% of the total daily urine output.

The administration of urea increases urine flow by causing an osmotic diuresis. This permits a more liberal water intake without worsening the hyponatremia and without altering urine concentration. The dose for urea is usually 30 to 60 g/day. The major limitations are gastrointestinal distress and unpalatability.

Pharmacologic Inhibition of Vasopressin *Vaptans* are novel oral V_2 receptor antagonists that block vasopressin binding to the collecting duct tubular epithelial cells and increase free water excretion without significantly altering electrolyte excretion. Vaptans are effective in the treatment of hyponatremia in euvolemic and hypervolemic patients.[33,34] Conivaptan, a V_2 and V_{1a} antagonist, is the only vaptan available for intravenous use.[35] It is used in the treatment of hyponatremia in hospitalized patients with transient SIADH, but treatment should be limited to 4 days because it is a potent cytochrome P-450 3A4 (CYP3A4) inhibitor. Tolvaptan, an oral V_2 antagonist, is now available in some countries at doses of 15 to 60 mg/day. In the Tolvaptan trials in patients with polycystic kidney disease (TEMPO), higher doses were used and some cases of hepatic toxicity, as well as rhabdomyolysis, were encountered. This has led to a U.S. Food and Drug Administration (FDA) warning requiring careful monitoring of liver function tests and creatine kinase (CK, CPK) levels.

An alternative pharmacologic treatment is demeclocycline, 600 to 1200 mg/day given 1 to 2 hours after meals; calcium-, aluminum-, and magnesium-containing antacids should be avoided. Onset of action is usually 3 to 6 days after initiation of treatment. Dose should be titrated to the minimum to keep serum $[Na^+]$ within the desired range with unrestricted water intake. Skin photosensitivity may develop and tooth or bone abnormalities may occur in children. Polyuria leads to noncompliance, and nephrotoxicity may occur, especially in patients with underlying liver disease. Lithium was previously used to block vasopressin action in the collecting duct but has been superseded by the vaptans and demeclocycline.

Hypovolemic Hyponatremia

When thiazides are prescribed, especially in elderly women, serum $[Na^+]$ should be monitored and water intake restricted. If hyponatremia develops, the thiazide needs to be discontinued.

Neurologic syndromes directly related to hyponatremia are unusual in hypovolemic hyponatremia because both Na^+ and water loss limits any osmotic shifts in the brain. Restoration of ECF volume with crystalloids or colloids interrupts the nonosmotic release of vasopressin. Vasopressin antagonists should not be used in these patients.[34]

Hypervolemic Hyponatremia

Congestive Heart Failure In patients with CHF, sodium and water restriction is critical. Patients may be treated with a combination of angiotensin-converting enzyme (ACE) inhibitors and diuretics. The resulting increase in cardiac output decreases the neurohumorally mediated processes that limit water excretion. Loop diuretics diminish the action of vasopressin on the collecting tubules, thereby decreasing water reabsorption. Thiazides should be avoided because they impair urinary dilution and may worsen hyponatremia. V_2 antagonists increase serum $[Na^+]$ in patients with heart failure,[33,36] and correction of serum $[Na^+]$ is associated with better long-term outcomes.[37] However, in the much larger randomized controlled EVEREST trial in patients with decompensated heart failure, treatment with tolvaptan did not alter any long-term clinical outcomes. In principle, a vaptan with V_1 antagonist activity could have additional benefit in the CHF patient, but this is unproven.

Cirrhosis In patients with cirrhosis, water and sodium restriction is the mainstay of therapy. Loop diuretics increase C_{water} once a negative sodium balance has been achieved. V_2 antagonists increase water excretion, accompanied by an increase in serum $[Na^+]$.[36] In one study, satavaptan led to a mean increase in serum $[Na^+]$ of 6.6. mmol/l,[38] but this drug has not yet gained FDA approval. The response to vaptans in cirrhosis is more attenuated than in patients with SIADH or CHF, which suggests that vasopressin-independent mechanisms may also contribute to their hyponatremia. The administration of V_2 antagonists to patients with liver failure is not associated with decrements in blood pressure. Combined V_1 and V_2 antagonists (e.g., conivaptan) should not be used in these patients.

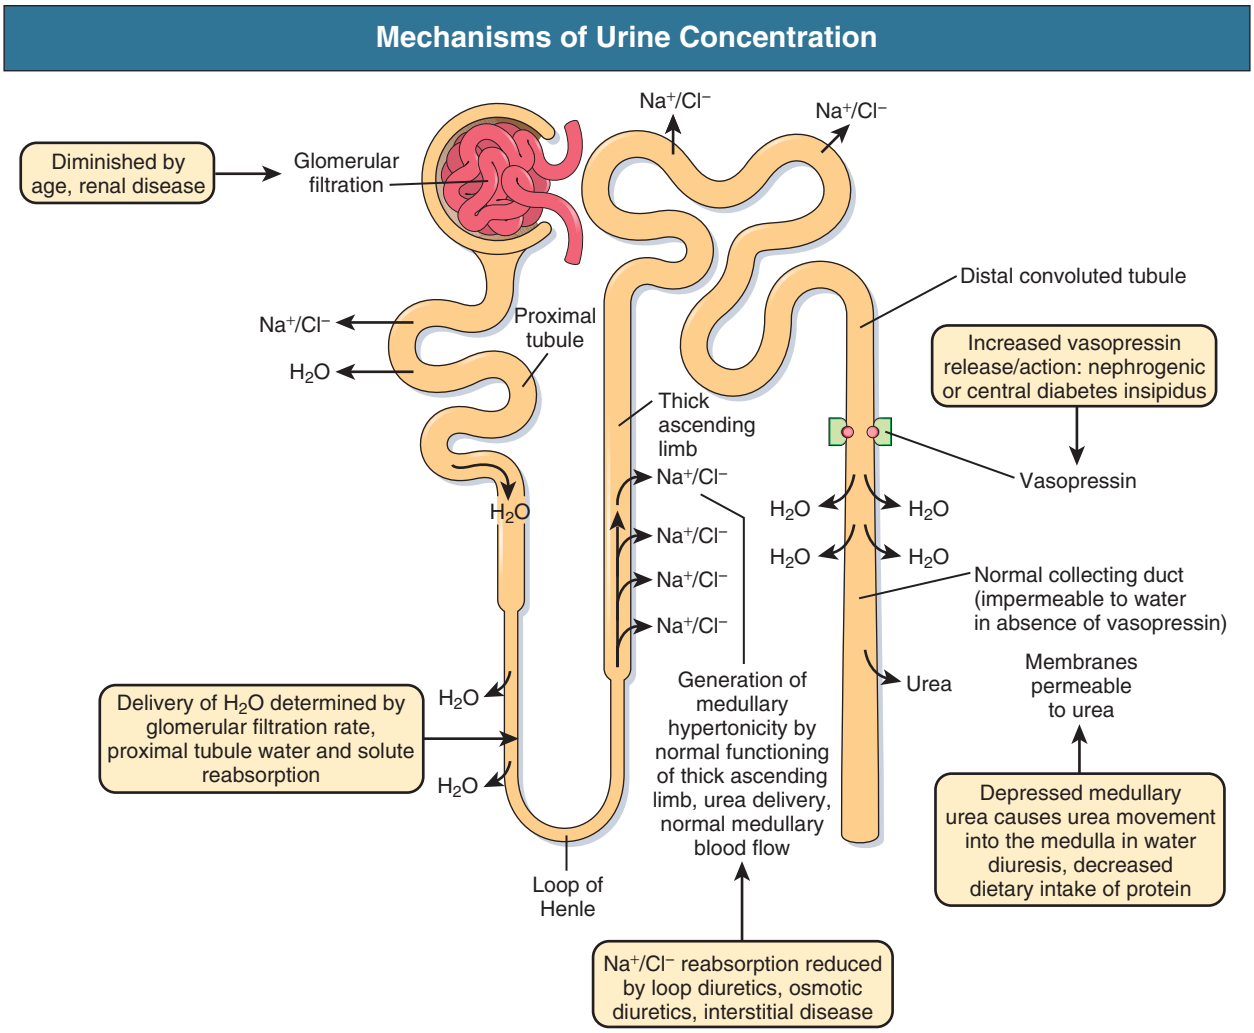

Figure 8-9 Urine-concentrating mechanisms. Determinants of normal urine concentration and disorders causing hypernatremia. *(Modified from reference 7.)*

HYPERNATREMIC DISORDERS

Hypernatremia is defined as serum [Na^+] above 145 mmol/l and reflects serum hyperosmolarity. The renal concentrating mechanism provides the first defense mechanism against water depletion and hyperosmolarity. The components of the normal concentrating mechanism are shown in Figure 8-9. Disorders of urine concentration may result from decreased delivery of solute (with decreasing GFR) or the inability to generate interstitial hypertonicity because of decreased Na^+ and Cl^- reabsorption in the ascending limb of Henle loop (loop diuretics), decreased medullary urea accumulation (poor dietary intake), or alterations in medullary blood flow. Hypernatremia may also result from failure to release or respond to AVP. Thirst is the first and most important defense mechanism in preventing hypernatremia.

Etiology and Classification of Hypernatremia

As with hyponatremia, patients with hypernatremia fall into three broad categories based on volume status.[15] A diagnostic algorithm is helpful in the evaluation of these patients (Fig. 8-10).

Hypovolemia: Hypernatremia Associated with Low Total Body Sodium

Patients with hypovolemic hypernatremia sustain losses of both Na^+ and water, but with a relatively greater loss of water. On physical examination, there are signs of hypovolemia, including orthostatic hypotension, tachycardia, flat neck veins, and poor skin turgor; some patients have altered mental status. Patients generally have hypotonic water loss from the kidneys or the gastrointestinal tract; in the GI tract, the urine [Na^+] will be low.

Hypervolemia: Hypernatremia Associated with Increased Total Body Sodium

Hypernatremia with increased total body Na^+ is the least common form of hypernatremia. It results from the administration of hypertonic solutions such as 3% NaCl and $NaHCO_3$ for the treatment of metabolic acidosis, hyperkalemia, and cardiorespiratory arrest. It may also result from inadvertent dialysis against a dialysate with a high Na^+ concentration or from consumption of salt tablets. Therapeutic hypernatremia is also becoming common as hypertonic saline solutions have emerged as an alternative to mannitol for treatment of increased intracranial pressure.[39] Hypernatremia is also increasingly recognized in hypoalbuminemic hospitalized patients with

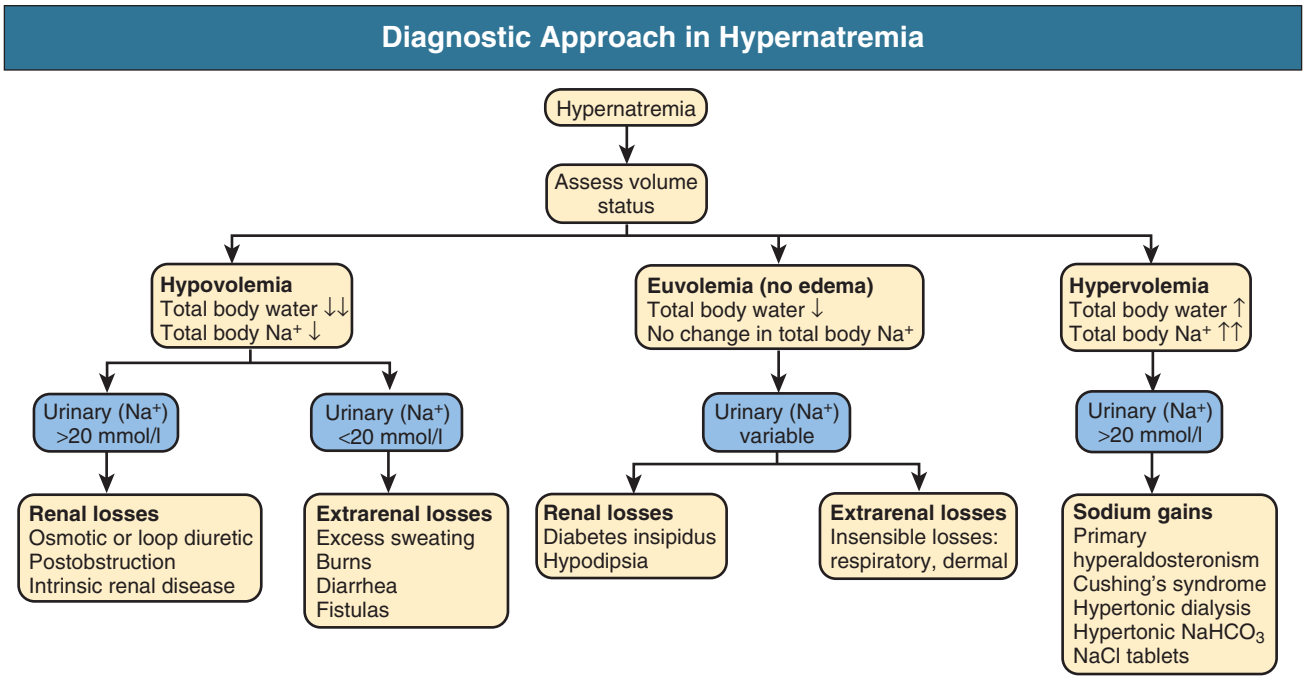

Figure 8-10 Algorithm for diagnostic assessment of the patient with hypernatremia. *(Modified from reference 5.)*

renal failure who are edematous and unable to concentrate their urine.

Euvolemia: Hypernatremia Associated with Normal Body Sodium

Most patients with hypernatremia secondary to water loss appear euvolemic with normal total body Na^+ because loss of water without Na^+ does not lead to overt volume contraction. Water loss need not result in hypernatremia unless unaccompanied by water intake. Because hypodipsia is uncommon, hypernatremia usually develops only in those who have no access to water and in very young children and old persons, who may have an altered perception of thirst. Extrarenal water loss occurs from the skin and respiratory tract in febrile or other hypermetabolic states and is associated with a high urine osmolality because the osmoreceptor-vasopressin-renal response is intact. The urine Na^+ concentration varies with the intake. Renal water loss leading to euvolemic hypernatremia results either from a defect in vasopressin production or release (central diabetes insipidus) or from a failure of the collecting duct to respond to the hormone (nephrogenic diabetes insipidus). Defense against the development of hyperosmolality requires the appropriate stimulation of thirst and the patient's ability to respond by drinking water.

Polyuric disorders can result from either an increase in C_{osm} or an increase in C_{water}. An increase in C_{osm} occurs with diuretic use, renal salt wasting, excess salt ingestion, vomiting (bicarbonaturia), alkali administration, and administration of mannitol (as a diuretic, for bladder lavage, or for the treatment of cerebral edema). An increase in C_{water} occurs with excess ingestion of water (psychogenic polydipsia) or in abnormalities of the renal concentrating mechanism (diabetes insipidus).

Diabetes Insipidus

Diabetes insipidus (DI) is characterized by polyuria and polydipsia and is caused by defects in vasopressin action. Patients with central and nephrogenic DI and primary polydipsia present with polyuria and polydipsia. These entities can be differentiated by clinical evaluation, with measurements of vasopressin levels and response to a water deprivation test, followed by vasopressin administration (Table 8-6).[40]

Water Deprivation Test

Condition	Urinary Osmolality with Water Deprivation (mOsm/kg H_2O)	Plasma Vasopressin after Dehydration (pg/ml)	Increase in Urinary Osmolality with Exogenous Vasopressin
Normal	>800	>2	Little or no increase
Complete central diabetes insipidus	<300	Undetectable	Substantially increased
Partial central diabetes insipidus	300-800	<1.5	Increase of >10% of urinary osmolality after water deprivation
Nephrogenic diabetes insipidus	<300-500	>5	Little or no increase
Primary polydipsia	>500	<5	Little or no increase

Table 8-6 Water deprivation test. Test procedure: Water intake is restricted until the patient loses 3% to 5% of body weight or until three consecutive hourly determinations of urinary osmolality are within 10% of each other. (Caution must be exercised to ensure that patient does not become excessively dehydrated.) Aqueous vasopressin is given, 5 U subcutaneously, and urinary osmolality is measured after 60 minutes. Expected responses are outlined in the table. *(From reference 40.)*

Central Diabetes Insipidus

Clinical Features Central DI usually has an abrupt onset. Patients have a constant need to drink, have a predilection for cold water, and typically have nocturia. By contrast, the compulsive water drinker may give a vague history of the onset and has large variations in

Etiology of Central Diabetes Insipidus

Congenital Causes
Autosomal dominant
Autosomal recessive

Acquired Causes
Post-traumatic
Iatrogenic (postsurgical)
Tumors (metastatic from breast, craniopharyngioma, pinealoma)
Histiocytosis
Granuloma (tuberculosis, sarcoid)
Aneurysm
Meningitis
Encephalitis
Guillain-Barré syndrome
Idiopathic

Box 8-2 Causes of central diabetes insipidus. Entries in italics are the common causes.

water intake and urine output. Nocturia is unusual in compulsive water drinkers. A plasma osmolality of more than 295 mOsm/kg suggests central DI, and less than 270 mOsm/kg suggests compulsive water drinking.

Causes Central DI is caused by infection, tumors, granuloma, and trauma affecting the CNS in 50% of patients; in the other 50% it is idiopathic (Box 8-2). In a survey of 79 children and young adults, central DI was idiopathic in half the patients. The other half had tumors and Langerhans cell histiocytosis; these patients had an 80% risk for development of anterior pituitary hormone deficiency compared with the patients with idiopathic disease.[41]

Autosomal dominant DI is caused by point mutations in a precursor gene for vasopressin that cause "misfolding" of the provasopressin peptide, preventing its release from the hypothalamic and posterior pituitary neurons.[42] Patients present with a mild polyuria and polydipsia in the first year of life. These children have normal physical and mental development. There is a rare autosomal recessive central DI associated with diabetes mellitus, optic atrophy, and deafness (Wolfram syndrome).[43] DI is usually partial and gradual in onset in Wolfram syndrome. It is linked to chromosome 4 and involves abnormalities in mitochondrial DNA.

A rare clinical entity involving the combination of central DI and deficient thirst has been reported in a total of 70 patients in 41 studies.[44] When vasopressin secretion and thirst are both impaired, affected patients are vulnerable to recurrent episodes of hypernatremia. Formerly called essential hypernatremia, the disorder is now called central DI with deficient thirst, or *adipsic* DI.

Differential Diagnosis Measurement of circulating vasopressin by radioimmunoassay is preferred to the tedious water deprivation test. Under basal conditions, vasopressin levels are unhelpful because there is a significant overlap among the polyuric disorders. Measurement after a water deprivation test is more useful (Table 8-6).

Treatment Central DI is treated with hormone replacement or pharmacologic agents (Table 8-7). In acute settings, when renal water losses are extensive, aqueous vasopressin (Pitressin) is useful. It has a short duration of action, allows careful monitoring, and avoids complications such as water intoxication. Aqueous vasopressin should be used with caution in patients with underlying coronary artery disease and peripheral vascular disease because it may cause vascular spasm and prolonged vasoconstriction. For chronic central DI, desmopressin acetate is the agent of choice. It has a long half-life and none of the significant vasoconstrictive effects of aqueous vasopressin. Desmopressin is administered at the dose of 10 to 20 µg intranasally every 12 to 24 hours. It is tolerated well, safe to use in pregnancy, and resistant to degradation by circulating vasopressinase. Oral desmopressin (0.1 to 0.8 mg every 12 hours) is available as second-line therapy. In patients with partial DI, in addition to desmopressin itself, agents that potentiate the release of vasopressin may be used, including chlorpropamide, clofibrate, and carbamazepine.

Treatment of Central Diabetes Insipidus

Disease	Drug	Dose	Interval
Complete central diabetes insipidus	Desmopressin (DDAVP)	10-20 µg intranasally	12-24 hours
	Desmopressin (DDAVP)	0.1-0.8 mg orally	Every 12 hours
Partial central diabetes insipidus	Desmopressin (DDAVP)	10-20 µg intranasally	12-24 hours
	Aqueous vasopressin	5-10 U subcutaneously	4-6 hours
	Chlorpropamide	250-500 mg	24 hours
	Clofibrate	500 mg	6 or 8 hours
	Carbamazepine	400-600 mg	24 hours

Table 8-7 Treatment of central diabetes insipidus.

Congenital Nephrogenic Diabetes Insipidus Inherited forms of DI are caused by mutations in genes for aquaporins or vasopressin receptors. Urine volumes are typically very high, and there is a risk for severe hypernatremia if patients do not have free access to water. These entities are discussed further in Chapter 49.

Acquired Nephrogenic Diabetes Insipidus Acquired nephrogenic DI is more common than congenital nephrogenic DI but rarely as severe. In patients with acquired DI, the ability to elaborate a maximal concentration of urine is impaired, but urine-concentrating mechanisms are partially preserved. For this reason, urine volumes are less than 3 to 4 l/day, which contrasts with the much higher volumes seen in patients with congenital or central DI or compulsive water drinking. Table 8-8 outlines the causes and mechanisms of acquired nephrogenic DI.

Chronic Kidney Disease A defect in urine-concentrating ability may develop in patients with chronic kidney disease of any etiology, but this defect is most prominent in tubulointerstitial diseases, particularly medullary cystic disease. Disruption of inner medullary structures and diminished medullary concentration are thought to play a role; alterations in V_2 receptor and AQP2 expression also contribute (see Fig. 8-6). To achieve daily osmolar clearance, an amount of fluid commensurate with the severity of the concentrating defect is necessary in patients who still make urine. Patients should be advised to maintain a fluid intake that matches their urine volume.

Electrolyte Disorders Hypokalemia causes a reversible abnormality in urine-concentrating ability. Hypokalemia stimulates water intake and reduces interstitial tonicity, which relates to the decreased Na^+-Cl^- reabsorption in the TAL. Hypokalemia resulting from diarrhea, chronic diuretic use, and primary aldosteronism also decreases intracellular cyclic adenosine monophosphate accumulation and causes a reduction in vasopressin-sensitive AQP2 expression (see Fig. 8-6).

Hypercalcemia also impairs urine-concentrating ability, resulting in mild polydipsia. The pathophysiologic mechanism is multifactorial and includes a reduction in medullary interstitial tonicity caused by decreased vasopressin-stimulated adenylate cyclase in the TAL and a defect in adenylate cyclase activity with decreased AQP2 expression in the collecting duct.

Acquired Nephrogenic Diabetes Insipidus: Causes and Mechanisms				
Disease State	**Defect in Medullary Interstitial Tonicity**	**Defect in cAMP Generation**	**Downregulation of Aquaporin 2**	**Other**
Chronic kidney disease	Yes	Yes	Yes	Downregulation of V_2 receptor message
Hypokalemia	Yes	Yes	Yes	—
Hypercalcemia	Yes	Yes	—	—
Sickle cell disease	Yes	—	—	—
Protein malnutrition	Yes	—	Yes	—
Demeclocycline therapy	—	Yes	—	—
Lithium therapy	—	Yes	Yes	—
Pregnancy	—	—	—	Placental secretion of vasopressinase

Table 8-8 Acquired nephrogenic diabetes insipidus: causes and mechanisms. *cAMP,* Cyclic adenosine monophosphate.

Pharmacologic Agents Lithium is the most common cause of nephrogenic DI, occurring in up to 50% of patients receiving long-term lithium therapy. Lithium causes downregulation of AQP2 in the collecting duct; experimentally, it also increases cyclooxygenase-2 (COX-2) expression and urinary prostaglandins, which may contribute to the polyuria.[45] The concentrating defect of lithium may persist even when the drug is discontinued. The epithelial sodium channel (ENaC) is the entrance pathway for lithium into collecting duct principal cells. Amiloride inhibits lithium uptake through ENaC and has been used clinically to treat nephrogenic DI caused by lithium. Aldosterone administration dramatically increased urine production in experimental nephrogenic DI caused by lithium[46] (an effect associated with decreased expression of AQP2 on luminal membranes of collecting duct), whereas administration of the mineralocorticoid receptor blocker spironolactone decreased urine output and increased AQP2 expression.[47] It is not yet known if spironolactone is a useful treatment for humans with lithium-induced nephrogenic DI.

Other drugs impairing urine-concentrating ability include amphotericin, foscarnet, and demeclocycline, which reduces renal medullary adenylate cyclase activity, thereby decreasing the effect of vasopressin on the collecting ducts.

Sickle Cell Anemia Patients with sickle cell disease and trait often have a urine-concentrating defect. In the hypertonic medullary interstitium, the "sickled" red cells cause occlusion of the vasa recta and papillary damage. The resultant medullary ischemia may impair Na^+-Cl^- transport in the ascending limb and diminish medullary tonicity. Although initially reversible, medullary infarcts occur with longstanding sickle cell disease, and the concentrating defects become irreversible.

Dietary Abnormalities Extensive water intake or a marked decrease in salt and protein intake leads to impairment of maximal urine-concentrating ability through a reduction in medullary interstitial tonicity. On a low-protein diet with excessive water intake, there is a decrease in vasopressin-stimulated osmotic water permeability that is reversed with feeding.

Gestational Diabetes Insipidus In gestational DI, there is an increase in circulating vasopressinase, which is produced by the placenta. Patients are typically unresponsive to vasopressin but respond to desmopressin, which is resistant to vasopressinase.

Clinical Manifestations of Hypernatremia

Certain patients are at increased risk for development of severe hypernatremia (Box 8-3). Signs and symptoms mostly relate to the CNS and include altered mental status, lethargy, irritability, restlessness, seizures (usually in children), muscle twitching, hyperreflexia, and spasticity. Fever, nausea or vomiting, labored breathing, and intense thirst can also occur. In children, mortality of acute hypernatremia ranges from 10% to 70%. As many as two thirds of survivors have neurologic sequelae. In contrast, mortality in patients with chronic hypernatremia is 10%. In adults, serum [Na^+] above 160 mmol/l is associated with 75% mortality, although this may reflect associated comorbidities rather than hypernatremia.

Patients at Risk for Severe Hypernatremia

- Elderly patients
- Infants
- Hospitalized patients
  - Hypertonic infusions
  - Tube feedings
  - Osmotic diuretics
  - Lactulose
  - Mechanical ventilation
- High-risk patient groups
  - Altered mental status
  - Uncontrolled diabetes mellitus
  - Underlying polyuric disorders

Box 8-3 Patient groups at risk for development of severe hypernatremia. *(From reference 24.)*

Treatment of Hypernatremia

Hypernatremia occurs in predictable clinical settings, allowing opportunities for prevention. Elderly and hospitalized patients are at high risk because of impaired thirst and inability to access free water independently.[48] Certain clinical situations, such as recovery from acute kidney injury, catabolic states, therapy with hypertonic solutions, uncontrolled diabetes, and burns, should prompt close attention to serum sodium concentration and increased administration of free water.

Hypernatremia always reflects a hyperosmolar state. The primary goal in the treatment of these patients is the restoration of serum tonicity. Figure 8-11 outlines specific management options.[24] Since restoration of volume takes precedence over restoration of tonicity, in hypovolemic hypernatremic patients, sodium-containing solutions should be used until euvolemia is achieved. Thereafter, dextrose

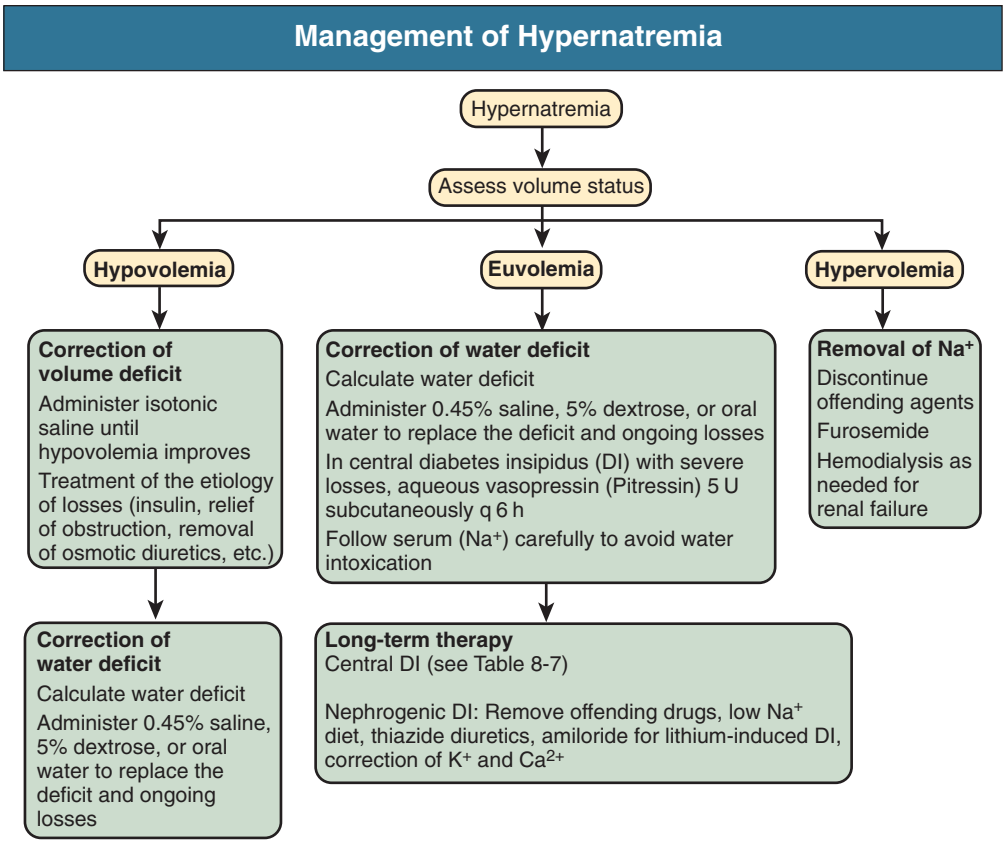

Figure 8-11 Algorithm for management of the patient with hypernatremia. *(From reference 24.)*

in water or oral water intake should be given to decrease serum sodium concentration.

The rapidity with which hypernatremia should be corrected is controversial. Some animal studies and case series in pediatric patients suggest that a correction rate of more than 0.5 mmol/l/h in [Na^+] can cause seizures. Cerebral edema also can be caused by rapid correction of hypernatremia by the net movement of water into the brain. Most clinicians believe that even in adults, correction should be achieved during 48 hours at a rate no greater than 2 mmol/l/h.

CHAPTER 9

Disorders of Potassium Metabolism

I. David Weiner, Stuart L. Linas, and Charles S. Wingo

Potassium disorders are some of the most frequently encountered fluid and electrolyte abnormalities in clinical medicine. Patients with disorders of potassium metabolism may be asymptomatic or they may have symptoms ranging from mild weakness to sudden death. When the serum potassium level is verified as abnormal, correction is essential, but inappropriate treatment can worsen symptoms and even lead to death.

NORMAL PHYSIOLOGY OF POTASSIUM METABOLISM

Potassium Intake

Potassium is essential for many cellular functions, is present in most foods, and is excreted primarily by the kidney. The typical Western diet contains about 70 to 150 mmol of potassium daily. The gastrointestinal (GI) tract efficiently absorbs potassium, and total dietary potassium intake varies the composition of the diet. Table 9-1 shows the potassium content of several foods high in potassium.[1]

Potassium Distribution

After absorption from the GI tract, potassium distributes into the extracellular fluid (ECF) and intracellular fluid (ICF) compartments. Potassium is the major intracellular cation, with K^+ concentrations from about 100 to 120 mmol/l in the cytosol. Total intracellular K^+ content is 3000 to 3500 mmol in healthy adults, found primarily in muscle (70%), with a lesser amount in bone, red blood cells, liver, and skin (Table 9-2). Only 1% to 2% total body potassium is present in the ECF. The electrogenic sodium pump, Na^+-K^+-ATPase, which is present in virtually all cells, affects this asymmetric potassium distribution by active cellular K^+ uptake. Na^+-K^+-ATPase transports two potassium ions into cells in exchange for extrusion of three sodium ions, which results in high intracellular potassium concentration (high $[K^+]$) and low intracellular sodium concentration (low $[Na^+]$). Potassium-selective ion channels are the predominant determinant of the resting membrane potential. Therefore, the intracellular/extracellular $[K^+]$ ratio largely determines the resting cell membrane potential and the intracellular electronegativity. Normal maintenance of this ratio and membrane potential is critical for normal nerve conduction and muscular contraction.

Serum potassium is tightly regulated through multiple mechanisms. Recent studies support a "feed forward" regulatory system involving gut or portal potassium sensors. This system adjusts renal potassium excretion through mechanisms independent of serum potassium and aldosterone.[2,3] This reflex system, which is still not understood fully, allows the kidney to "sense" dietary intake and alter renal potassium excretion despite no discernible changes in serum potassium or aldosterone concentration.

In addition, several hormones and factors can induce potassium shifts between the extracellular and intracellular potassium pools (Fig. 9-1). The most common causes include acid-base disorders, specific hormones, plasma osmolality, and exercise.

Acidosis caused by inorganic anions (e.g., NH_4Cl, HCl) can cause hyperkalemia, but the mechanism is not fully understood. In contrast, organic acids (e.g., lactic acid) generally do not cause transcellular potassium shifts. Insulin and β_2-adrenergic receptor activation induce cellular potassium uptake by stimulating Na^+-K^+-ATPase. Stimulation of Na^+-K^+-ATPase by insulin occurs through a mechanism separate from its stimulation of glucose entry. β_2-Adrenoceptor activation increases intracellular cAMP production, which stimulates Na^+-K^+-ATPase-mediated potassium uptake, whereas α-adrenergic receptor activation has the opposite effect. The effects of insulin and β_2-adrenoceptor activation are synergistic, as expected given the differing cellular mechanisms.

Aldosterone lowers serum potassium by two major mechanisms. First, aldosterone stimulates potassium movement into cells through stimulation of Na^+-K^+-ATPase (i.e., redistribution). Second, it can increase potassium excretion by the kidney and, to a lesser extent, by the GI tract. In the kidney, aldosterone stimulates sodium reabsorption in both the distal convoluted tubule and the collecting duct, and if there is sufficient sodium delivery to the collecting duct, this increased sodium reabsorption promotes potassium secretion. Mineralocorticoids can also stimulate potassium absorptive pumps, which may explain the equivocal effects of mineralocorticoids on potassium excretion despite their consistent effect on sodium absorption.[4,5]

Another important factor that alters cellular potassium uptake is plasma osmolality. Increased plasma osmolality, or hyperosmolality, when resulting from "effective osmoles," can cause hyperkalemia. The likely mechanism is that increased plasma osmolality induces water movement out of the cells, which decreases cell volume and increases intracellular $[K^+]$. This in turn results in feedback inhibition of Na^+-K^+-ATPase, decreasing cellular potassium uptake and normalizing intracellular $[K^+]$. The clinician should remember that this occurs only with effective osmoles, such as with mannitol, or with hyperglycemia in diabetic patients. Both glucose in patients with intact insulin secretion and urea are "ineffective osmoles" because they rapidly cross plasma membranes and therefore do not alter cell volume. Importantly, administration of a glucose load to a nondiabetic patient, through stimulation of endogenous insulin secretion, can cause insulin-induced cellular potassium uptake and result in hypokalemia.

Exercise may result in hyperkalemia due to α-adrenergic receptor activation that shifts potassium out of the skeletal muscle cells. The increased serum potassium induces arterial dilation, which increases skeletal muscle blood flow and acts as an adaptive mechanism during exercise. Simultaneous β_2-adrenoceptor activation stimulates

Potassium Content of Select High-Potassium Foods

skeletal muscle cellular potassium uptake and minimizes the severity of exercise-induced hyperkalemia, but this can lead to hypokalemia after cessation of exercise. In patients with preexisting potassium depletion, postexercise hypokalemia may be severe and can cause rhabdomyolysis.[6]

Renal Potassium Handling with Normal Renal Function

Long-term potassium homeostasis is accomplished primarily through changes in renal potassium excretion, almost entirely through regulated collecting duct potassium transport. Serum potassium is almost completely ionized, is not bound to plasma proteins, and is filtered efficiently by the glomerulus (Fig. 9-2). The proximal tubule reabsorbs the majority (~65% to 70%) of filtered potassium, but there is relatively little variation in proximal tubule potassium reabsorption in response to hypokalemia or hyperkalemia. In the loop of Henle, potassium is secreted in the descending loop, at least in deep nephrons, and is reabsorbed in the ascending loop through the action of the Na^+-K^+-$2Cl^-$ cotransporter (Fig. 9-3, *A*). However, the majority of K^+ transported by this protein is recycled back into the tubular lumen through an apical K^+ channel. As a result, there is only modest net potassium reabsorption in the Henle loop. This absorption can be reversed to secretion, however, by administration of a loop diuretic or by substantial potassium

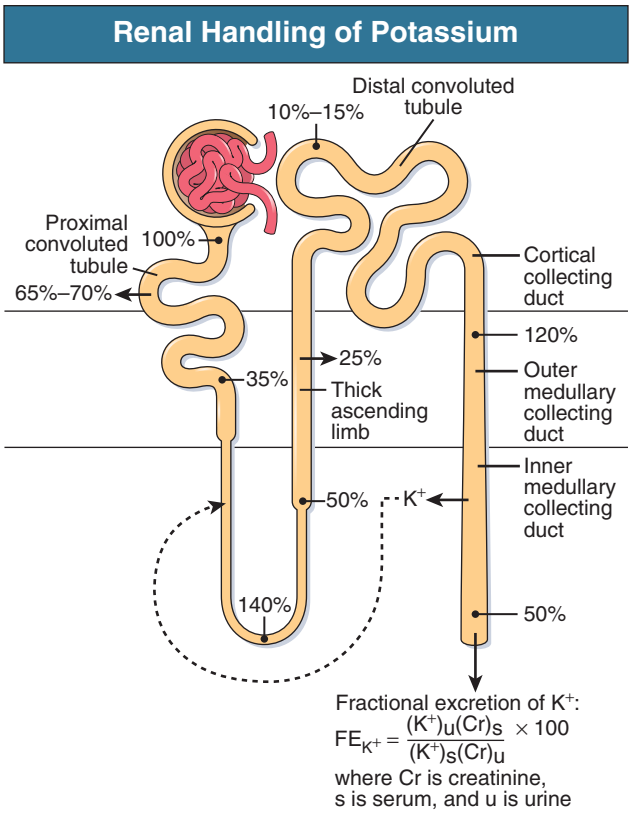

Figure 9-2 **Renal handling of potassium.**

loading. However, the magnitude of the change in Henle loop potassium transport in various physiologic conditions is rather small. Consequently, potassium excretion is regulated under most conditions through variations in distal convoluted tubule and collecting duct potassium transport.

The collecting duct consists of two fundamentally different cell types with distinctly different roles in potassium transport. The principal cell in the cortical collecting duct secretes potassium, whereas intercalated (IC) cells appear to reabsorb potassium. In the principal cell, sodium is reabsorbed through the apical epithelial sodium channel (ENaC), which stimulates basolateral Na^+-K^+-ATPase (Fig. 9-3, *B*); active potassium uptake by this protein maintains a high intracellular [K^+]. Subsequent to basolateral potassium uptake, K^+ is secreted across the apical plasma membrane of principal cells into the luminal fluid by apical potassium channels and KCl cotransporters. IC cells, in contrast, reabsorb potassium through an apical H^+-K^+-ATPase[7] (Fig. 9-3, *C*); this protein actively secretes H^+ into the luminal fluid in exchange for reabsorption of luminal potassium. The presence of two separate potassium transport processes, secretion by principal cells and reabsorption by IC cells, enables rapid and effective regulation of renal potassium excretion.

Several factors regulate principal cell potassium secretion and, in relative order of importance, include luminal flow rate, distal sodium delivery, aldosterone, extracellular potassium, and extracellular pH. An increase in luminal flow rate reduces luminal [K^+], thereby increasing the concentration gradient across the apical membrane, which stimulates potassium secretion. In addition, flow rate directly influences cellular potassium secretion, possibly by modulating the activity of potassium channels. Conversely, reduced luminal flow, such as occurs in pre-renal azotemia and obstruction, may result in hyperkalemia. Decreased sodium reabsorption, whether from reduced luminal sodium delivery or sodium channel inhibitors, decreases K^+ secretion by altering electrochemical forces for K^+ secretion. "Potassium-sparing diuretics" function by blocking principal cell ENaC-mediated sodium reabsorption, which inhibits principal cell potassium secretion. Conversely, increased sodium delivery to the collecting duct, as may occur with loop or thiazide diuretics, increases principal cell sodium reabsorption and causes a secondary increase in potassium secretion. Aldosterone has many effects that increase principal cell potassium secretion, including increases in Na^+-K^+-ATPase expression and increased apical expression of eNaC. The net effect is increased K^+ secretion. Increasing extracellular potassium directly stimulates Na^+-K^+-ATPase activity, leading to increased K^+ secretion. Metabolic acidosis decreases K^+ secretion, both through direct effects on potassium channels and through changes in interstitial ammonia concentration, which decreases K^+ secretion.[8] Respiratory acidosis has minimal effect on K^+ secretion, whereas chronic respiratory alkalosis causes marked increases in K^+ excretion because of increases in urinary bicarbonate excretion.

Potassium reabsorption, which occurs in parallel with potassium secretion, decreases net renal K^+ excretion, and occurs through the action of the potassium-reabsorbing protein, H^+-K^+-ATPase. The major factors regulating H^+-K^+-ATPase expression and activity include potassium balance, aldosterone, and acid-base status. Potassium depletion increases H^+-K^+-ATPase expression, resulting in increased active potassium reabsorption and decreased potassium excretion. Aldosterone also increases H^+-K^+-ATPase expression and activity and, by decreasing net potassium excretion, may function to minimize the hypokalemia that otherwise results from aldosterone's effect on both potassium redistribution and principal cell–mediated K^+ secretion. Metabolic acidosis has both direct and indirect effects, mediated through alterations in ammonia metabolism, that increase H^+-K^+-ATPase potassium transport. In some patients, this may contribute to the hyperkalemia that can occur with metabolic acidosis.

An important class of intracellular signaling proteins have been identified that are fundamental in the regulation of renal K^+ transport in the distal nephron. The "with no lysine" or "WNK" kinases are a family of proteins expressed in many cells of the body including the kidney. Under basal conditions, WNK kinases inhibit Na^+ reabsorption as well as decreasing potassium secretion, in part by inhibiting the rectifying renal outer medulla potassium (ROMK) channel. Genetic defects that inactivate WNK kinases result in enhanced Na^+ reabsorption and reduced K^+ secretion.

Renal Potassium Handling in Chronic Kidney Disease

Potassium homeostasis is relatively well preserved and serum potassium usually remains in the normal range until glomerular filtration rate is reduced substantially. This adaptation is due largely to increased rates of per nephron potassium excretion in the connecting segment and the collecting duct. Both aldosterone and an increase in serum potassium may contribute to this adaptation. Intestinal potassium secretion increases, also, although quantitatively this is less important.

Patients with chronic kidney disease (CKD) have more difficulty handling an acute potassium load, even when they have a normal serum [K^+]. Because these patients have decreased nephron number, their maximal capacity for K^+ secretion is limited. Patients with CKD are also routinely treated with medications that alter renal potassium handling, such as angiotensin-converting enzyme (ACE) inhibitors, angiotensin receptor blockers (ARBs), and β-blockers. These can decrease renal potassium sensitivity and result in higher serum potassium concentrations.

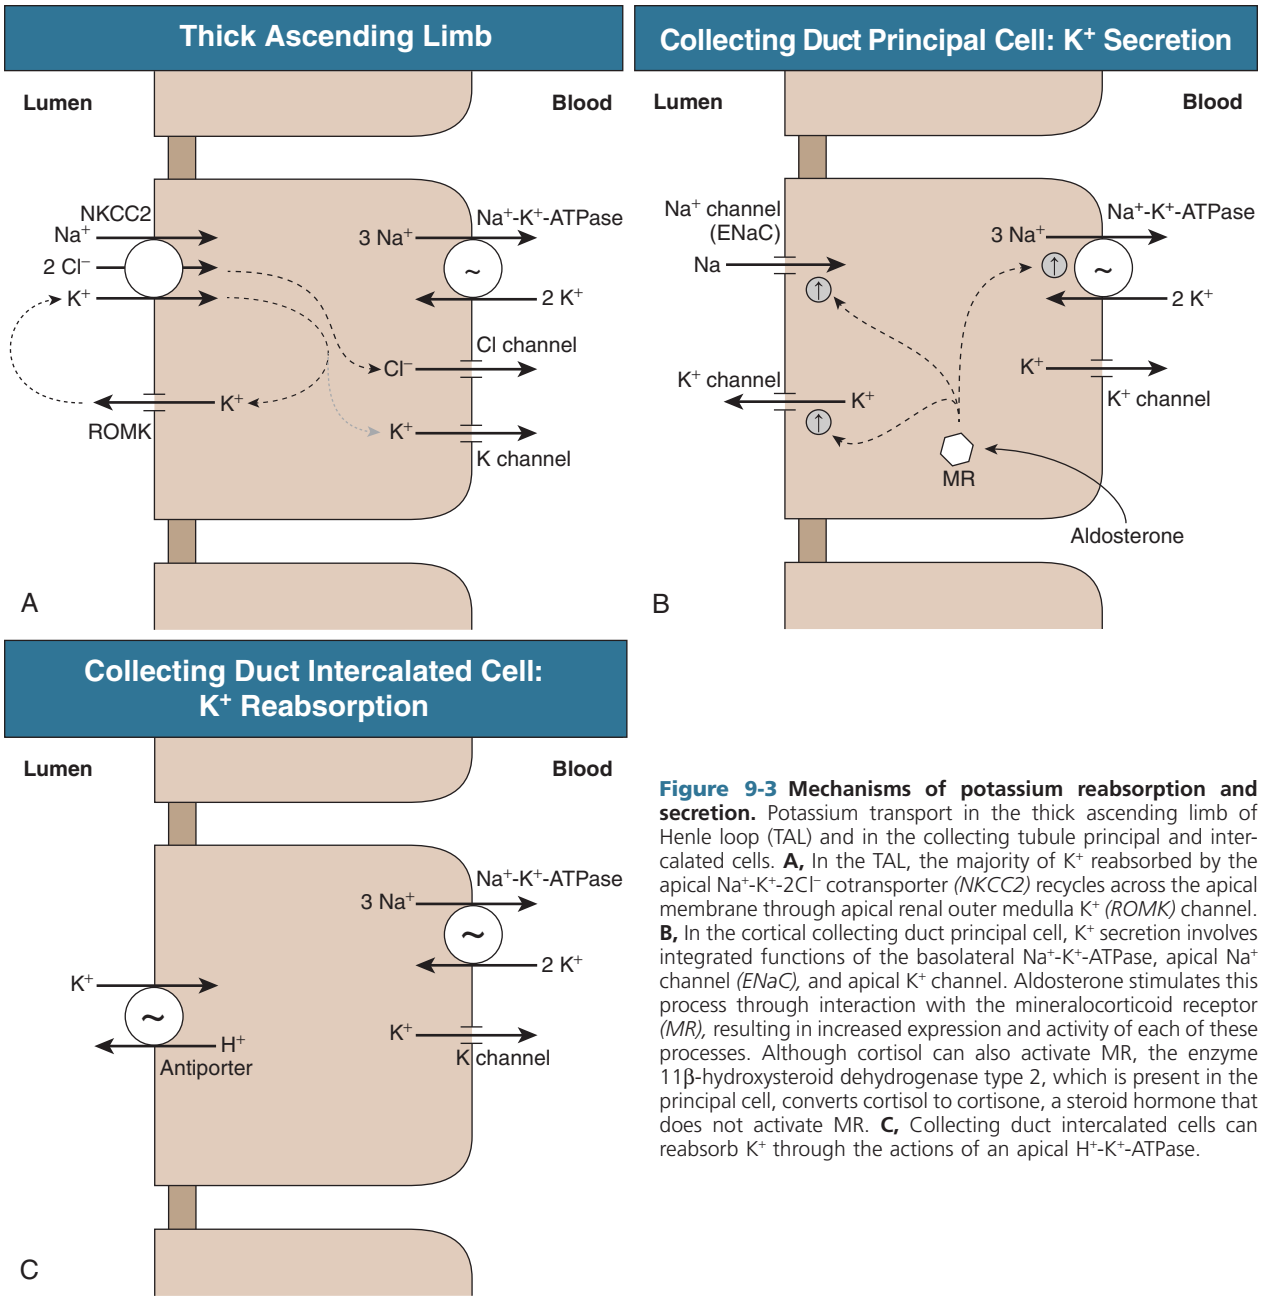

Figure 9-3 Mechanisms of potassium reabsorption and secretion. Potassium transport in the thick ascending limb of Henle loop (TAL) and in the collecting tubule principal and intercalated cells. **A,** In the TAL, the majority of K^+ reabsorbed by the apical Na^+-K^+-$2Cl^-$ cotransporter *(NKCC2)* recycles across the apical membrane through apical renal outer medulla K^+ *(ROMK)* channel. **B,** In the cortical collecting duct principal cell, K^+ secretion involves integrated functions of the basolateral Na^+-K^+-ATPase, apical Na^+ channel *(ENaC),* and apical K^+ channel. Aldosterone stimulates this process through interaction with the mineralocorticoid receptor *(MR),* resulting in increased expression and activity of each of these processes. Although cortisol can also activate MR, the enzyme 11β-hydroxysteroid dehydrogenase type 2, which is present in the principal cell, converts cortisol to cortisone, a steroid hormone that does not activate MR. **C,** Collecting duct intercalated cells can reabsorb K^+ through the actions of an apical H^+-K^+-ATPase.

Patients with CKD generally tolerate hyperkalemia with fewer cardiac and electrocardiographic (ECG) abnormalities than do patients with normal renal function. The mechanism of this adaptation is incompletely understood. In particular, patients with CKD appear to tolerate serum [K^+] of 5.0 to 5.5 mmol/l with no significant adverse effect, and levels of 5.5 to 6.0 mmol/l are associated with lower mortality than [K^+] of 3.5 to 3.9 mmol/l.[9] Nevertheless, severe hyperkalemia (>6.0 mmol/l or presence of ECG changes) can have lethal effects and should be treated aggressively.

HYPOKALEMIA

Epidemiology

The incidence of potassium disorders depends greatly on the patient population. Less than 1% of adults with normal renal function who are not receiving medicines develop hypokalemia or hyperkalemia; however, diets with high sodium and low potassium content may lead to potassium depletion. Thus, identification of hypokalemia or hyperkalemia should suggest either that an underlying disease is present or that the individual is taking medications that alter potassium handling. For example, hypokalemia may be present in as many as half of patients taking diuretics[10] and is present frequently in patients with primary or secondary hyperaldosteronism.

Clinical Manifestations

Potassium deficiency, because it alters the ratio of extracellular to intracellular potassium, alters the resting membrane potential, which can impair normal functioning of almost every cell in the body. This particularly is true for cells in the heart and blood vessels, nerves, muscles, gut, and kidneys. Overall, children and young adults

tolerate hypokalemia better than elderly persons. Prompt correction is warranted in patients with coronary heart disease or in patients receiving digitalis glycosides, because of an increased risk of lethal cardiac arrhythmias.

Cardiovascular

Epidemiologic studies link hypokalemia and a low-potassium diet with an increased prevalence of hypertension. Experimental studies show that hypokalemia increases blood pressure by 5 to 10 mm Hg, and that potassium supplementation can lower blood pressure by a similar amount.[11] Potassium deficiency increases blood pressure through multiple mechanisms, including stimulating sodium retention and causing intravascular volume expansion, and by sensitizing the vasculature to endogenous vasoconstrictors.[11] In part, sodium retention is related to decreased expression of the kidney-specific isoform of WNK1, which leads to increased NaCl cotransporter (NCC)–mediated and ENaC-mediated sodium reabsorption in the distal convoluted tubule and cortical collecting duct, respectively.[12]

Hypokalemia increases the risk of a variety of ventricular arrhythmias, including ventricular tachycardia and ventricular fibrillation.[13] Diuretic-induced hypokalemia is of particular concern, because sudden cardiac death may occur more frequently in those treated with thiazide diuretics.[13] Ventricular arrhythmias are also more common in patients receiving digoxin.

Hormonal

Hypokalemia both impairs insulin release and induces insulin resistance, resulting in worsened glucose control in diabetic patients.[14] The insulin resistance that usually occurs with thiazide diuretic therapy is caused by endothelial dysfunction mediated by thiazide-induced hypokalemia and hyperuricemia.[15,16]

Muscular

Hypokalemia hyperpolarizes skeletal muscle cells, thereby impairing muscle contraction. Hypokalemia also reduces skeletal muscle blood flow, possibly by impairing local nitric oxide release; this effect can predispose patients to rhabdomyolysis during vigorous exercise.[17]

Renal

Hypokalemia leads to several important disturbances of renal function. Reduced medullary blood flow and increased renal vascular resistance may predispose to hypertension, tubulointerstitial and cystic changes, alterations in acid-base balance, and impairment of renal concentrating mechanisms.

Potassium depletion causes tubulointerstitial fibrosis that is generally greatest in the outer medulla. The degree of reversibility is related to the duration of hypokalemia, and if prolonged, hypokalemia may result in renal failure. Experimental studies suggest increased risk for irreversible renal injury when hypokalemia is present during the neonatal period.[18] Longstanding potassium depletion also causes renal hypertrophy and predisposes to renal cyst formation, particularly when there is increased mineralocorticoid activity.

Metabolic alkalosis is a common acid-base consequence of potassium depletion and results from increased renal net acid excretion caused by increased renal ammonia excretion.[19] Conversely, *metabolic alkalosis* may increase renal potassium excretion and cause potassium depletion. Severe hypokalemia can lead to respiratory muscle weakness and development of respiratory acidosis.

Severe hypokalemia also impairs concentrating ability, causing mild polyuria, typically 2 to 3 l/day. Both increased thirst and mild nephrogenic diabetes insipidus contribute to the polyuria.[20] The nephrogenic diabetes insipidus is caused by decreased expression of several proteins, such as the water transporter aquaporin 2 (AQP2), and the urea transporters UT-A1, UT-A3, and UT-B, which are involved in urine concentration and water reabsorption.

Hypokalemia has substantial effects to increase renal ammonia production. Some ammonia is excreted in the urine, increasing net acid excretion and leading to development of metabolic alkalosis. In addition, approximately half of this increase returns to the systemic circulation via the renal veins. In patients with acute or chronic liver disease, this increased ammonia delivery may exceed hepatic ammonia clearance capacity, increase plasma ammonia levels, and either precipitate or worsen hepatic encephalopathy.[21]

Etiology

Hypokalemia results typically from one of four etiologies: pseudohypokalemia, redistribution, extrarenal potassium loss, or renal potassium loss. However, multiple etiologies may coexist in the specific patient.

Pseudohypokalemia

Pseudohypokalemia refers to the condition in which serum potassium decreases, artifactually, following phlebotomy. The most common cause is acute leukemia; the large numbers of abnormal leukocytes take up potassium when the blood is stored in a collection vial for prolonged periods at room temperature. Rapid separation of plasma and storage at 4°C is used to confirm this diagnosis and should be used for subsequent testing once pseudohypokalemia is diagnosed, to avoid this artifact leading to inappropriate treatment.

Redistribution

Because less than 2% of total body potassium is in the ECF compartment, quantitatively small potassium shifts from the ECF to the ICF compartment can result in substantial hypokalemia. As previously discussed, many hormones, particularly including insulin, aldosterone, and β_2-adrenergic agonists, stimulate transcellular potassium uptake.

A rare but important cause of redistribution-induced hypokalemia is *hypokalemic periodic paralysis*.[22] In this condition, attacks characterized by flaccid paralysis or severe muscular weakness typically occur during the night or the early morning, or after a carbohydrate-rich meal, and persist for 6 to 24 hours. A genetic defect in a dihydropyridine-sensitive calcium channel has been identified in some patients,[23] whereas other cases are associated with hyperthyroidism.

Nonrenal Potassium Loss

The skin and the GI tract excrete small amounts of potassium under normal circumstances. Occasionally, excessive sweating or chronic diarrhea results in substantial potassium loss and leads to hypokalemia.[24] Vomiting or nasogastric suction may also result in loss of potassium, although gastric fluids typically contain only 5 to 8 mmol/l of potassium. However, the concomitant metabolic alkalosis and the intravascular volume depletion results in secondary hyperaldosteronism that can increase urinary potassium loss and contribute to development of hypokalemia.[24]

Renal Potassium Loss

The most common cause of hypokalemia is renal potassium loss, resulting from medications, endogenous hormone production, or rarely intrinsic renal defects.

Medications Both thiazide and loop diuretics increase urinary potassium excretion, and the incidence of diuretic-induced hypokalemia is related to both dose and treatment duration. If the effect of

loop and thiazide diuretics on sodium excretion is compared and adjusted, thiazide diuretics actually cause more urinary potassium loss than loop diuretics. Certain antibiotics increase urinary potassium excretion. Some penicillin analogues, such as piperacillin/tazobactam, increase distal tubular delivery of a non-reabsorbable anion, which obligates the presence of a cation such as potassium, thereby increasing urinary potassium excretion.[25] The antifungal agent amphotericin B directly increases collecting duct potassium secretion.[26] Aminoglycosides may cause hypokalemia either with or without simultaneous nephrotoxicity. The mechanism is incompletely understood but may relate to magnesium depletion (see later discussion). Cisplatin is a common antineoplastic agent that can induce hypokalemia. Toluene exposure, from sniffing certain glues, can also cause renal tubular acidosis with renal potassium wasting, leading to hypokalemia.[27] In addition, certain herbal products, including herbal cough mixtures, licorice tea, licorice root, and gan cao, contain glycyrrhizic and glycyrrhetinic acids, which have mineralocorticoid-like effects.[28]

Endogenous Hormones Endogenous hormones are important and common causes of hypokalemia. Aldosterone is the most important hormone regulating total body potassium homeostasis. Aldosterone causes hypokalemia both by stimulating potassium uptake into cells and by stimulating renal potassium excretion. Primary aldosteronism is a common cause of hypokalemia (see Chapter 40).

Genetic Causes Genetic defects leading to excessive aldosterone production are occasionally seen as causes of renal potassium wasting (see Chapter 49). *Glucocorticoid-remediable aldosteronism* (GRA) is a condition in which a corticotropin (ACTH)–regulated promoter is linked to the gene for aldosterone synthase, the rate-limiting enzyme for aldosterone synthesis.[29] As a result, aldosterone synthase expression is regulated by ACTH, leading to excessive aldosterone synthase expression and the development of severe hyperaldosteronism. In *congenital adrenal hyperplasia,* there is persistent adrenal synthesis of 11-deoxycorticosterone, a potent mineralocorticoid.[30] This condition can be recognized by the associated effects on sex steroid production.

Genetic defects can also lead to abnormal activation of the mineralocorticoid receptor, resulting in the same clinical manifestations as excessive aldosterone production. The glucocorticoid hormone cortisol can activate the mineralocorticoid receptor. Under normal conditions, the enzyme 11β-hydroxysteroid dehydrogenase, type 2 (11β-HSDH-2) rapidly metabolizes cortisol to cortisone, thereby preventing inappropriate mineralocorticoid receptor activation.[31] If this does not occur, glucocorticoid hormones are able to activate mineralocorticoid receptors. Genetic deficiency of 11β-HSDH-2 is rare, but leads to severe hypertension and hypokalemia. Some compounds, such as glycyrrhetinic acid, found in some chewing tobacco and licorice preparations, inhibit 11β-HSDH-2, allowing cortisol to exert mineralocorticoid-like effects.[32] Also, in severe Cushing syndrome circulating cortisol levels can exceed the metabolic capacity of 11β-HSDH-2, resulting in mineralocorticoid receptor activation and hypokalemia.[33]

Magnesium Depletion Magnesium deficiency inhibits renal potassium retention and causes inappropriately high renal potassium excretion despite hypokalemia.[34] This occurs most frequently as a complication of prolonged diuretic use and can also result from aminoglycoside- and cisplatin-induced renal toxicity. Magnesium deficiency should be suspected when potassium replacement does not correct hypokalemia; treatment with magnesium replacement generally reverses the potassium wasting.

Intrinsic Renal Defect Intrinsic renal potassium transport defects leading to hypokalemia are rare but have led to important advances in our understanding of renal solute transport. *Bartter syndrome* is characterized by hypokalemia, reduced blood pressure, hyperreninemia, metabolic alkalosis, and hypercalciuria. Patients with Bartter syndrome typically develop clinical manifestations at a young age, which include severe volume depletion and growth retardation. Bartter syndrome results from genetic abnormalities in any of several proteins involved in sodium and potassium transport in the thick ascending limb of the loop of Henle.[35] *Gitelman syndrome* is similar to Bartter syndrome, except patients have hypocalciuria and milder clinical manifestations and are usually diagnosed later in life. Gitelman syndrome results from genetic abnormalities in the proteins involved in distal convoluted tubule sodium and potassium transport.[36] When Bartter or Gitelman syndrome is suspected, it is critical to evaluate the patient for surreptitious diuretic use, because loop and thiazide diuretics give the same clinical phenotype as Bartter and Gitelman syndrome, respectively. *Liddle syndrome* is characterized by severe hypertension, hypokalemia and suppressed renin and aldosterone levels. Liddle syndrome is caused by a mutation that increases collecting duct ENaC expression and activity, leading to excessive sodium reabsorption, potassium excretion, volume expansion, and hypertension.[37] (See Chapter 49.)

Bicarbonaturia Bicarbonaturia can result from metabolic alkalosis, distal renal tubular acidosis, or treatment of proximal renal tubular acidosis. In each case, the increased distal tubular bicarbonate delivery increases potassium secretion.

Diagnostic Evaluation

The evaluation of hypokalemia is summarized in Figure 9-4. The nephrologist should first consider the possibility of either pseudohypokalemia or potassium redistribution from the extracellular to the intracellular space. Insulin, aldosterone, and its synthetic analogue, fludrocortisone, and sympathomimetic agents such as theophylline and β_2-adrenoceptor agonists are common causes of potassium redistribution. In the hypertensive patient, frank hypokalemia in the absence of diuretic use or substantial hypokalemia with diuretic use should suggest primary aldosteronism.

If neither pseudohypokalemia nor potassium redistribution is present, the hypokalemia represents total body potassium depletion caused by renal, GI, or skin losses. Renal potassium loss is most frequently caused by diuretics or metabolic alkalosis. Hypomagnesemia-induced hypokalemia causes renal potassium wasting and is frequently a complication of diuretic use. Rarer causes of renal potassium loss include renal tubular acidosis, diabetic ketoacidosis, and ureterosigmoidostomy. Primary aldosteronism, surreptitious diuretic use or vomiting, concomitant magnesium depletion, and Bartter or Gitelman syndrome should be considered when the cause of the hypokalemia is not obvious. Lastly, excessive potassium loss may result from the skin through excessive sweating or from diarrhea, vomiting, nasogastric suction, or GI fistula. Occasionally, patients are reluctant to admit to self-induced diarrhea, and the diagnosis may need to be confirmed by sigmoidoscopy or direct testing of the stool for cathartic agents.

Treatment

As with any condition, the risks associated with untreated or slowly treated hypokalemia must be balanced against the risks of therapy. Usually, the primary short-term risks are cardiovascular arrhythmias and neuromuscular weakness. Overaggressive therapy can cause acute hyperkalemia, which can cause ventricular fibrillation and sudden death.

Conditions requiring urgent therapy are rare. The clearest indications are hypokalemic periodic paralysis, severe hypokalemia in a

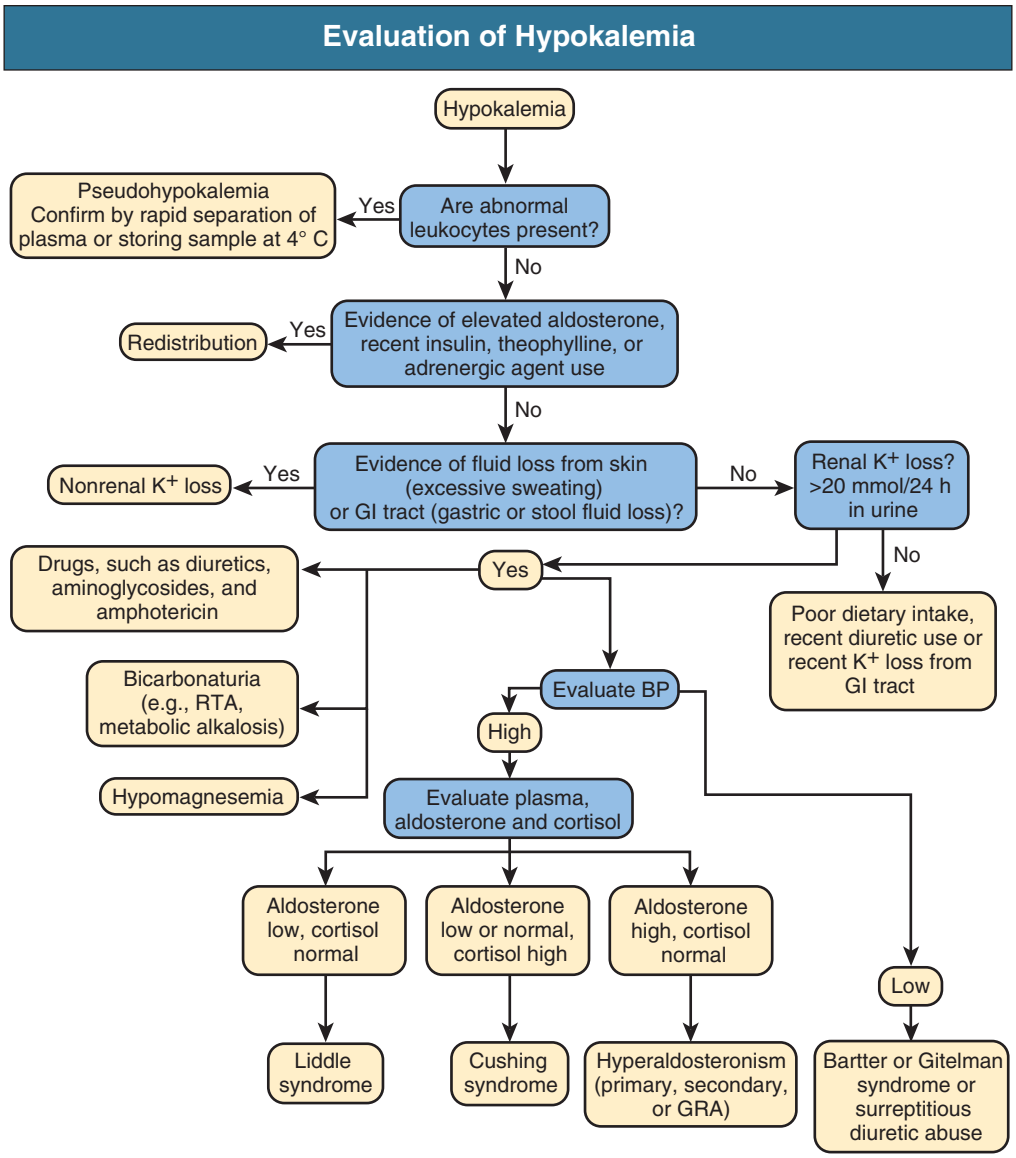

Figure 9-4 Diagnostic evaluation of hypokalemia. *BP,* Blood pressure; *GI,* gastrointestinal; *GRA,* glucocorticoid-remediable aldosteronism; *RTA,* renal tubular acidosis.

patient requiring urgent surgery, and the patient with an acute myocardial infarction and significant ventricular ectopy. In these patients, potassium chloride (KCl) can be administered intravenously at a dose of 5 to 10 mmol over 15 to 20 minutes. This dose can be repeated as needed. Close, continuous monitoring of the serum [K^+] and the electrocardiogram are necessary to reduce the risk of potentially lethal acute hyperkalemia.

In the great majority of hypokalemic patients, emergency therapy is not necessary, and instead a slower approach to replacing the potassium deficit is appropriate. In doing so, it is important to recognize that the amount of potassium required may be much greater than predicted from the deficit in serum potassium concentration. This occurs because the body responds to chronic hypokalemia resulting from potassium losses by shifting potassium from ICF to ECF compartment, thereby minimizing the change in extracellular [K^+]. Consequently, the amount of potassium replacement needed is much greater than predicted by the change in extracellular [K^+] and the ECF volume (Fig. 9-5).

Potassium replacement can be given through the intravenous (IV) or oral (PO) route. Oral or enteral administration is preferred if the patient can take oral medication and has normal GI tract function. Acute hyperkalemia is highly unusual when potassium is given orally. This reflects several factors, most prominently gut sensors that minimize changes in serum potassium levels. When potassium is given intravenously, acute hyperkalemia can occur if the IV rate is too rapid and can cause sudden cardiac death. IV replacement can be given safely at a rate of 10 mmol KCl/h. Although significant variations can occur between patients, IV administration of 20 mmol KCl typically increases the serum potassium by about 0.25 mmol/l.[38] If more rapid replacement is necessary, 20 or 40 mmol/h can be administered through a central venous catheter, but continuous ECG monitoring should be used under these circumstances.

The parenteral fluids used for potassium administration can affect the response. In patients without diabetes mellitus, dextrose administration increases serum insulin levels, which causes redistribution

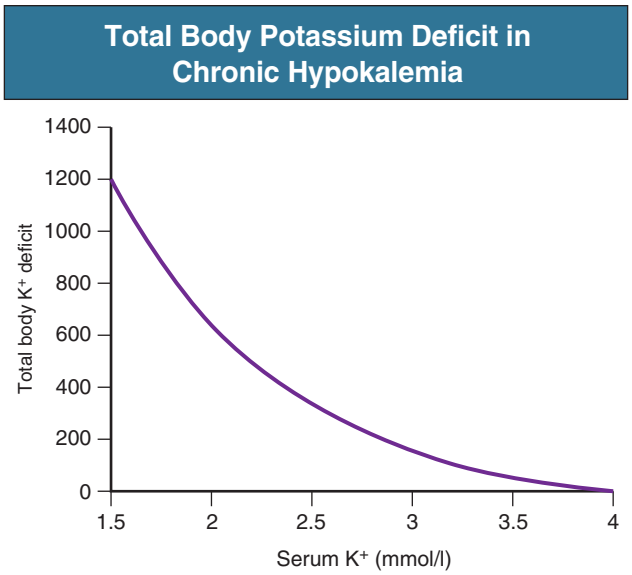

Figure 9-5 Total body potassium deficit in hypokalemia. Because of shift of potassium from the intracellular fluid (ICF) to the extracellular fluid (ECF) compartment during chronic potassium depletion, the magnitude of deficiency can be masked and is generally much larger than would be calculated solely from the ECF volume and the change in serum potassium.

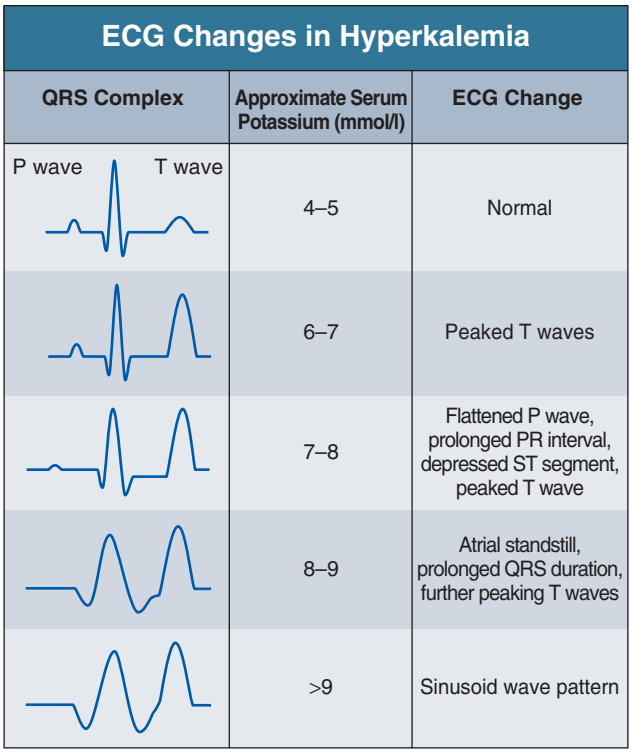

Figure 9-6 Electrocardiographic (ECG) changes in hyperkalemia. Progressive hyperkalemia results in identifiable changes in the electrocardiogram. These include peaking of the T wave, flattening of the P wave, prolongation of the PR interval, depression of the ST segment, prolongation of the QRS complex, and eventually, progression to a sine wave pattern. Ventricular fibrillation may occur at any time during this ECG progression.

of potassium from ECF to ICF compartment. As a result, if KCl is administered in dextrose-containing solutions such as 5% dextrose in water (D5W), the dextrose load may actually stimulate cellular potassium uptake to an extent that exceeds the KCl replacement rate, resulting, paradoxically, in worsening of the hypokalemia.[39] Consequently, parenteral KCl should be administered in dextrose-free solutions.

The underlying condition should be treated whenever possible. If patients with diuretic-induced hypokalemia require ongoing diuretic administration, addition of potassium-sparing diuretics may be considered. When oral replacement therapy is required, KCl is the preferred drug in all patients, except those with metabolic acidosis, in whom potassium citrate may be considered as a concomitant alkali source. If clinically indicated for other reasons, the use of β-blockers, ACE inhibitors, or ARBs can assist in maintaining serum potassium levels.

Hypomagnesemia can lead to refractoriness to potassium replacement because of inability of the kidneys to decrease potassium excretion.[34] Correction of the hypokalemia may not occur until the hypomagnesemia is corrected. Patients with unexplained hypokalemia or with diuretic-induced hypokalemia should have serum magnesium checked and, if indicated, magnesium replacement therapy instituted, usually with $MgSO_4$, and periodic measurement of serum $[Mg^{2+}]$.

HYPERKALEMIA

Epidemiology

Hyperkalemia is distinctly unusual in healthy individuals, with less than 1% of normal healthy adults developing hyperkalemia in the absence of significant underlying disease or medication use. This low frequency is a testament to the potent renal mechanisms for potassium excretion. Accordingly, hyperkalemia should suggest an underlying impairment of renal potassium excretion. Rarely, pseudohyperkalemia or a condition that shifts potassium from intracellular to extracellular space is present.

Clinical Manifestations

Hyperkalemia can be asymptomatic, can cause mild symptoms, or can be life threatening. Importantly, the mortality risk of hyperkalemia is independent of the patient's clinical symptoms and reflects acute effects of hyperkalemia on cardiac conduction. This is demonstrable on the electrocardiogram (Fig. 9-6). The initial effect of hyperkalemia is a generalized increase in the height of the T waves, most evident in the precordial leads, but typically present in all leads, which is known as "tenting." More severe hyperkalemia is associated with delayed electrical conduction, resulting in an increased PR interval and a widened QRS complex. This is followed by progressive flattening and eventual absence of the P waves. Under extreme conditions, the QRS complex widens sufficiently that it merges with the T wave, resulting in a sine-wave pattern. Finally, ventricular fibrillation develops. Although the ECG findings correlate generally with the degree of hyperkalemia, the rate of progression from mild to severe cardiac effects may be unpredictable and may not correlate well with changes in the serum potassium concentration.

Hyperkalemia also affects muscular contraction. Skeletal muscle cells are particularly sensitive to hyperkalemia, causing weakness ("rubbery" or "spaghetti" legs). In patients with severe hyperkalemia, respiratory failure may occur from paralysis of the diaphragm.

Etiology

Hyperkalemia can result from pseudohyperkalemia, potassium redistribution from intracellular to extracellular space, or imbalances between potassium intake and renal potassium excretion. A diagnostic approach is shown in Figure 9-7.

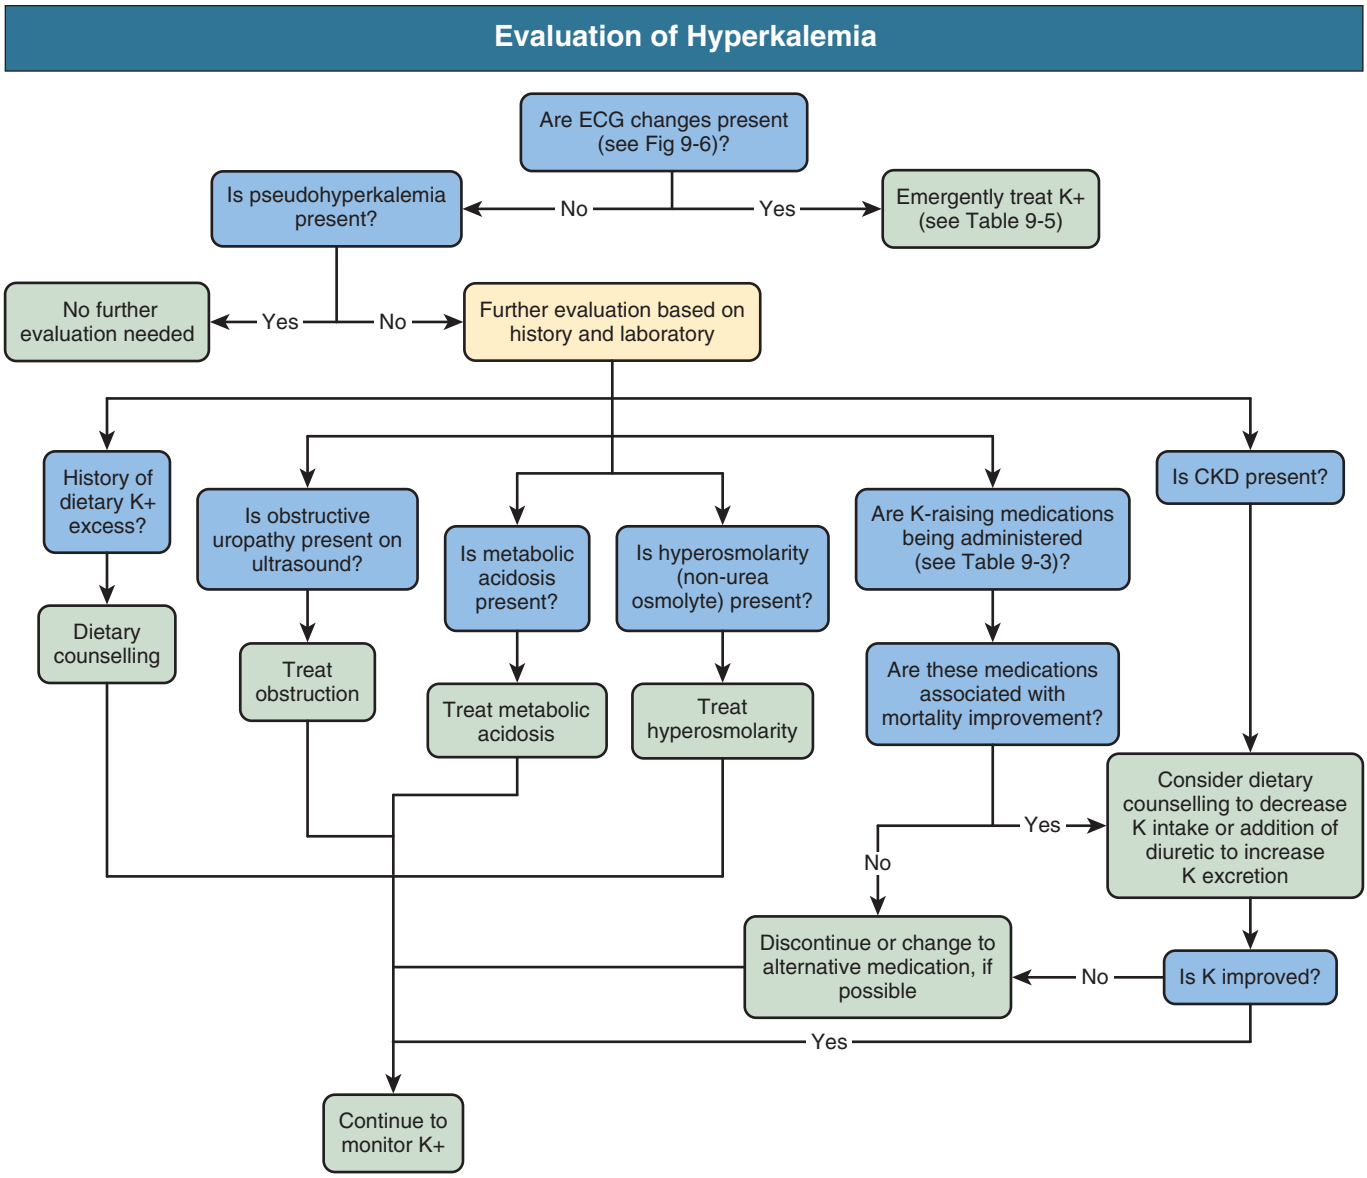

Figure 9-7 Workup of hyperkalemia. *CKD,* Chronic kidney disease.

Pseudohyperkalemia

Pseudohyperkalemia refers to the condition of potassium release from cellular elements in the blood occurring after the phlebotomy procedure. The most common cause of pseudohyperkalemia is potassium release from damaged erythrocytes. This is identified clinically by the presence of free hemoglobin in the plasma, reported as "hemolysis" by most clinical laboratories. If hemolysis is present, the serum $[K^+]$ cannot be accurately assessed, and a repeat measurement is necessary. Ischemia from prolonged tourniquet time or exercise of the limb in the presence of a tourniquet can also lead to abnormally increased potassium values. Pseudohyperkalemia may also occur with hemolysis in patients with rheumatoid arthritis or infectious mononucleosis, as well as in families who have abnormal red blood cell (RBC) membrane potassium permeability. Potassium can also be released from the other cellular elements present in blood during clotting. This can occur in patients with severe leukocytosis (>70,000/cm^3) or thrombocytosis. About one third of patients with platelet counts of 500 to 1000 × 10^9/l exhibit pseudohyperkalemia.

Pseudohyperkalemia is diagnosed by showing that the serum $[K^+]$ is more than 0.3 mmol/l higher than in a simultaneous plasma sample. If not caused by hemolysis, future potassium levels may need to be measured in plasma samples to allow accurate measurement of extracellular $[K^+]$.

Redistribution

Redistribution of potassium from ICF to ECF compartment can result in rapid development of hyperkalemia. This may occur with severe hyperglycemia (from development of hyperosmolarity), in association with severe nonorganic acidosis, and rarely with β-blockers. Patients who have received mannitol may also develop hyperosmolarity-induced hyperkalemia. Digoxin overdose can block cellular potassium uptake and lead to hyperkalemia that requires rapid treatment.

Excess Intake

Excessive potassium ingestion generally does not lead to hyperkalemia unless other contributing factors are present. Under normal conditions, the kidney has the capacity to excrete several multiples of the mean daily potassium intake. However, if renal potassium excretion is impaired, as from medications, acute kidney injury

Medications Associated with Hyperkalemia		
Class	**Mechanism**	**Representative Example(s)**
Potassium-containing drugs	Increased potassium intake	KCl, PCN G, Na citrate, K citrate
β-Adrenergic receptor blockers (β-blockers)	Inhibit renin release	Propranolol, metoprolol, atenolol
Angiotensin-converting enzyme (ACE) inhibitors	Inhibit conversion of angiotensin I to angiotensin II	Captopril, lisinopril
Angiotensin receptor blockers (ARBs)	Inhibit activation of AT_1 receptor by angiotensin II	Losartan, valsartan, irbesartan
Direct renin inhibitors	Inhibit renin activity, leading to decreased angiotensin II production	Aliskiren
Heparin	Inhibit aldosterone synthase, rate-limiting enzyme for aldosterone synthesis	Heparin sodium
Aldosterone receptor antagonists	Block aldosterone receptor activation	Spironolactone, eplerenone
Potassium-sparing diuretics	Block collecting duct apical ENaC Na channel, decreasing gradient for K^+ secretion	Amiloride, triamterene; certain antibiotics, specifically trimethoprim and pentamidine
NSAIDs and COX-2 inhibitors	Inhibit prostaglandin stimulation of collecting duct K^+ secretion; inhibit renin release	Ibuprofen
Digitalis glycosides	Inhibit Na^+, K^+-ATPase necessary for collecting duct K^+ secretion and regulation of K^+ distribution into cells	Digoxin
Calcineurin inhibitors	Inhibit Na^+, K^+-ATPase necessary for collecting duct K^+ secretion	Cyclosporine, tacrolimus

Table 9-3 Classes of medications associated with hyperkalemia. *NSAIDs,* Nonsteroidal anti-inflammatory drugs, *COX-2,* cyclooxygenase-2.

(AKI), or CKD, excessive potassium intake can contribute to the development of hyperkalemia.

Common sources of excess potassium intake are potassium supplements, salt substitutes, enteral nutrition products, and several common foods. As many as 4% of patients receiving potassium supplements develop hyperkalemia. "Salt substitutes" contain an average of 10 to 13 mmol K/g. Many enteral nutrition products contain 40 mmol/l or more of KCl; administration of 100 ml/h of such products can result in a potassium intake of about 100 mmol/day. Also, many food products are particularly high in potassium (see Table 9-1). In some countries, pharmacies routinely label medication bottles containing diuretics with recommendations to increase intake of high-potassium dietary sources such as bananas.

Impaired Renal Potassium Secretion

The normal kidney possesses a remarkable ability to excrete potassium, so chronic hyperkalemia is difficult to produce unless renal potassium secretion is impaired. Factors that affect renal potassium excretion are classified into those resulting from reduced nephron number and those from intrinsic impairment of renal potassium handling.

Because the kidney is the primary organ regulating potassium excretion, impaired renal function decreases maximal potassium excretion. In the absence of other contributing factors, renal potassium excretion is moderately well preserved until glomerular filtration rate (GFR) is reduced to 10 to 20 ml/min. However, both CKD and AKI limit maximal renal potassium excretion. This factor is particularly important to consider in patients who are elderly or cachectic or have limb amputation, in whom low serum creatinine production rates lead to underestimation of the degree of renal impairment.

Obstructive uropathy leads frequently to hyperkalemia,[40] at least in part from decreased Na^+-K^+-ATPase expression and activity.[41] In many patients, hyperkalemia may persist for weeks following relief of the obstruction.

Specific Medicine The renin-angiotensin system (RAS) is the primary hormonal system regulating renal potassium excretion. Accordingly, medications that interfere with the RAS or that inhibit the cellular mechanisms of renal potassium excretion are frequent causes of hyperkalemia. Table 9-3 summarizes classes of medications that inhibit potassium secretion and their mechanism of action.

Intrinsic Renal Defect A rare genetic disorder, pseudohypoaldosteronism type 2 (PHA2), also known as *Gordon syndrome,* is characterized by hypertension, hyperkalemia, non–anion gap metabolic acidosis and normal GFR.[42] Mutations in either of two proteins, WNK1 or WNK4, increase sodium absorption and inhibit potassium secretion in the distal convoluted tubule and collecting duct and lead to this phenotype.[12,43] Recognizing this diagnosis can be particularly beneficial because patients typically respond to low doses of thiazide diuretics, with dramatic clinical improvement in both hyperkalemia and hypertension.

Distinguishing Between Renal and Nonrenal Mechanisms of Hyperkalemia

In most patients, a careful history and a 24-hour urine K^+ excretion rate will distinguish renal (K^+ <20 to 30 mmol/day) from extrarenal (K^+ >40 mmol/day) causes of hyperkalemia. In selected patients, assessment of the urine potassium–creatinine ratio in a random urine specimen may be used, with potassium excretion less than 20 to 30 mmol/g creatinine suggesting inadequate renal excretion in the patient with hyperkalemia. However, urinary K^+ measurements may be difficult to interpret, since K^+ excretion depends on multiple factors, including GFR, tubule lumen flow, and water reabsorption in the distal tubule and collecting duct. When urine K^+ is equivocal, the transtubular K^+ gradient (TTKG) may be informative (Table 9-4).

Treatment

Acute Therapy

Acute therapies for hyperkalemia are divided into those that minimize the cardiac effects of hyperkalemia, those that induce potassium uptake by cells resulting in a decrease in serum potassium, and those that remove potassium from the body (Table 9-5). Treatment

of hyperkalemia should not include sodium bicarbonate ($NaHCO_3$) therapy unless the patient is frankly acidotic (pH <7.2) or unless substantial endogenous renal function is present. Administering hypertonic $NaHCO_3$ (e.g., 50 mmol in 50 ml of sterile water) can worsen intravascular volume overload, as frequently seen in the patient with oliguric AKI; can cause acute hypernatremia; and in general, has minimal effect on serum potassium.[44]

Blocking Cardiac Effects Intravenous calcium administration specifically antagonizes the effects of hyperkalemia on the myocardial conduction system and on myocardial repolarization. Calcium is the most rapid way to stabilize the membrane voltage and treat the cardiac effects of hyperkalemia. Calcium should be given intravenously if unambiguous ECG changes of hyperkalemia are present. If the electrocardiogram is ambiguous, comparison to a previous ECG may be helpful. Patients with a prolonged PR interval, a widened QRS complex, or the absence of P waves should receive IV calcium without delay. Responses can occur within 1 to 3 minutes, but typically last for only 30 to 60 minutes. The dose may be repeated as needed if ECG changes persist or they recur. If a delay in more definitive therapy, such as institution of dialysis, is anticipated, a continuous calcium infusion can be used since the effect of a calcium bolus is transient.

Intravenous calcium is relatively safe if certain precautions are taken. IV calcium should not be administered in $NaHCO_3$-containing solutions because calcium carbonate ($CaCO_3$) precipitation can occur. Hypercalcemia, which occurs during rapid calcium infusion, can potentiate the myocardial toxicity of digoxin. Patients taking digoxin, particularly if they have evidence of digoxin toxicity as a contributing cause of hyperkalemia, should be given calcium as a slow infusion over 20 to 30 minutes. Calcium should be administered with caution in patients with advanced CKD or end-stage renal disease because these patients frequently have hyperphosphatemia, and increases in calcium could result in calcium phosphate deposition in many tissues, including the cardiac conduction system. The preferred calcium preparation is calcium gluconate. However, calcium chloride ($CaCl_2$) should be used in patients who have undergone cardiac arrest from hyperkalemia, because the active calcium is released immediately on infusion, unlike calcium gluconate, which requires liver metabolism to release the calcium.

Cellular Potassium Uptake The second most rapid way to treat hyperkalemia is to stimulate cellular potassium uptake, with either insulin or β_2-adrenergic agonist administration. Insulin rapidly stimulates cellular potassium uptake and should be administered through the IV, not the subcutaneous (SC), route to ensure rapid and predictable bioavailability. Insulin's effects on serum [K^+] are seen generally within 10 to 20 minutes and can last for 4 to 6 hours. Glucose is coadministered to avoid hypoglycemia but may not be needed if hyperglycemia coexists. This is particularly important because extracellular glucose in patients with diabetes mellitus can function as an "ineffective osmole" and can increase serum potassium. Conversely, in patients with impaired renal function, there is delayed insulin clearance, and hypoglycemia can result from IV insulin administration, even if glucose is coadministered, because glucose uptake may occur more rapidly than insulin clearance. Accordingly, patients given IV insulin for treatment of hyperkalemia should be closely monitored for the development of hypoglycemia. If dialysis is indicated and a delay in its initiation is anticipated, administering a continuous infusion of insulin, 4 to 10 U/h (with D10W) may be beneficial; periodic monitoring of serum glucose and potassium is required.

β_2-Adrenoceptor agonists directly stimulate cellular potassium uptake and can be administered through the IV, inhaled, or SC route.

Transtubular Potassium Gradient

TTKG is a measurement of net K^+ secretion by the distal nephron after correcting for changes in urinary osmolality and is often used to determine whether hyperkalemia is caused by aldosterone deficiency/resistance or whether the hyperkalemia is secondary to nonrenal causes. As with all diagnostic aids, clinical correlation is indicated, and potassium intake should be assessed.

TTKG = $(K_u/K_s) \times (S_{osm}/U_{osm})$, where K_u and K_s are the concentration of K^+ in urine and serum, respectively, and U_{osm} and S_{osm} are the osmolalities of urine and serum, respectively.

TTKG Value		Indication
6 to 12		Normal
>10		Suggests normal aldosterone action and extrarenal cause of hyperkalemia
<5 to 7		Suggests aldosterone deficiency or resistance
After 0.05 mg 9α-fludrocortisone	>10 No change	Hypoaldosteronism is likely. Suggests a renal tubule defect from either K^+-sparing diuretics (amiloride, triamterene, spironolactone), aldosterone resistance (interstitial renal disease, sickle cell disease, urinary tract obstruction, PHA1), or increased distal K^+ reabsorption (PHA2, urinary tract obstruction)

Table 9-4 Transtubular potassium gradient. *PHA1, PHA2,* Pseudohypoaldosteronism types 1 and 2.

Treatment of Hyperkalemia

Mechanism	Therapy	Dose	Onset	Duration
Antagonize membrane effects	Calcium	Calcium gluconate, 10% solution, 10 ml IV over 10 min	1-3 min	30-60 min
Cellular potassium uptake	Insulin	Regular insulin, 10 U IV, with dextrose 50%, 50 ml, if plasma glucose <250 mg/dl	30 min	4-6 hr
	β_2-Adrenergic agonist	Nebulized albuterol, 10 mg	30 min	2-4 hr
Potassium removal	Sodium polystyrene sulfonate or calcium polystyrene sulfonate (calcium resonium)	30-60 g PO in 20% sorbitol *or* 30-60 g in water, per retention enema	1-2 hr	4-6 hr
	Hemodialysis	—	Immediate	Until dialysis completed

Table 9-5 Treatment of hyperkalemia

However, β_2-agonist therapy frequently induces substantial tachycardia, and as many as 25% of patients do not respond to β-blocker given by nebulizer.[45] A frequent mistake when administering nebulized β_2-adrenoceptor agonists is underdosage; the dose required is two to eight times that usually given by nebulizer for bronchodilation and is 50 to 100 times greater than the dose administered by metered dose inhalers.

Potassium Removal Most patients with severe hyperkalemia have increased total body potassium content. Definitive treatment of these patients requires potassium elimination, through the kidneys, GI route, or dialysis.

In select patients, treatment that focuses on increasing renal potassium elimination may be adequate. With chronic or mild hyperkalemia, loop or thiazide diuretics increase renal potassium excretion; loop diuretics may be the therapy of choice for patients with hyperkalemic renal tubular acidosis.[46] With life-threatening hyperkalemia, diuretics should be avoided because the rate of renal potassium excretion usually will not be adequate, and most patients will have renal impairment, which decreases the response to diuretic therapy. Although synthetic mineralocorticoids such as fludrocortisone increase renal potassium excretion, the accompanying renal sodium retention, intravascular volume expansion, and increased blood pressure are relative contraindications to their use. Furthermore, mineralocorticoids can increase the rate of progression of CKD. If a rapidly reversible cause of renal failure is identified, such as obstructive uropathy, or pre-renal failure from volume depletion, treating the underlying condition, along with close observation of serum potassium and continuous ECG observation, may be sufficient therapy.

A second mode of potassium elimination is with cation exchange resins such as sodium polystyrene sulfonate (Kayexalate) or calcium polystyrene sulfonate (calcium resonium). These resins exchange sodium or calcium, respectively, for potassium in the GI tract, enabling potassium elimination. It can be administered orally or rectally as a retention enema. The rate of potassium removal is relatively slow, requiring about 4 hours for full effect, although administering the resin as a retention enema results in more rapid onset of action. When given orally, cation exchange resins are generally administered with 20% sorbitol to avoid constipation. If given as an enema, sorbitol should be avoided, because rectal administration of cation exchange resins with sorbitol can cause colonic perforation.[47] Questions have been raised recently as to the efficacy of these compounds and whether the risk of colonic perforation exceeds their benefits.[48]

Acute hemodialysis is the primary method of potassium removal when renal function is significantly impaired, either from AKI or advanced CKD, and hyperkalemia is severe. Serum potassium can decrease as much as 1.2 to 1.5 mmol/h with a low potassium (1 mmol/l) dialysate. In general, the more severe the hyperkalemia, the more rapid should be the reduction in serum potassium and the lower the dialysate potassium concentration. However, care should be taken to avoid rapidly reducing the serum potassium in patients with coronary heart disease or severe cardiac arrhythmias. In these patients, it may be necessary to dialyze for a longer period with dialysate potassium of 3 mmol/l, because serum potassium can equilibrate to these levels during the dialysis. Continuous dialysis modalities, such as peritoneal dialysis and continuous venovenous hemodialysis, generally do not remove potassium sufficiently quickly for use in patients with life-threatening hyperkalemia.

If dialysis is delayed, as when access to equipment or nursing support is not immediate, or while vascular access is established, other therapies should be instituted and continued until hemodialysis is begun.

Specific therapies are available for certain causes of hyperkalemia. For example, digoxin-specific Fab fragments are beneficial in patients with severe digitalis glycoside toxicity.[49] Patients with acute urinary tract obstruction and hyperkalemia may be treated with relief of the obstruction, but the rate of potassium excretion afterward is variable, and frequent measurement of serum potassium is necessary.

Chronic Treatment

Management of chronic hyperkalemia is a common and often challenging problem, particularly in the CKD patient. Patients with CKD have impaired capacity to excrete potassium and are often treated with many medications, including ACE inhibitors, ARBs, β-blockers, and mineralocorticoid receptor antagonists. All these medicines have, as a well-recognized side effect, further increase in serum potassium concentration.

The optimal serum potassium level for patients with CKD and the serum potassium level that requires management may differ from the laboratory's report of the normal range of serum potassium. As noted previously, CKD patients tolerate hyperkalemia with fewer cardiac side effects than do most patients with normal renal function. Recent studies have suggested that serum potassium levels of up to 5.5 mmol/l or associated with optimal reduction of cardiovascular risk, and that levels between 5.5 and 6.0 mmol/l are associated with only minimal risk.[9]

Although the majority of patients with chronic hyperkalemia are receiving medicines associated with the development of hyperkalemia, discontinuing all medications that can cause hyperkalemia may not be the correct approach. Many medicines, such as ACE inhibitors, ARBs, β-blockers, and mineralocorticoid receptor blockers, have significant renoprotective and cardioprotective benefits. Discontinuing these medications simply because of hyperkalemia prevents the patient from receiving these important benefits, and this is not recommended in the first-line management of these patients. However, if the patient is receiving combined therapy with ACE inhibitor and ARB, discontinuing one of these medications may decrease the risk of further hyperkalemia, and this does not appear to be associated with adverse renal effects. Similarly, if a patient is receiving combination therapy of either an ACE inhibitor or an ARB with a direct renin inhibitor, such as aliskiren, the direct renin inhibitor may be discontinued.

Instead of immediately discontinuing such beneficial drugs without review, a careful assessment should be made for medicines that cause hyperkalemia but are not necessary for renoprotective or cardioprotective benefits and therefore can be discontinued, such as nonsteroidal anti-inflammatory agents (NSAIDs), COX-2 inhibitors, potassium-sparing diuretics (e.g., amiloride, triamterene), and oral KCl or potassium citrate supplementation. If hyperkalemia persists, the addition of diuretics to increase renal potassium excretion should be considered. Thiazide diuretics may be preferred, because when adjusted for their effect on sodium excretion, thiazide diuretics are associated with a greater increase in renal potassium excretion than loop diuretics. In the patient with CKD, the thiazide diuretic metolazone may be effective.[50]

A dietary history should be obtained, and if the patient is ingesting a diet with potassium-rich foods, instruction on avoidance of these foods should be provided. However, routine instruction in a low-potassium diet for CKD patients is not recommended. Recent studies have suggested that a diet higher in potassium-rich foods may be associated with slower progression of CKD.[51]

Finally, intermittent administration of exchange resins may be necessary for patients with persistent hyperkalemia. This should be limited to intermittent use because of the risk of bowel infarction.

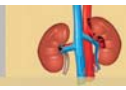
CHAPTER 10



Disorders of Calcium, Phosphate, and Magnesium Metabolism

Bryan Kestenbaum and Tilman B. Drüeke

CALCIUM HOMEOSTASIS AND DISORDERS OF CALCIUM METABOLISM

Distribution of Calcium in the Organism

Most calcium is bound and associated with bony structures (99%). The majority of free calcium, either in diffusible (ultrafilterable) nonionized form or in ionized form (Ca^{2+}), is found in the intracellular fluid (ICF) and extracellular fluid (ECF) compartments. Similar to potassium, there is a steep concentration gradient between Ca^{2+} in the ICF versus ECF milieu (Fig. 10-1).

The serum concentration of Ca^{2+} is tightly regulated within a narrow range by the actions of parathyroid hormone (PTH, parathormone) and calcitriol (1,25-dihydroxycholecalciferol). The physiologic role of other calcium regulatory hormones, such as calcitonin, estrogens, and prolactin, is less clear. Figure 10-2 demonstrates the physiologic defense mechanisms used to counter changes in serum Ca^{2+} levels.[1] Serum Ca^{2+} levels are also influenced by acid-base status, with alkalosis causing a decrease in Ca^{2+} and acidosis an increase in Ca^{2+}. Long-term maintenance of calcium homeostasis depends on (1) the adaptation of intestinal Ca^{2+} absorption to the needs of the organism, (2) the balance between bone accretion and resorption, and (3) urinary excretion of calcium (Fig. 10-3).

Intestinal, Skeletal, and Renal Handling of Calcium

Gastrointestinal (GI) calcium absorption is a selective process; only about 25% of total dietary calcium is absorbed. Ca^{2+} transport across the intestinal wall occurs in two directions: absorption and secretion. Absorption can be subdivided into transcellular and paracellular flow (Fig. 10-4). Transcellular calcium flux takes place through the transient receptor potential TRPV6 calcium channel.[2] Calcitriol is calcium's most important hormonal regulatory factor. After binding to and activating the vitamin D receptor (VDR), calcitriol increases active transport by inducing the expression of TRPV6, calbindin-D_{9k}, and Ca^{2+}-ATPase (PMCA1b).[3] Other hormones, including estrogens, prolactin, growth hormone, and PTH, also stimulate Ca^{2+} absorption, either directly or indirectly. The amount of dietary calcium intake also regulates the proportion of calcium absorbed through the GI tract (Fig. 10-5).[4]

Cutaneous synthesis on exposure to ultraviolet (UV) light converts 7-dehydrocholesterol into vitamin D substrate (cholecalciferol). Vitamin D substrate is also obtained through the diet and supplementation. Cholecalciferol (and ergocalciferol) have minimal inherent biologic activity and require two hydroxylation steps for full hormonal activity. 25-Hydroxylation occurs in the liver, is thought to be non–rate limiting, and is widely accepted as a summary measure of vitamin D stores. Further hydroxylation to 1,25-dihydroxyvitamin D (calcitriol) occurs predominantly in the kidney; however, other tissues can also perform this hydroxylation step, in particular macrophages and parathyroid tissue.

Increased calcium absorption is required in puberty, pregnancy, and lactation. In each of these states, calcitriol synthesis is increased to enhance GI calcium absorption. Intestinal Ca^{2+} absorption is also increased in states of vitamin D excess and acromegaly. Rarely, ingestion of calcium and alkali in large quantities can overwhelm GI checks on calcium absorption, resulting in hypercalcemia (milk-alkali syndrome). However, innate limitations on GI calcium absorption prevent this condition from occurring in most individuals. A decrease in intestinal Ca^{2+} transport occurs in advanced age, chronic kidney disease (CKD), gastrectomy, intestinal malabsorption syndromes, diabetes mellitus, corticosteroid treatment, and estrogen deficiency and with dietary factors such as high vegetable fiber and fat content, low Ca^{2+}–phosphate ratio in food, and fructose ingestion. The decrease in Ca^{2+} absorption in older adults probably results from multiple factors in addition to lower serum calcitriol and intestinal VDR levels.[5]

The net balance between Ca^{2+} entry and exit fluxes is positive during skeletal growth in children, zero in young adults, and negative in the elderly. Exchangeable skeletal Ca^{2+} contributes to maintaining extracellular Ca^{2+} homeostasis. Several growth factors, hormones, and genetic factors participate in the differentiation from the mesenchymal precursor cell to the osteoblast and the maturation of the osteoclast from its granulocyte-macrophage precursor cell (Fig. 10-6). The regulation of bone formation and resorption involves many hormones, growth factors, and mechanical factors[6,7] (Fig. 10-7).

The kidneys play a major role in the minute-by-minute regulation of calcium, and the intestine and skeleton ensure homeostasis in the midterm and long term. To perform its task, the kidney uses a complex system of filtration and reabsorption (Fig. 10-8).[8] Moreover, the kidney controls conversion of substrate 25-hydroxyvitamin D to calcitriol, which then regulates GI calcium absorption through the TRPV6 channel. Renal calcitriol production is stimulated by PTH and inhibited by hyperphosphatemia and fibroblast growth factor 23 (FGF-23).The adjustment of blood Ca^{2+} is mainly achieved by modulation of tubular Ca^{2+} reabsorption in response to the body's needs, perfectly compensating minor increases or decreases in the filtered load of calcium at the glomerular level, which is normally about 220 mmol (8800 mg) in 24 hours (see Fig. 10-3). In the proximal tubule, Ca^{2+} reabsorption follows the convective flow of salt and water, whereas the transport mechanisms are more complex in the distal segments.

States of excess volume delivery to the kidney, such as a high-sodium diet, diminish the concentration gradient between proximal tubule and peritubular capillary, reducing calcium absorption and

increasing calcium in the urine. This mechanism likely plays a role in the pathogenesis of calcium-based kidney stones. On the other hand, volume depletion increases salt, water, and (by convection) calcium reabsorption in the proximal tubule, exacerbating states of hypercalcemia. For this reason, intravascular volume repletion is an essential component of the treatment for hypercalcemia. In the thick ascending limb of Henle loop (TAL), Ca^{2+} transport is linked with activity of the Na^+-K^+-$2Cl^-$ transporter. Stimulation of the Ca^{2+}-sensing receptor (CaR_G) on the basolateral membrane decreases activity of rectifying outer medulla potassium (ROMK) channels located on apical cell surfaces, impeding activity of the Na^+-K^+-$2Cl^-$ cotransporter. The result is dissipation of the electrochemical gradient and decreased calcium reabsorption through claudin-16 in the tight junction. In contrast, understimulation of CaR_G because of lower serum calcium levels enhances ROMK activity, resulting in greater calcium reabsorption. In the distal tubule, active Ca^{2+} transport

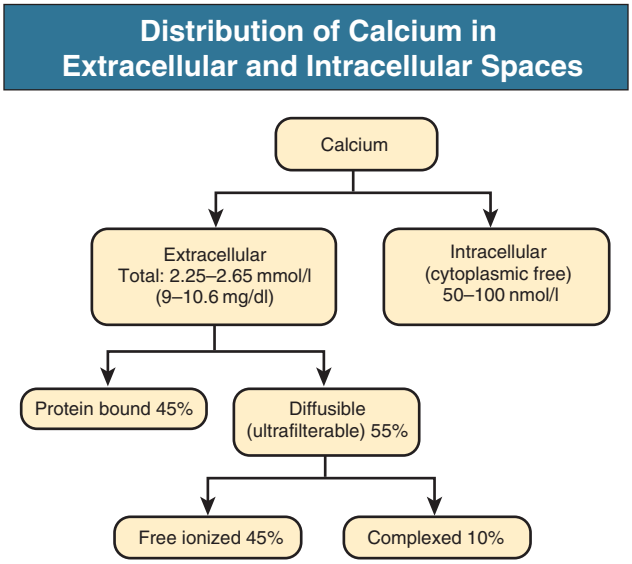


Figure 10-1 Calcium distribution in extracellular and intracellular spaces.

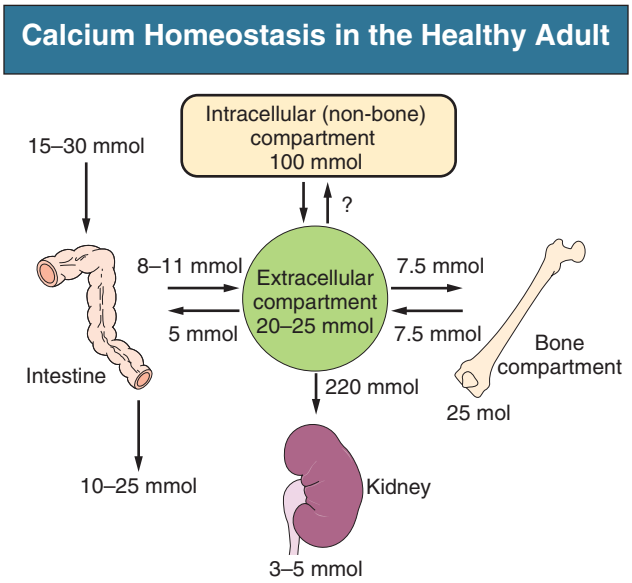

Figure 10-3 Calcium homeostasis in healthy adults. Net zero Ca^{2+} balance is the result of net intestinal absorption (absorption minus secretion) and urinary excretion, which by definition are the same. After its passage into the extracellular fluid, Ca^{2+} enters the extracellular space, is deposited in bone, or is eliminated via the kidneys. Entry and exit fluxes between the extracellular and intracellular spaces (skeletal and nonskeletal compartments) are also of identical magnitude under steady-state conditions.

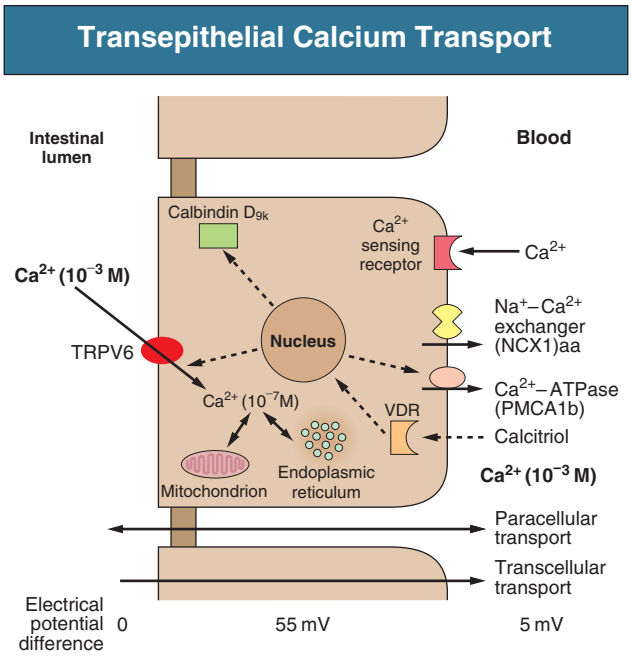

Figure 10-4 Transepithelial calcium transport in small intestine. Calcium penetrates into the enterocyte channels via a transient receptor potential calcium channel *(TRPV6)* through the brush border membrane along a favorable electrochemical gradient. Under physiologic conditions, the cation is pumped out of the cell at the basolateral side against a steep electrochemical gradient by the adenosine triphosphate–consuming pump Ca^{2+}-ATPase. When there is a major elevation of intracytoplasmic Ca^{2+}, the cation leaves the cell using the Na^{+}-Ca^{2+} exchanger. Passive Ca^{2+} influx as well as efflux is sensitive to calcitriol, which binds the vitamin D receptor *(VDR)*.

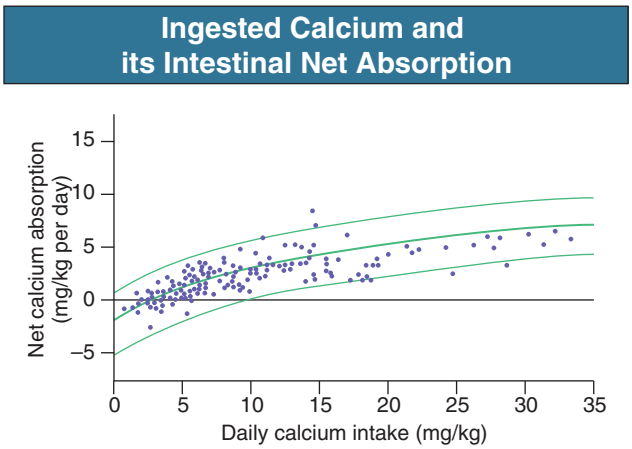

Figure 10-5 Calcium ingestion and absorption. Relationship between ingested calcium and its absorption in the intestinal tract (net) in healthy young adults. *(From reference 4.)*

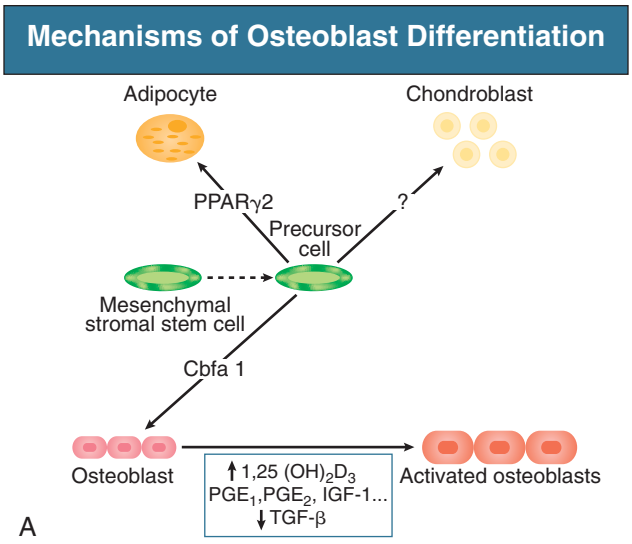
occurs via the transcellular route through the calcium transient receptor potential channel V5 (TRPV5) located in the apical membrane and coupled with a specific basolateral calcium-ATPase (PMCa1b) and a Na^{+}-Ca^{2+} exchanger (NCX1). Both PTH and calcitriol regulate distal tubular Ca^{2+} transport. The expression and role of CaR_G in tubular segments other than TAL has recently been questioned.[9]

Numerous factors control the glomerular filtration and tubular Ca^{2+} reabsorption.[2,10,11] Elevated renal blood flow and glomerular filtration pressure (during ECF volume expansion) lead to an increase in filtered load, as do changes in the ultrafiltration coefficient K_f and



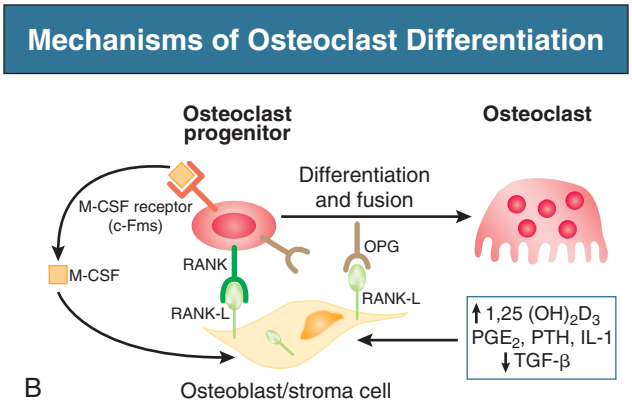


Figure 10-6 Mechanisms of osteoblast differentiation. an increase in glomerular surface. True hypercalcemia also increases ultrafilterable calcium; whereas true hypocalcemia decreases it. PTH decreases glomerular K_f and thus reduces the ultrafiltered calcium load; PTH increases Ca^{2+} reabsorption in the distal nephron. However, PTH and PTH-related peptide (PTHrp) also induce hypercalcemia, and, because of the increase in serum calcium, the excretion of filtered calcium is elevated overall. Both extracellular Ca^{2+} and intracellular Ca^{2+} reduce tubular calcium reabsorption by activating CaR_G, and the effect of extracellular Ca^{2+} is enhanced by the calcimimetics (discussed later). Respiratory acidosis leads to hypercalciuria through an increase in plasma Ca^{2+}, whereas metabolic acidosis leads to hypercalciuria through Ca^{2+} release from bone and an inhibitory effect on tubular Ca^{2+} reabsorption. Conversely, alkali ingestion reduces renal excretion of calcium. The enhancing effect of phosphate depletion on urinary calcium elimination can partly occur through changes in PTH and calcitriol secretion. Dietary factors modify urinary excretion of calcium mostly by their effects on intestinal Ca^{2+} absorption. Several classes of diuretics act directly on the tubules. Loop diuretics and mannitol favor hypercalciuria, with a major impact on TAL, whereas the thiazide diuretics and amiloride induce hypocalciuria.

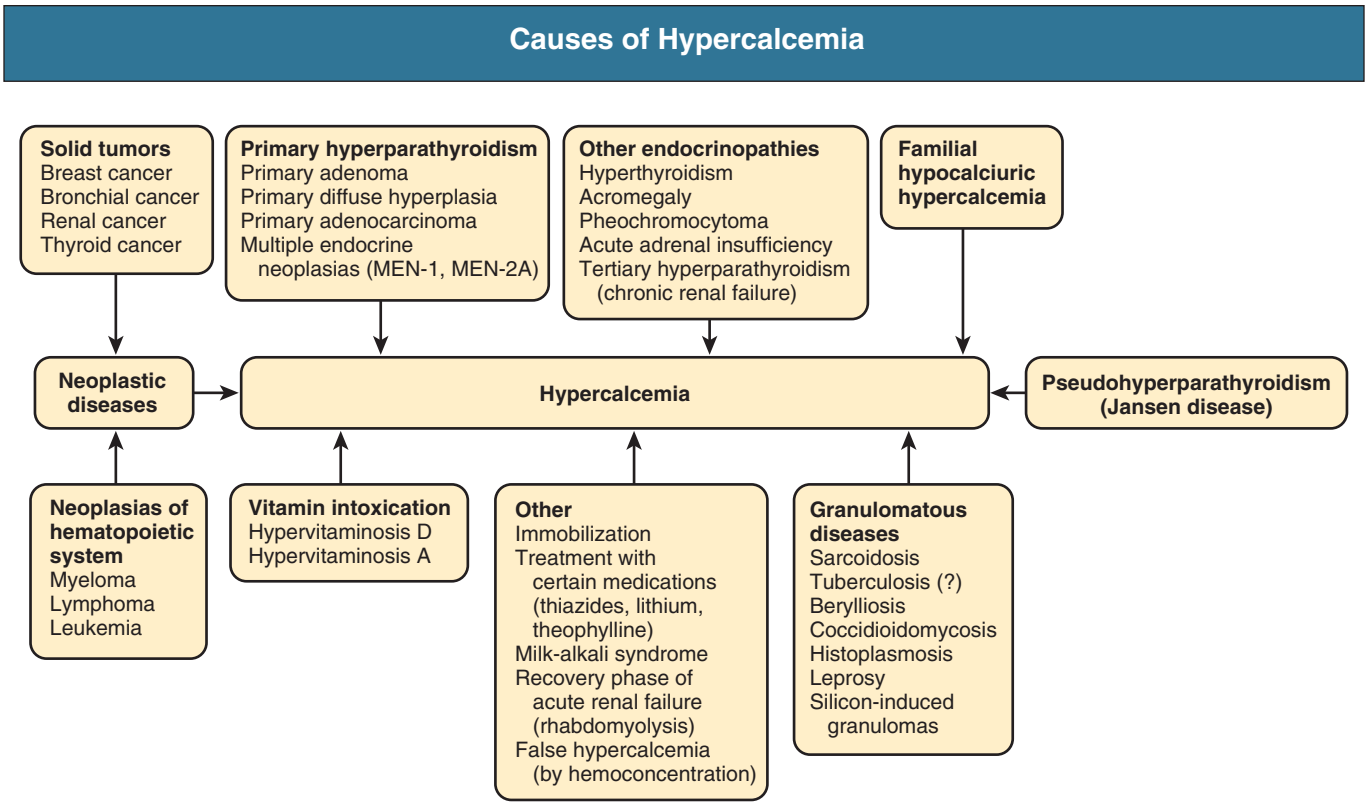

Figure 10-9 Causes of hypercalcemia. Neoplastic diseases and primary hyperparathyroidism are the most common causes of hypercalcemia. *(From reference 8.)*

HYPERCALCEMIA

Increased total plasma calcium concentration (plasma [Ca^{2+}]) can result from an increase in plasma proteins (false hypercalcemia) or from an increase in plasma ionized Ca^{2+} (true hypercalcemia). Only increased Ca^{2+} leads to clinically relevant hypercalcemia. When only the value for the total plasma [Ca^{2+}] is available rather than the free level ions, as generally occurs in clinical practice, plasma [Ca^{2+}] can be estimated by taking into account plasma albumin; an increase in albumin of 1.0 g/dl reflects a concomitant increase of 0.20 to 0.25 mmol/l (0.8 to 1.0 mg/dl) plasma calcium. However, simple correction of total calcium for serum albumin may not be valid in patients with CKD. A study of 691 individuals with CKD stages 3 to 5 showed that the albumin-corrected total serum [Ca^{2+}] correlated poorly with the ionized [Ca^{2+}].[11a] Moreover, the two most common assays used to measure serum albumin yield discordant results in uremic patients, the bromcresol purple method providing lower albumin values than the bromcresol green method.

The Ca^{2+}-sensing receptor has been identified in numerous tissues, and its function and role in various disease states are well defined.[12] Mutations of the gene for CaR_G result in various clinical syndromes characterized by hypercalcemia or hypocalcemia (see later discussion). Other Ca^{2+} receptors subsequently cloned include GPRC6A, which is expressed in osteoblasts and is clearly distinct from CaR_G.[13] Although its functional properties have been characterized, however, the role of GPRC6A in regulation of osteoblast function and in human disease is still unknown.

Causes of Hypercalcemia

True hypercalcemia results from an increase in intestinal Ca^{2+} absorption, a stimulation of bone resorption, or a decrease in urinary Ca^{2+} excretion. Enhanced bone resorption is the predominant mechanism in most cases of hypercalcemia (Fig. 10-9).

Malignant Neoplasias

The main cause of hypercalcemia is excessive bone resorption induced by neoplastic processes, usually solid tumors. Tumors of the breast, lung, and kidney are the most common, followed by hematopoietic neoplasias, particularly myeloma. Most hypercalcemic tumors act on the skeleton either by direct invasion (metastases) or by producing factors that stimulate osteoclastic activity, including most frequently PTHrp, as well as other factors activating osteoclasts, transforming growth factors (TGFs), prostaglandin E (PGE), and rarely calcitriol and tumor necrosis factor α (TNF-α), and even more rarely PTH, as produced by parathyroid cancer.

Only 8 of the 13 first amino acids of PTHrp are identical with those of the N-terminal fragment of PTH, but the effects of both hormones on target cells are mostly the same. In addition to their common receptor, the PTH/PTHrp receptor, at least one other receptor exists, the PTH_2 receptor, which recognizes only PTH, with similar or identical signal transduction systems. In pathologic conditions, most of the PTHrp in the body is synthesized by solid tumors. PTHrp stimulates osteoclastic activity and thus liberates excess quantities of calcium from the skeleton.

Osteoclast-activating factors secreted by myeloma plasmocytes and the lymphoblasts of malignant lymphomas include interleukins (IL-1α, IL-1β, IL-6) and TNF-α, which stimulate osteoclast activity. Other osteoclast-activating factors include PGE_1 and PGE_2, which can be secreted in large amounts by some tumors, especially renal masses. Some lymphoid tumors synthesize excess quantities of calcitriol. This capacity has been described in Hodgkin disease, T cell lymphoma, and leiomyoblastoma.

Primary Hyperparathyroidism

The second most common cause of hypercalcemia is primary hyperparathyroidism. Early diagnosis is achieved through the widespread use of routine plasma calcium determination. In more than 80% of patients, the disease is caused by adenoma of a single parathyroid gland; 10% to 15% have diffuse hyperplasia of all glands and less than 5%, a parathyroid cancer. Primary hyperparathyroidism can be inherited either as diffuse hyperplasia of the parathyroid glands alone or as a component in multiple glandular hereditary endocrine disorders. Patients with multiple endocrine neoplasia type 1 (MEN-1) have various combinations of parathyroid, anterior pituitary, enteropancreatic, and other endocrine tumors, resulting in hypersecretion of prolactin and gastrin in addition to parathormone. MEN-1 is caused by inactivating germ-line mutations of a tumor suppressor gene *(MEN-1)* that is inherited as an autosomal dominant trait. In MEN-2A, the thyroid medulla and the adrenal medulla are involved with the parathyroid, resulting in hypersecretion of calcitonin and catecholamines. MEN-2A is caused by activating mutations of the *RET* proto-oncogene. It is also inherited as an autosomal dominant trait. Not all patients with mildly elevated plasma PTH levels develop hypercalcemia. The development of the latter may depend on a concomitant elevation of plasma calcitriol.

Jansen Disease

Jansen disease is a rare hereditary form of short-limbed dwarfism characterized by severe hypercalcemia, hypophosphatemia, and metaphyseal chondrodysplasia. It is the result of activating mutations of the gene coding for the PTH/PTHrp receptor, a particular form of pseudohyperparathyroidism.

Familial Hypocalciuric Hypercalcemia

Familial hypocalciuric hypercalcemia (FHH) is a rare hereditary disease caused by inactivating mutations in the gene for CaR_G with autosomal dominant transmission.[14] The key clinical finding in FHH is an inappropriately low urinary calcium excretion in the setting of high-normal serum calcium. Other features include hypophosphatemia, hyperchloremia, and hypermagnesemia. Plasma PTH concentration is normal or moderately elevated, and the fractional excretion of calcium is lower than that observed in hyperparathyroidism. The fractional excretion of calcium is best assessed by calculating the calcium-to-creatinine clearance ratio from a 24-hour urine collection, as follows:

$$\text{Calcium-creatinine clearance ratio} = \frac{(\text{24-hour urine calcium}) \times (\text{Serum creatinine})}{(\text{24-hour urine creatinine}) \times (\text{Serum calcium})}$$

In FHH, the urine calcium–creatinine clearance ratio (calculated using milligrams) is usually less than 0.01. The urine Ca–creatinine concentration ratio is most often less than 0.07 mg/mg (0.2 mmol/mmol). In patients with FHH, hypercalcemia never leads to severe clinical signs, except in the neonatal period, when malignant hypercalcemia can be observed in the patient with severe hyperparathyroidism.

Other Endocrine Causes

Other endocrine disorders associated with moderate hypercalcemia include hyperthyroidism, acromegaly, and pheochromocytoma. In addition, acute adrenal insufficiency should also be considered in the differential diagnosis, although in these patients, hypercalcemia is usually false and results from hemoconcentration. Hypercalcemia can also occur in severe forms of the secondary hyperparathyroidism of CKD, which have also been called "tertiary hyperparathyroidism." However, this is relatively uncommon to date because low circulating calcitriol concentrations in CKD patients limit GI calcium absorption, and overfunctioning parathyroid glands can be controlled more easily.

Other Causes

Several other disorders sometimes induce hypercalcemia. Among the granulomatoses, sarcoidosis results in increased plasma Ca^{2+}, particularly in patients exposed to sunlight. The cause is uncontrolled production of calcitriol by macrophages, a result of 1α-hydroxylase in the macrophages within the granulomas. Tuberculosis, leprosy, berylliosis, and many other granulomatous diseases are occasionally (but rarely compared with sarcoidosis) the origin of hypercalcemia, probably through the same mechanism.

Hypercalcemia may also result from prolonged bed rest, especially in patients with preexisting high bone turnover rates, such as children, adolescents, and patients with Paget disease. Recovery from acute renal failure secondary to rhabdomyolysis-induced renal failure has been associated with hypercalcemia in 25% of cases and likely results from mobilization of soft tissue calcium deposits and through increases in PTH and calcitriol. Other causes include intoxication by vitamin D or its derivatives, vitamin A overload, and thiazide diuretics. Large doses of calcium (5 to 10 g/day), especially when ingested with alkali (antacids), can also lead to hypercalcemia and nephrocalcinosis (milk-alkali syndrome).

Clinical Manifestations

The severity of clinical symptoms and signs caused by hypercalcemia depends on not only the degree but also the velocity of its development. Severe hypercalcemia can be accompanied by few manifestations in some patients because of its slow, progressive development, whereas much less severe hypercalcemia can lead to major disorders if it develops rapidly.

In general, the first symptoms are increasing fatigue, muscle weakness, inability to concentrate, nervousness, increased sleepiness, and depression. Subsequently, GI signs may occur, such as constipation, nausea and vomiting, and rarely peptic ulcer disease or pancreatitis. Renal-related signs include polyuria (secondary to nephrogenic diabetes insipidus), urinary tract stones and their complications, and occasionally tubulointerstitial disease with medullary and to a lesser extent cortical deposition of calcium (nephrocalcinosis). Neuropsychiatric manifestations include headache, loss of memory, somnolence, stupor, and rarely coma. Ocular symptoms include conjunctivitis from crystal deposition and rarely band keratopathy. Osteoarticular pain in primary hyperparathyroidism has become rare in Western countries because of earlier diagnosis of hypercalcemia. High blood pressure can be induced by hypercalcemia, but it is more frequently a chance association. Soft tissue calcifications can occur with longstanding hypercalcemia. The electrocardiogram (ECG) may show shortening of the QT interval and coving of the ST wave. Hypercalcemia may also increase cardiac contractility and can amplify digitalis toxicity.

Diagnosis

When the history and clinical examination are not helpful, primary hyperparathyroidism should be investigated first. Although this is only the second most frequent cause, its laboratory diagnosis is at present easier than that of tumoral involvement. The initial step should be to measure plasma PTH and total or ionized $[Ca^{2+}]$, as available. When the PTH value is high-normal or high in the presence of high-normal or high $[Ca^{2+}]$, the diagnosis of primary hyperparathyroidism is likely (although FHH is not excluded). Other

helpful laboratory tests may include phosphate, creatinine, total alkaline phosphatases, and urinary calcium and creatinine. Note that prolonged hypercalcemia is often associated with (reversible) increased serum creatinine. Cervical ultrasound and sestamibi isotope scanning may be performed to locate a parathyroid adenoma, although some surgeons still consider these examinations unnecessary before an initial neck exploration. However, imaging is indispensable in patients with recurrent hyperparathyroidism and having unilateral neck surgery under local anesthesia. If the plasma PTH level is low-normal or low, the possibility of a neoplastic disorder should be seriously considered. A low serum anion gap may be caused by multiple myeloma, because occasionally the monoclonal IgG is positively charged. In addition to the usual examinations, such as serum protein electrophoresis, measurement of the plasma PTHrp level can now be done in specialized laboratories. Exogenous vitamin D overload is associated with increased serum 25-hydroxyvitamin D levels, and granulomatous diseases such as sarcoidosis are associated with elevated calcitriol levels and with increased serum angiotensin-converting enzyme (ACE) activity.

Treatment

Treatment of the patient with hypercalcemia is aimed at the underlying cause. However, severe and symptomatic hypercalcemia requires rapid correction, whatever the cause. Initially, the patient must be rapidly rehydrated with isotonic saline to correct the often marked volume depletion, to reduce proximal tubule calcium reabsorption and enhance calcium excretion. Only when euvolemia is established should loop diuretics be used (e.g., IV furosemide, 100 to 200 mg every other hour) to facilitate urinary excretion of calcium; however, intravenous saline should be continued to prevent hypovolemia. Oral intake and IV administration of fluids and electrolytes should be carefully monitored, and urinary and gastric excretions measured if excessive, especially potassium, magnesium, and phosphate. Acid-base balance should also be carefully monitored. Severe cardiac failure and CKD are contraindications to massive ECF volume expansion along with diuretics.

Bisphosphonates are the treatment of first choice, especially in patients with hypercalcemia associated with cancer.[15] These agents inhibit bone resorption as well as calcitriol synthesis. Bisphosphonates can be administered orally (PO) in less severe disease or intravenously (IV) in severe hypercalcemia. Common bisphosphonates include clodronate (1600 to 3200 mg/day PO), pamidronate (15 to 90 mg IV over 1 to 3 days, once a month), and alendronate (10 mg/day PO). IV doses should be infused in 500 ml of isotonic saline or dextrose over at least 2 hours and up to 24 hours. Although package warnings state that bisphosphonates should be used with caution in patients with CKD, virtually no safety data support such warnings. Bisphosphonates have been safely used in CKD patients for the correction of hypercalcemia. A reasonable strategy is first to attempt correcting acute kidney injury before administering a bisphosphonate, and to avoid repetitive dosing; a single 60-mg dose of pamidronate can maintain normal [Ca^{2+}] for weeks. Calcitonin acts within hours, especially after IV administration. Human, porcine, or salmon calcitonin can be given. However, calcitonin often has no effect, or only a short-term effect, because of the rapid development of tachyphylaxis.

Mithramycin is a cytostatic drug with remarkable power to inhibit bone resorption. Administration of a single IV dose is generally followed by a rapid decline in plasma calcium within a few hours, and this effect lasts several days. However, mithramycin is reserved for malignant hypercalcemia, and its cytotoxic effect and side effects (thrombocytopenia, liver function abnormalities) preclude prolonged administration. The maximal daily dose of mithramycin is 25 μg/kg.

Corticosteroids such as prednisone (or prednisolone), 0.5 to 1.0 mg/kg daily, are mainly indicated in hypervitaminosis D of endogenous origin, as in patients with sarcoidosis or tuberculosis, to decrease macrophage synthesis of calcitriol. Ketoconazole, an antifungal agent that can inhibit renal and extrarenal calcitriol synthesis, has also been proposed in hypervitaminosis D. Corticosteroids can also be used in patients with hypercalcemia associated with some hematopoietic tumors (e.g., myeloma, lymphoma) and even for some solid tumors such as breast cancer.

In rare cases of malignant hypercalcemia, treatment with prostaglandin antagonists such as indomethacin or aspirin can be successful. Hyperkalemia and impaired renal function may occur with indomethacin. Hypercalcemia caused by thyrotoxicosis can rapidly resolve with IV administration of propranolol or less rapidly with oral administration.

In moderate and nonsymptomatic hypercalcemia of primary hyperparathyroidism, treatment with estrogens has been tried, at least in female patients. In patients with primary hyperparathyroidism, cinacalcet, the first of a newer therapeutic class of CaR_G agonists, the *calcimimetics,* can achieve normalization of serum Ca^{2+} in most cases, together with a reduction in serum PTH.[16] However, surgical removal of benign parathyroid adenomas remains the first option in patients with no overt contraindications because this allows definitive cure in most patients; surgery is also less expensive than life-long cinacalcet therapy. In dialysis patients with secondary (and many cases of so-called tertiary) uremic hyperparathyroidism, long-term administration of cinacalcet is superior to standard therapy in controlling serum PTH, calcium, and phosphate, and in avoiding surgical parathyroidectomy[17] (see Chapter 85). Surgical parathyroidectomy remains an alternative solution in dialysis patients who are unresponsive to medical treatment. Of note, cinacalcet may also be effective in patients with parathyroid carcinoma.

HYPOCALCEMIA

As with hypercalcemia, hypocalcemia can be secondary either to reduced plasma albumin (false hypocalcemia) or to a change in ionized [Ca^{2+}] (true hypocalcemia). False hypocalcemia can be excluded by directly measuring plasma [Ca^{2+}], by determining plasma total protein or albumin levels, by the clinical context, or by other laboratory results (Figure 10-10). Acute hypocalcemia is often observed during acute hyperventilation and the respiratory alkalosis that follows, regardless of the cause of hyperventilation. Hyperventilation can result from cardiopulmonary or cerebral diseases. After excluding false hypocalcemia linked to hypoalbuminemia, hypocalcemia can be divided into that associated with elevated and that associated with low plasma phosphate concentration.

Hypocalcemia Associated with Hyperphosphatemia

Chronic kidney disease leads to diminished calcitriol production and subsequently a low-normal serum [Ca^{2+}]. In parallel, declining glomerular ultrafiltration of phosphate leads to a progressive rise in serum phosphate levels once the glomerular filtration rate (GFR) falls below about 35 ml/min/1.73 m^2. Acute kidney injury (AKI) may also cause hypocalcemia and hyperphosphatemia through these mechanisms in combination with hypocalcemia of critical illness. This finding may be particularly pronounced in AKI caused by rhabdomyolysis or pancreatitis.

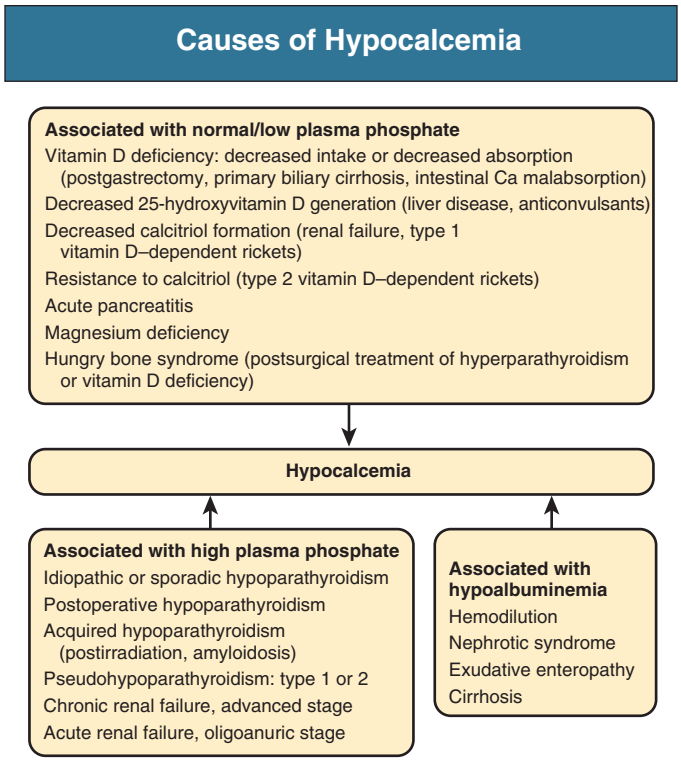

Figure 10-10 Causes of hypocalcemia.

Hypoparathyroidism may be caused by surgical removal of the parathyroid glands (post thyroidectomy or parathyroidectomy), radiation, autoimmune destruction of parathyroid tissue, or infiltrative diseases. Sporadic cases of hypoparathyroidism are occasionally seen in patients with pernicious anemia or adrenal insufficiency. Pseudohypoparathyroidism (Albright hereditary osteodystrophy) is characterized by a particular phenotype including short neck, round face, and short metacarpals, with end-organ resistance to PTH.

In addition, massive phosphate administration, such as that used in bowel preparations, can also lead to hypocalcemia with hyperphosphatemia, often with AKI.[18]

Hypocalcemia Associated with Hypophosphatemia

Hypocalcemia with hypophosphatemia may occur in vitamin D–deficient states. This may result from insufficient sunlight exposure, dietary deficiency of vitamin D, decreased absorption after gastrointestinal surgery, intestinal malabsorption syndromes (steatorrhea), or hepatobiliary disease (primary biliary cirrhosis). Hyperuricemia or gout may also be associated with low 1,25-dihydroxyvitamin D levels. Hypocalcemia may also be caused by magnesium deficiency, often in conjunction with hypokalemia, which may be caused by inappropriate kaliuresis or diarrhea. The mechanism for hypocalcemia in this setting appears to be decreased PTH release and end-organ resistance. AKI in the polyuric phase, especially following rhabdomyolysis, may also be associated with hypocalcemia and hypophosphatemia.

Clinical Manifestations

As with hypercalcemia, the symptoms of hypocalcemia depend on rate of development and severity. The most common manifestations, in addition to fatigue and muscular weakness, are increased irritability, loss of memory, a state of confusion, hallucination, paranoia, and depression. The best known clinical signs are Chvostek sign (tapping of facial nerve branches leading to twitching of facial muscle) and Trousseau sign (carpal spasm in response to forearm ischemia caused by inflation of a sphygmomanometer cuff). Patients with acute hypocalcemia may have paresthesias of the lips and the extremities, muscle cramps, and occasionally frank tetany, laryngeal stridor, or convulsions. Chronic hypocalcemia may be associated with cataracts, brittle nails with transverse grooves, dry skin, and decreased or even absent axillary and pubic hair, especially in idiopathic hypoparathyroidism, which is often of autoimmune origin.

Laboratory and Radiographic Signs

Plasma phosphate is elevated in hypoparathyroidism, pseudohypoparathyroidism, and advanced CKD, whereas it is decreased in steatorrhea, vitamin D deficiency, acute pancreatitis, and the polyuric phase during recovery from AKI. Plasma PTH is reduced in hypoparathyroidism and also during chronic magnesium deficiency, whereas it is normal or increased in pseudohypoparathyroidism and in CKD. Urinary calcium excretion is increased only in patients with hypoparathyroidism receiving calcium or vitamin D derivatives, in whom it may lead to nephrocalcinosis; excretion is low in all other patients with hypocalcemia. *Fractional* urinary calcium excretion, however, is high in hypoparathyroidism, in the polyuric phase during recovery from AKI, and in severe CKD; it is low in all other hypocalcemic patients. Urinary phosphate excretion is low in hypoparathyroidism, pseudohypoparathyroidism, and magnesium deficiency; it is high in vitamin D deficiency, steatorrhea, CKD, and during phosphate administration. Determination of serum 25-hydroxyvitamin D and calcitriol levels may also be useful.

On the ECG the corrected QT interval is frequently prolonged, and arrhythmias may occur. The electroencephalogram (EEG) shows nonspecific signs such as an increase in slow, high-voltage waves. Intracranial calcifications, notably of the basal ganglia, are observed radiographically in 20% of patients with idiopathic hypoparathyroidism, but much less frequently in patients with postsurgical hypoparathyroidism or pseudohypoparathyroidism.

Treatment

Therapy for the patient with hypocalcemia is directed toward the underlying cause. Severe and symptomatic (tetany) hypocalcemia requires rapid treatment. Acute respiratory alkalosis, if present, should be corrected if possible. When the cause is functional, simple CO_2 retention, as by breathing into a paper bag, may suffice. In other patients, and to obtain a prolonged effect, IV infusion of calcium salts is most often required. In the patient with seizures or tetany, calcium gluconate should be administered as an IV bolus (e.g., 10 ml 10% w/v [2.2 mmol of calcium], diluted in 50 ml of 5% dextrose in water [D5W] or isotonic saline), followed by 12 to 24 g over 24 hours (in D5W or isotonic saline). Calcium gluconate is preferred to calcium chloride, which can lead to extensive skin necrosis in accidental extravasation.

Treatment of chronic hypocalcemia includes oral administration of calcium salts, thiazide diuretics, or vitamin D. Several oral presentations of calcium are available, each with their advantages and disadvantages. It should be remembered that the amount of elemental calcium of the various salts differs greatly. For example, the calcium content is 40% in carbonate, 36% in chloride, 12% in lactate, and only 8% in gluconate salts. The daily amount prescribed can be 2 to 4 g elemental Ca. Concurrent magnesium deficiency (serum [Mg^{2+}]

<0.75 mmol/l) should be treated either with oral magnesium oxide (250 to 500 mg every 6 days) or with magnesium sulfate: intramuscular (IM, 4 to 8 mmol/day) or IV (e.g., 12 ml 50% magnesium sulfate in 1000 ml D5W over 3 to 4 hours).

Treatment of hypocalcemia secondary to hypoparathyroidism is difficult as urinary calcium excretion increases markedly with calcium supplementation and can lead to nephrocalcinosis and loss of renal function. To reduce urinary calcium concentration, thiazide diuretics can be used in association with restricted salt intake and high fluid intake.

Therapy with active forms of vitamin D—calcitriol or its analogue 1α-hydroxycholecalciferol (alfacalcidol), 0.25 to 1.0 μg/day—is the treatment of choice for idiopathic or acquired hypoparathyroidism, because these compounds are better tolerated than massive doses of calcium salts. Administration of vitamin D derivatives generally leads to hypercalciuria and rarely to nephrocalcinosis. The patient requires regular monitoring to avoid hypercalcemia.

PHOSPHATE HOMEOSTASIS

Distribution of Phosphate in the Organism

Phosphate plays a crucial role in cell structure, signaling, and metabolism. Phosphate is found in the organism both as mineral phosphate and organic phosphate (phosphoric esters). As with calcium, the vast majority of phosphate in the body resides in bone, teeth, and inside cells, with less than 1% circulating in the serum. The serum phosphorus concentration is maintained within a narrow range under the direction of hormonal regulators FGF23, PTH, and calcitriol. Phosphate circulates as HPO_4^{2-} and $H_2PO_4^-$, in a 4:1 ratio at normal pH. Normal serum phosphate levels of 2.8 to 4.5 mg/dl (0.9 to 1.5 mmol/l) fluctuate in a circadian rhythm, with levels approximately 0.6 mg/dl higher in the afternoon, compared to an 11 AM nadir. Figure 10-11 shows the distribution of phosphate in the ECF and ICF compartments.

Figure 10-12 shows the balance of ingestion, body distribution, and excretion of phosphate in a healthy human. A young adult requires approximately 0.5 mmol/kg of phosphate daily. These needs are much greater in the child during growth. Phosphate is widely found in milk products, meat, eggs, and cereals and is used extensively as food additives. Bone permanently exchanges phosphate with the surrounding milieu. Entry and exit of phosphate amount to approximately 100 mmol daily (slowly exchangeable phosphate), for a total skeleton content of about 20,000 mmol. The net balance is positive during growth, zero in the young adult, and negative in the elderly adult.

Phosphate enters cells by active transport through a variety of sodium-phosphate (Na-Pi) cotransporters. In the small intestine, phosphate is absorbed through the type 2b Na-Pi cotransporter (NPT2b).The major hormonal regulator of NPT2b is calcitriol, which increases phosphate transport into the body. In contrast, the lipid-lowering agent niacin inhibits NPT2b activity, thereby decreasing phosphate uptake. In CKD patients, niacin treatment lowers serum phosphate by approximately 0.4 mg/dl. A genome-wide association study of more than 16,000 normal adults found that a common genetic variant in NPT2a was associated with serum phosphate concentrations.[19] In the proximal tubule of the kidney, most of the filtered phosphate load is reabsorbed through type 2a and type 2c Na-Pi cotransporters (NPT2a, NPT2c). The phosphaturic hormones FGF-23 and PTH are the principal factors that downregulate NPT2a, increasing phosphate excretion in the urine. Now recognized as a central hormone in phosphate homeostasis, FGF-23 is made by osteocytes but possesses weak inherent binding properties, requiring a cofactor, klotho, for optimal binding and function within the kidney.[20] Disruption of klotho or FGF-23 genes in animal models leads to a similar hyperphosphatemic phenotype. In addition to promoting phosphate excretion, FGF-23 potently suppresses calcitriol by inhibiting CYP27B1 and stimulating CYP24A1. Other hormones that may influence phosphate transport within the kidney include growth hormone, insulin-like growth factor 1 (IGF-1), insulin, thyroid hormone, secreted frizzled-related protein 4 (sFRP-4), and FGF-7.

Phosphate transport across the intestinal wall occurs via both the transepithelial and the paracellular routes (Fig. 10-13). Absorption is a linear, nonsaturable function of phosphate intake (Fig. 10-14). Absorption amounts to 60% to 75% of total phosphate intake (15 to 50 mmol/day). Calcitriol, which stimulates the NP2b cotransporter,

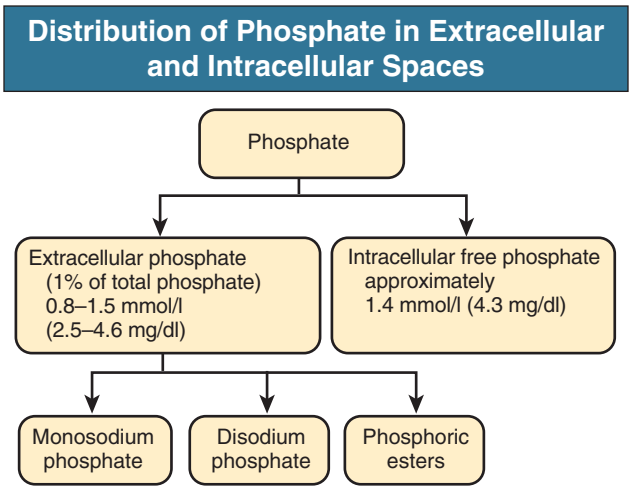

Figure 10-11 Phosphate distribution in extracellular and intracellular spaces.

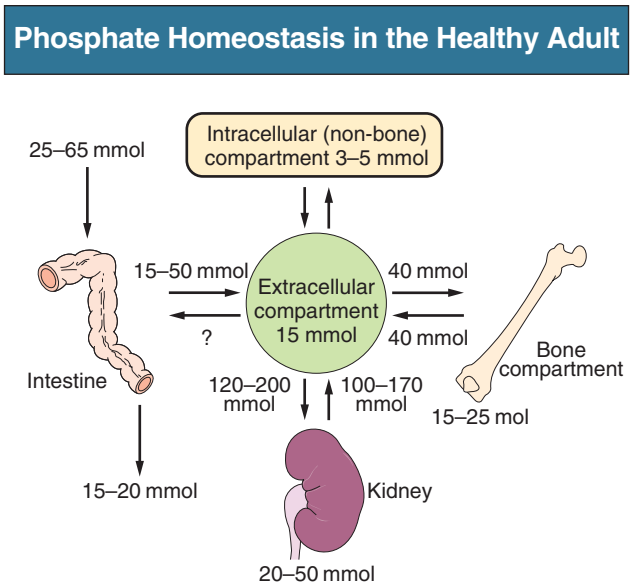

Figure 10-12 Phosphate homeostasis in healthy young adults. At net zero balance, identical net intestinal uptake (absorption minus secretion) and urinary loss occur. After its passage into the extracellular fluid, phosphate enters the intracellular space, is deposited in bone or soft tissue, or is eliminated via the kidneys. Entry and exit fluxes between the extracellular and intracellular spaces (skeletal and nonskeletal compartments) are also the same under steady-state conditions.

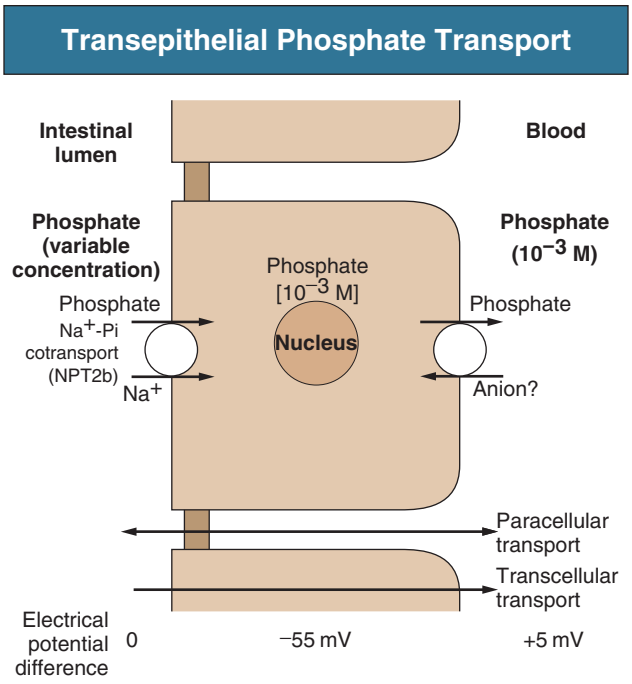

Figure 10-13 Transepithelial phosphate transport in the small intestine. Phosphate enters the enterocyte (influx) through the brush border membrane using the Na^+/Pi cotransport system, with a stoichiometry of 2 : 1, operating against an electrochemical gradient. Phosphate exit at the basolateral side possibly occurs by passive diffusion or more probably by anion exchange.

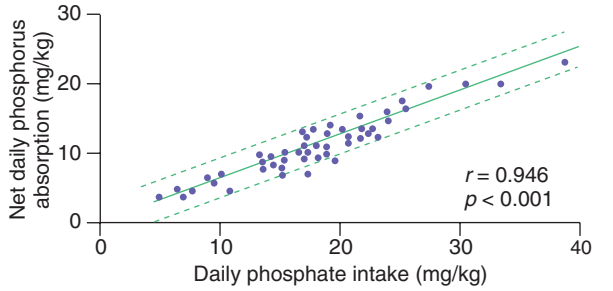

Figure 10-14 Phosphate ingestion and absorption. Relationship between ingested phosphate and phosphorus absorbed in the digestive tract (net absorption) in healthy young adults. *(From reference 4.)*

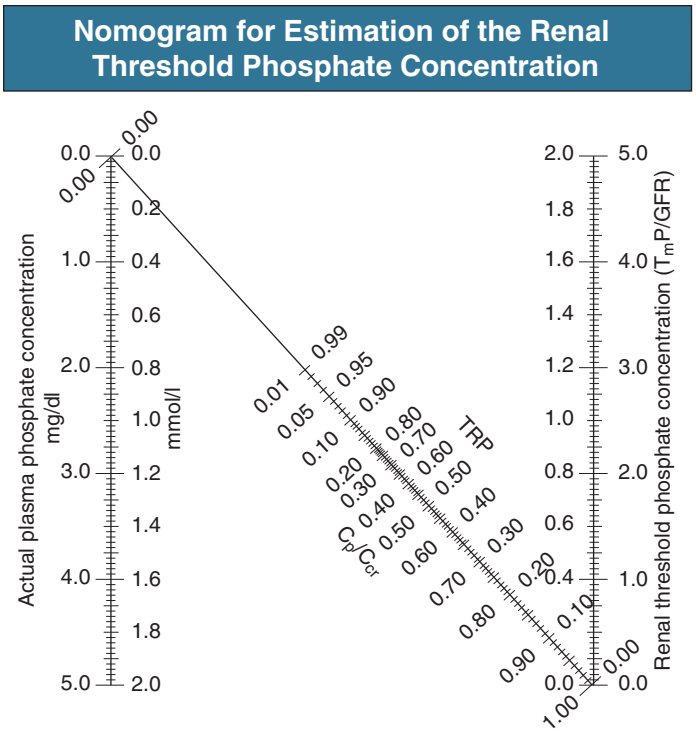

Figure 10-15 Nomogram for estimation of renal threshold phosphate concentration. A straight line through the appropriate values of phosphate concentration and TRP (amount of phosphate reabsorbed, or C_P/C_{cr}, where C is clearance for phosphate or creatinine) passes through the corresponding value of T_mP/GFR. *(From reference 23.)*

is the major hormonal determinant of intestinal phosphate absorption. Cations, such as calcium, magnesium, or aluminum, bind to phosphate in the GI tract, limiting its absorption. In both animals and humans, ingestion of a high-phosphate meal results in the rapid excretion of phosphate in the urine, without detectable changes in serum phosphate levels.

The kidneys play a central role in controlling extracellular phosphate homeostasis.[21,22] Phosphate is minimally protein bound, freely filtered at the glomerulus, and reabsorbed primarily in the proximal tubule. To maintain steady-state homeostasis, the daily amount of phosphate excreted in urine must equal that absorbed in the intestine. Normally, the kidneys excrete 5% to 20% of the filtered phosphate load to maintain phosphate balance. In CKD, however, fewer functioning nephrons necessitate the excretion of a higher proportion of the filtered phosphate load per nephron to maintain phosphate homeostasis. For this reason, the fractional excretion of phosphate may exceed 50% in late stages of CKD.

The amount of phosphate reabsorbed can be expressed in relation to the amount filtered as the urinary fractional excretion of phosphate (FE_{Po4}), as follows:

$$FE_{Po4} = (U_{Po4} \times S_{cr})/(S_{Po4} \times U_{cr})$$

where U_{Po4}, S_{Po4}, U_{cr}, and S_{cr} are urinary and serum phosphate and creatinine concentrations, respectively. Ideally FE_{Po4} should be calculated from 24-hour urine samples to incorporate dietary phosphate consumption and circadian changes in serum phosphate throughout the day. In practice, FE_{Po4} is typically calculated using spot urine samples, the validity and precision of which are unknown (Fig. 10-15).[23]

HYPERPHOSPHATEMIA

Causes of Hyperphosphatemia

The most common cause of increased serum phosphate levels is reduced urinary excretion caused by acute and chronic kidney diseases.[24] Although seen particularly in patients with disturbed urinary phosphate excretion, hyperphosphatemia can also be caused by increased exogenous or endogenous phosphate supply (Fig. 10-16).

Acute Kidney Injury

The kidneys are the major route for phosphate excretion. An acute reduction in GFR leads directly to a rise in the serum phosphate concentration, often in parallel with serum creatinine.

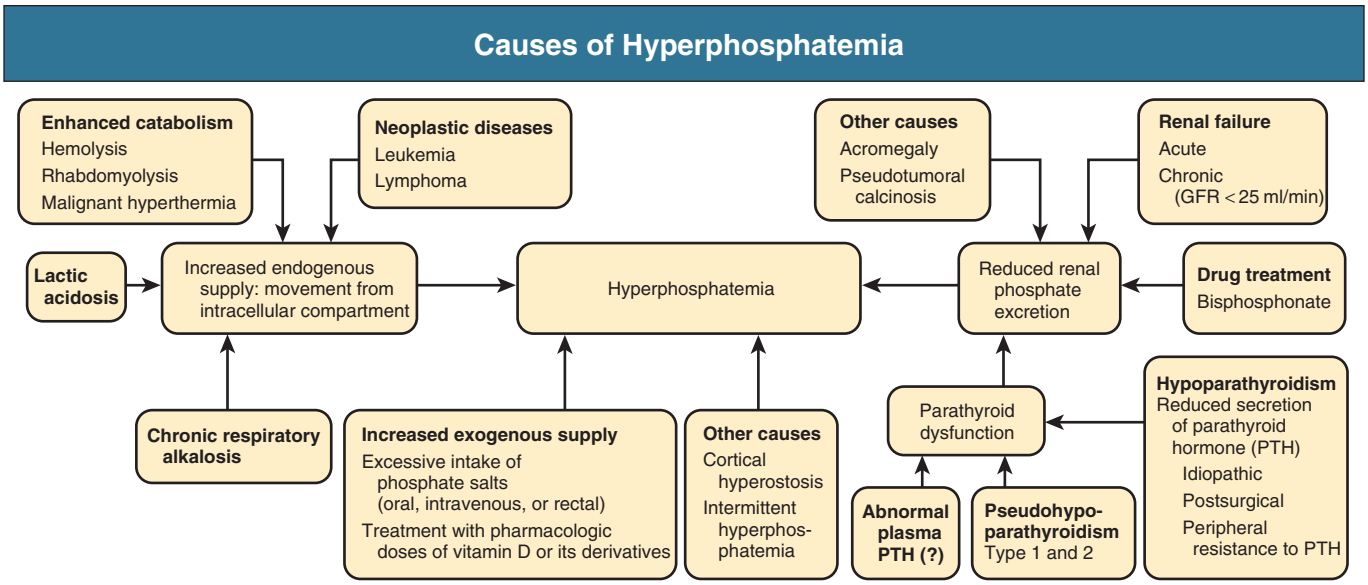

Figure 10-16 Causes of hyperphosphatemia.

Chronic Kidney Disease

Over time, the organism is able to respond to a loss of filtering nephrons by increasing the proportionate phosphate excretion in remaining nephrons to preserve serum phosphate concentrations. As kidney function slowly declines during CKD, levels of phosphaturic hormones FGF-23 and PTH rise to enhance the fractional excretion of phosphate in surviving nephrons and preserve phosphate homeostasis. This system is able to maintain phosphate balance until about 75% of normal kidney function has been lost. Once GFR falls below about 35 ml/min/1.73 m^2, inadequate nephron mass results in a steady rise in serum phosphate. Similar to acidosis and anemia, the presence of hyperphosphatemia in CKD patients generally suggests more advanced disease.

The price paid for preservation of serum phosphate in CKD is high circulating levels of FGF-23 and PTH. FGF-23 potently suppresses calcitriol, inhibiting intestinal phosphate absorption through NPT2b and further defending against phosphate excess. However, suppression of calcitriol may have an adverse impact on cardiovascular and kidney health because of biologic activities of calcitriol in downregulating renin expression, reducing inflammatory cytokines, and moderating ventricular hypertrophy. FGF-23 excess may have direct cardiovascular toxicity through stimulation of cardiac hypertrophy, as seen in animal models. A randomized controlled trial of phosphate binders in 148 nondialysis CKD patients recently assessed the hormonal impact of phosphate excess.[25] Compared with placebo, intensive therapy with phosphate binders over a median 8 months of follow-up prevented increased PTH, lowered serum phosphate by 0.3 mg/dl, and reduced mean 24-hour urine phosphate by 22%, but did not significantly lower FGF-23 levels.

Lytic States

Exaggerated phosphate loss by tissues is seen in states of extreme cell lysis, particularly rhabdomyolysis (crush injury), and in patients with malignancies, especially lymphoma and leukemia, and with their treatment. The hyperphosphatemia of rhabdomyolysis is typically accompanied by hypocalcemia, myoglobinuria, and AKI. Severe hypercatabolic states during severe infection or in diabetic ketoacidosis can also cause hyperphosphatemia through increased cellular release of phosphate, usually accompanied by an acute reduction in GFR.

Treatment-Induced Hyperphosphatemia

A massive supply of phosphate, as may accumulate with phosphate-based laxatives or enemas, can lead to hyperphosphatemia. Oral sodium phosphate solutions used to prepare for colonoscopy contain massive quantities of phosphate and can cause precipitation of calcium phosphate crystals within the renal tubules and AKI. Recovery from this condition is slow and often incomplete, with some cases resulting in permanent dialysis. For these reasons, patients with CKD should receive bowel preparations other than those based on sodium-phosphate salts. Bisphosphonates, in particular etidronate in Paget disease, can increase serum phosphate levels, possibly through increased liberation of tissue phosphate or an increase in renal tubular reabsorption.

Hypoparathyroidism

Parathormone (PTH) is a major phosphaturic hormone. In states of reduced PTH secretion (idiopathic or postsurgical hypoparathyroidism) or resistance to its peripheral action (pseudohypoparathyroidism), tubular excretion of phosphate is diminished. The resulting increase in plasma phosphate leads to an increase in the ultrafiltered load. This results in the regulation of plasma phosphate at a new steady-state level.

Chronic Hypocalcemia

Hyperphosphatemia may be observed in association with chronic hypocalcemia with normal or high plasma PTH levels. In the absence of characteristic abnormalities of pseudohypoparathyroidism, the existence of an abnormal form of plasma PTH has been suggested, perhaps caused by abnormal conversion of the prohormone to its secreted form.

Acromegaly

In acromegaly, hyperphosphatemia results from an increase in tubular reabsorption of phosphate caused by stimulation by growth hormone and IGF-1.

Familial Tumoral Calcinosis

This rare, autosomal recessive disorder seen primarily in people of Middle Eastern or African ancestry is caused by an inactivating mutation in *GALNT3, FGF23,* or klotho gene. The glycosyltransferase encoded by *GALNT3* is necessary for FGF-23 activity thus resulting in a shared phenotype.[26] The lack of functional FGF-23 results in an exaggerated tubular phosphate reabsorption and uninhibited vitamin D activation, leading to hyperphosphatemia and hypercalcemia, high circulating levels of calcitriol, and metastatic soft tissue calcifications. The most common finding is densely calcified masses surrounding major joints that recur after removal. Circulating PTH is not decreased.

Respiratory Alkalosis with Prolonged Hyperventilation

Respiratory alkalosis resulting from prolonged hyperventilation is characterized by resistance to the renal action of PTH, hyperphosphatemia, and hypocalcemia. There may also be functional pseudohypoparathyroidism because renal phosphate clearance is diminished, whereas plasma PTH is normal, despite hypocalcemia. There is no decrease in urinary calcium excretion.

Clinical Manifestations

The major clinical implication of hyperphosphatemia is deposition of phosphate and calcium in soft tissues. Chronic hyperphosphatemia is suspected to play a causal role in the pathogenesis of vascular calcification, particularly in CKD (see Chapter 82). In extreme cases, hyperphosphatemia can induce tumor-like soft tissue calcium phosphate deposits (Figure 10-17) or extensive vascular calcification within the arteries of the skin (calciphylaxis or calcific uremic arteriolopathy; see Chapter 88). Hyperphosphatemia also blocks the conversion of 25-hydroxyvitamin D to calcitriol, leading to concomitant hypocalcemia and the stimulation of PTH.

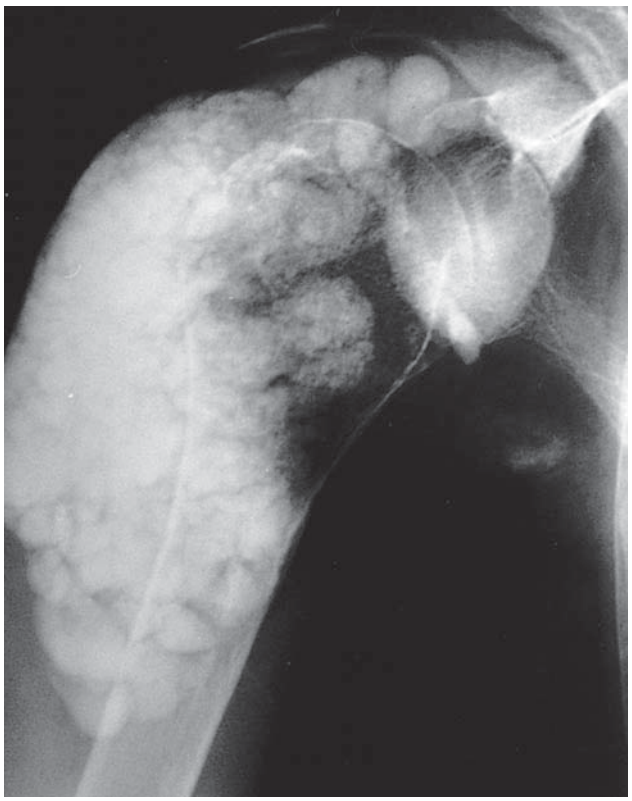

Figure 10-17 Tumor-like extraskeletal calcification in the shoulder.

Treatment

Treatment of acute hyperphosphatemia is usually targeted at improving phosphate excretion by IV fluids or by renal replacement therapy in patients with severe AKI. IV dextrose and insulin can also shift phosphate into cells, similar to its use in treating hyperkalemia.

Treatment of chronic hyperphosphatemia in CKD and dialysis patients remains a major component of CKD clinical care. Higher serum phosphate concentrations are *associated* with vascular calcification, cardiovascular events, and mortality in CKD.[27] However, no available treatment for hyperphosphatemia has proven clinical benefit, defined by placebo-controlled trials of hard outcomes. In chronic dialysis patients, dietary phosphate restriction and phosphate binders lower the serum phosphate concentration. Choices for phosphate binders include calcium acetate, calcium carbonate, sevelamer, lanthanum carbonate, and magnesium containing salts which must be taken multiple times per day with meals to complex with phosphate in the GI tract and limit absorption (see Chapter 85). Niacin is an intriguing possible alternative to phosphate binding agents due to its ease of administration (once daily) and novel mechanism of action (inhibition of NPT2b in small intestine, blocking phosphate absorption).[28]

HYPOPHOSPHATEMIA

Decreased plasma phosphate levels may reflect phosphate deficiency. This can theoretically be observed during a prolonged decrease in phosphate intake. However, several defense mechanisms counter a decrease in plasma phosphate resulting from low intake (Fig. 10-18). Moderately reduced plasma phosphate levels may also accompany maldistribution between the ICF and ECF compartments during acute respiratory alkalosis.

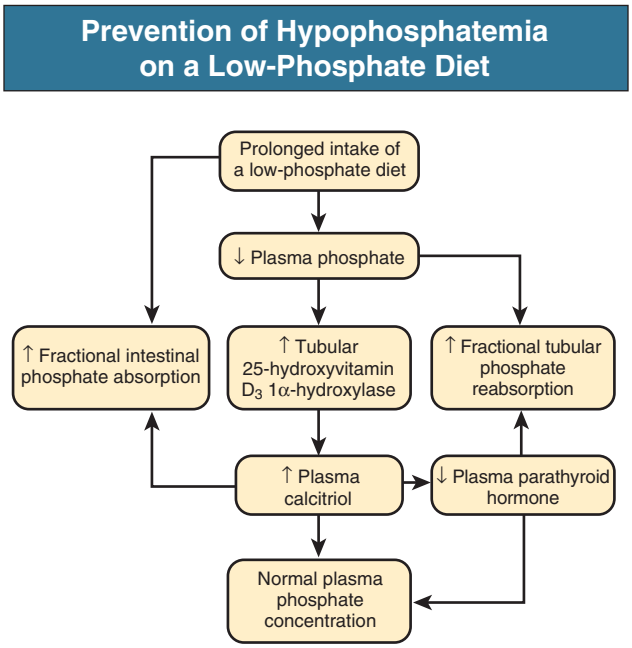

Figure 10-18 Prevention of hypophosphatemia. Compensatory mechanisms during prolonged intake of a phosphate-poor diet help to prevent hypophosphatemia.

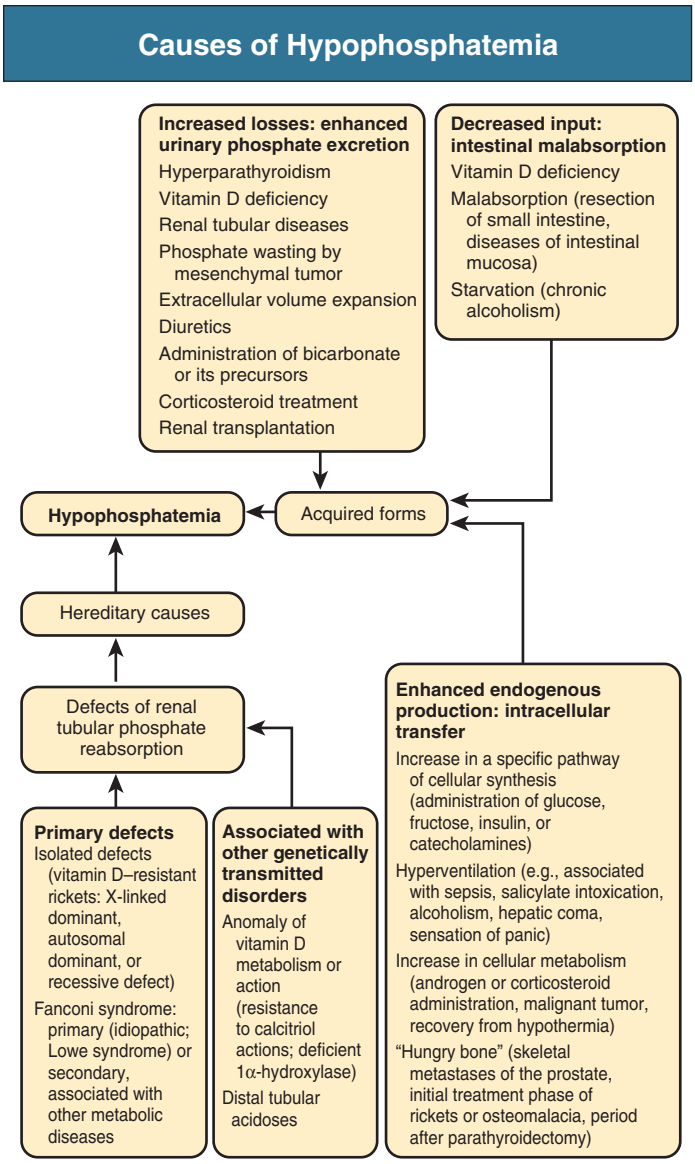

Figure 10-19 Causes of hypophosphatemia.

Causes of Hypophosphatemia

Moderate hypophosphatemia can be caused by genetic diseases or by acquired conditions (Fig. 10-19). The main acquired condition is malnutrition because of low food intake or anorexia during severe disease or alcoholism. Another cause is a shift of phosphate into cells, which can occur through various mechanisms, but especially with insulin administration. Although there are many genetic diseases and syndromes, overall these are rare. Severe forms of hypophosphatemia are all acquired conditions.

Inherited Forms of Hypophosphatemia

Inherited diseases associated with chronic hypophosphatemia are generally diagnosed in childhood.[29] Persistently low plasma phosphate usually leads to rickets or osteomalacia. Inherited hypophosphatemia results from primary defects, which are isolated or associated with tubular disorders (Fanconi syndrome) or defects secondary to another genetically transmitted disease, mainly metabolic disorders or disturbances in vitamin D activity.

Autosomal Dominant Hypophosphatemic Rickets Children with this phosphate wasting disorder present with skeletal defects, including bowing of the long bones and widening of costochondral joints. Autosomal dominant hypophosphatemic rickets is linked to mutations in *FGF23,* in which an aberrant form of the molecule is resistant to proteolytic cleavage.[30] Excess FGF-23 causes phosphate wasting by downregulating NPT2a in the proximal renal tubule.

X-Linked Hypophosphatemic Rickets This rare phosphate wasting syndrome is characterized by skeletal deformities, short stature, and osteomalacia. X-linked hypophosphatemic rickets has been associated with various mutations in the *PHEX* gene (phosphate-regulating endopeptidase on X chromosome). *PHEX* likely plays a role in the proteolysis of FGF-23.[31] *PHEX* mutations result in high circulating FGF-23 concentrations, renal phosphate wasting, and hypophosphatemia. Plasma calcium, calcitriol, and PTH levels are normal, and alkaline phosphatase level is elevated.

Autosomal Recessive Hypophosphatemic Rickets This inherited rickets disorder is caused by mutations in dentin matrix protein 1 gene *(DMP1),* which is believed to suppress FGF-23 secretion by bone.

Fanconi Syndrome and Proximal Renal Tubular Acidosis Fanconi syndrome is characterized by a complex transport defect of the proximal tubule that results in decreased reabsorption of glucose, amino acids, bicarbonate, and phosphate (see Chapter 50). Because 70% of the filtered phosphate load is typically reabsorbed in the proximal tubule, Fanconi syndrome can lead to phosphate wasting and hypophosphatemia. Causes of Fanconi syndrome can be classified as primary (e.g., idiopathic, Lowe syndrome, Dent disease) or associated with other metabolic diseases (e.g., cystinosis, Wilson disease). In Dent disease and Lowe syndrome, a defective recycling of megalin to the apical cell surface of the proximal tubule has implicated a role in abnormal tubular endocytic function.[32]

Fanconi syndrome with phosphate wasting can also occur as an acquired disorder in adults. Common causes are multiple myeloma and specific medications, including tenofovir, ifosfamide, and carbonic anhydrase inhibitors.

In addition to a tubular defect causing phosphate wasting, the activity of renal 1α-25-OH–vitamin D hydroxylase may be insufficient, resulting in decreased circulating calcitriol levels and bone disease such as rickets and osteomalacia. Functional disorders associated with the Fanconi syndrome, such as polyuria and ECF volume contraction, lead to hyperaldosteronism with hypokalemia and eventually to renal failure.

Vitamin D–Dependent Rickets Several rare inherited diseases are associated with hypophosphatemia and include vitamin D–dependent rickets type 1, caused by a defect of renal 1α-25-OH–vitamin D hydroxylase, and type 2, caused by peripheral resistance to the action of calcitriol. Clinical signs are similar to those of vitamin D–deficient rickets, but alopecia also occurs in 50% of patients. In type 1, calcitriol levels are low, whereas in type 2 there is normal circulating 1α-25-hydroxyvitamin D and high calcitriol. Treatment with low doses of calcitriol is sufficient to treat type 1, whereas extremely high doses of calcitriol or alfacalcidol are required for type 2 vitamin D–dependent rickets.

Distal Renal Tubular Acidosis (Type 1) Distal renal tubular acidosis (type 1 RTA) is associated with hypercalciuria and sometimes nephrocalcinosis. Chronic acidosis enhances the reabsorption of citrate in the proximal tubule, preventing it from forming soluble calcium-citrate complexes in the urine (see Chapter 12). Chronic acidosis also causes increased calcium and phosphate release from bone. Hypophosphatemia is inconstant, possibly resulting only with concomitant vitamin D deficiency.

Acquired Forms of Hypophosphatemia

The number of acquired diseases that can be associated with hypophosphatemia is even greater than inherited diseases and includes

hyperparathyroidism and vitamin D deficiency (Fig. 10-19). True phosphate deficiency associated with total body depletion must be distinguished from enhanced influx of phosphate from the extracellular to the intracellular space or increased skeletal mineralization.

Alcoholism Alcoholism is the most common cause of severe hypophosphatemia in Western countries. The multiple causes include prolonged poor food intake, excessive phosphate loss in urine secondary to hypomagnesemia, and phosphate transfer from the ECF to ICF compartment caused by hyperventilation or glucose infusion in patients with postalcoholic cirrhosis or in acute abstinence.

Hyperparathyroidism Parathormone enhances urinary phosphate excretion by downregulating the NPT2a cotransporter. Patients with primary hyperparathyroidism typically present with mild hypercalcemia and hypophosphatemia.

Post-Transplant Hypophosphatemia Renal phosphate wasting is exceedingly common in both cadaveric and living-related renal transplant recipients. At some point in their post-transplant course, most renal transplant patients develop hypophosphatemia which may be prolonged. Proposed explanations include residual hyperparathyroidism from CKD, but the best evidence implicates persistently high circulating levels of FGF-23 as the key factor responsible for post-transplant urinary phosphate wasting.

Acute Respiratory Alkalosis In intense and short-term hyperventilation, plasma phosphate can decrease to values as low as 0.1 mmol/l (0.3 mg/dl). Such a decrease is never observed in acute metabolic alkalosis. Hypophosphatemia following acute and intense hyperventilation is probably the result of muscle sequestration of extracellular phosphate. However, it must be remembered that prolonged chronic hyperventilation leads to hyperphosphatemia (see previous discussion).

Diabetic Ketoacidosis During decompensated diabetes associated with acidosis provoked by accumulation of ketone bodies, glycosuria, and polyuria, plasma phosphate can be normal or high, even in the presence of hyperphosphaturia. Correction of this complication by administering insulin and refilling the ECF compartment leads to massive transfer of phosphate into the intracellular compartment, hypophosphatemia, and subsequently less urinary loss of phosphate. In general, plasma phosphate does not decrease to less than 0.3 mmol/l (0.9 mg/dl), except when there is preexisting phosphate deficiency.

Total Parenteral Nutrition Hyperalimentation can also be associated with severe hypophosphatemia through the insulin-mediated shift of phosphate into cells, particularly if phosphate is omitted from the parenteral nutrition solution. Severe hypophosphatemia can also occur with acute feeding after starvation.

Oncogenic Hypophosphatemic Osteomalacia Hypophosphatemia associated with tumor-induced osteomalacia results from renal phosphate wasting in patients with mesenchymal tumors (hemangiopericytoma, fibroma, angiosarcoma). The mechanism of hypophosphatemia is tumor secretion of phosphatonins (FGF-23, sFRP-4, MEPE, FGF-7).[33] The condition resolves after tumor resection.

Drug-Induced Hypophosphatemia Imatinib mesylate, a tyrosine kinase inhibitor, has been reported to cause hypophosphatemia and elevated PTH levels. The mechanism of action is not yet clear.

Clinical Manifestations

Clinical manifestations depend more on the rate of onset of hypophosphatemia than on its severity or the total body phosphate deficit. In practice, it is not clinically evident when serum phosphate is greater than 0.65 mmol/l (2.0 mg/dl). Manifestations include metabolic encephalopathy, red and white blood cell dysfunction, sometimes hemolysis, and thrombocytopenia. Reduced muscle strength (e.g., diaphragmatic strength) and decreased myocardial contractility, with occasional rhabdomyolysis and cardiomyopathy, respectively, may occur.

Treatment

In general, phosphate deficiency is not an emergency. First, the mechanism involved should be defined to determine the most appropriate treatment. When phosphate deficiency is diagnosed, oral treatment by milk products or phosphate salts should always be tried first whenever possible, except in the presence of nephrocalcinosis or nephrolithiasis with urinary phosphate wasting. In severe symptomatic deficiency, phosphate can also be infused intravenously, in divided doses over 24 hours. In patients undergoing parenteral nutrition, 10 to 25 mmol potassium phosphate should be given for each 1000 kcal, taking care to avoid hyperphosphatemia because of the risk of inducing soft tissue calcifications. Dipyridamole reduces the urinary excretion of phosphate in patients with a low renal phosphate threshold.

MAGNESIUM HOMEOSTASIS AND DISORDERS OF MAGNESIUM METABOLISM

Distribution of Magnesium in the Organism

Magnesium (Mg^{2+}) is the second most abundant cation in the ICF in living organisms and the fourth most abundant cation in the body. Mg^{2+} is involved in the majority of metabolic processes. In addition, it plays a part in DNA and protein synthesis. Magnesium is involved in the regulation of mitochondrial function, in inflammatory processes and immune defense, allergy, growth, and stress, and the control of neuronal activity, cardiac excitability, neuromuscular transmission, vasomotor tone, and blood pressure. Figure 10-20 shows the distribution of Mg^{2+} within the intracellular and extracellular spaces. Figure 10-21 shows the balance of ingestion, body distribution, and excretion of Mg^{2+} in healthy humans. Cell influx and efflux are linked to carbohydrate-dependent active transport systems; stimulation of β-adrenoceptors favors Mg^{2+} exit, whereas insulin, calcitriol, and vitamin B_6 favor Mg^{2+} entry into cells.

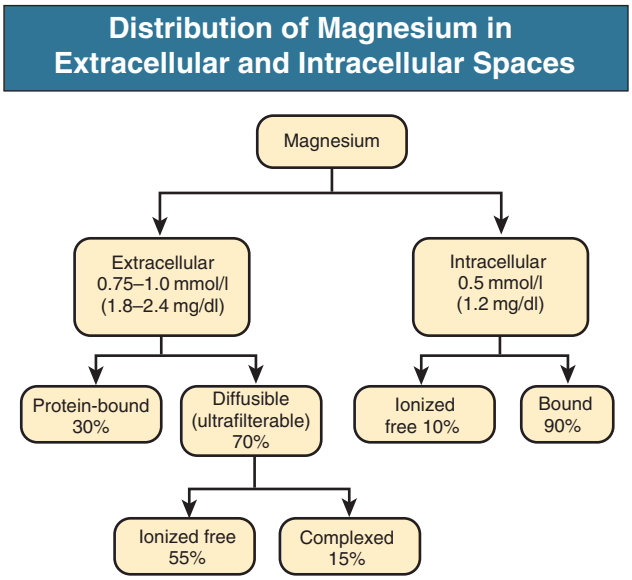

Figure 10-20 Magnesium distribution in extracellular and intracellular spaces.

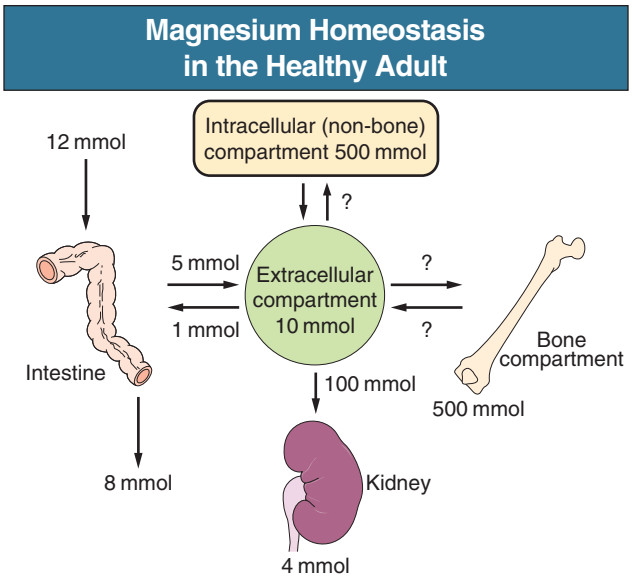

Figure 10-21 Magnesium homeostasis in healthy young adults. Net zero balance results from net intestinal uptake (absorption minus secretion) equaling urinary loss. After its passage into the extracellular fluid, Mg^{2+} enters the intracellular space, is deposited in bone or soft tissue, or is eliminated via the kidneys. Entry and exit fluxes between the extracellular and intracellular spaces (skeletal and nonskeletal compartments) are also of identical magnitude; however, precise values of exchange are still debated.

Intestinal and Renal Handling of Magnesium

The intestinal absorption of dietary Mg^{2+} occurs by both saturable and passive transport processes, the major part being absorbed in the distal small intestine and the colon. Paracellular Mg^{2+} absorption is responsible for 80% to 90% of intestinal Mg^{2+} uptake. It seems restricted primarily to areas that lack tightening claudins. Transcellular Mg^{2+} transport is mediated by transient receptor potential channel melastatin member 6 (TRPM6) and TRPM7 Mg^{2+} channels.[5] Mg^{2+} absorption can vary by as much as 25% to 60%, mainly depending on magnesium intake, with a mean absorption of approximately 30%. When magnesium intake is low, intestinal transport can rise up to 80%.[34]

Various factors modify intestinal Mg^{2+} absorption. In addition to high magnesium intake, high dietary phosphate intake is inhibitory, as is high phytate consumption. The effect of dietary calcium is complex, and calcitriol has an enhancing effect. Growth hormone slightly increases Mg^{2+} absorption, whereas aldosterone and calcitonin appear to reduce it. Vitamin B_6 has been reported to enhance absorption.

Magnesium is mainly eliminated by the kidney. Losses through intestinal secretion and sweat are negligible under normal conditions. With an ultrafilterable plasma magnesium concentration of 0.5 to 0.7 mmol/l (80% of total plasma magnesium), the filtered load of magnesium amounts to approximately 104 mmol (or 2500 mg) daily. The urine output represents approximately 5% of the filtered load (4 to 5 mmol, or 100 mg daily). The major portion of filtered magnesium is reabsorbed by the renal tubules: 25% in proximal tubule, 65% in TAL, and 5% in distal tubule (Fig. 10-22).[35]

Transport of Mg^{2+} in the TAL is primarily passive via the paracellular route. However, two conditions are necessary for normal Mg^{2+} reabsorption: (1) generation of an electrical, lumen-positive gradient induced by NaCl reabsorption that creates the driving force required for the reabsorption of divalent cations and (2) expression of claudins 16 and 19, which form a cation-selective tight junction, facilitating paracellular Mg^{2+} transport. Different anomalies associated with either NaCl reabsorption or with claudin-16/19 expression result in hypermagnesuria, such as Bartter syndrome, which is defined by genetic defects related to NaCl transport in the TAL.[36]

In the distal nephron (i.e., distal convoluted tubule and connecting tubule), Mg^{2+} is reabsorbed via the transcellular route against an uphill electrochemical gradient. The molecular identity of the gatekeeper channel that controls Mg^{2+} entry into the tubular epithelium across the brush border membrane is TRPM6.[5] Its activity is regulated by epidermal growth factor (EGF) and estrogen, but not by calcitriol or PTH.

Tubular Mg^{2+} transport is modulated by serum Mg^{2+} and Ca^{2+} and ECF volume. An increase in plasma Mg^{2+} or Ca^{2+} concentration results in impaired magnesium transport. ECF volume expansion produces a decrease in proximal tubular Mg^{2+} reabsorption, in parallel with that of Na^+ and Ca^{2+}. Dietary phosphate restriction results in marked hypercalciuria and hypermagnesuria and thus leads to overt hypomagnesemia. PTH, vasopressin, calcitonin, and glucagon increase tubular Mg^{2+} reabsorption, probably by the paracellular pathway, whereas acetylcholine, bradykinin, and atrial natriuretic peptide stimulate urinary Mg^{2+} excretion.

A number of drugs have also been shown to increase renal Mg^{2+} excretion, including the loop diuretics (furosemide, ethacrynic acid), distal diuretics (thiazides), and osmotic diuretics (mannitol, urea). Thiazide diuretics increase sodium delivery to the cortical collecting duct, dissipating the favorable electrochemical gradient for magnesium entry at this site. Thiazides also reduce TRPM6 expression in the distal convoluted tubule. Furthermore, renal Mg^{2+} wasting syndromes have been observed in patients treated with antibiotics such as gentamicin, antineoplastic agents such as cisplatin, and the calcineurin inhibitors cyclosporine and tacrolimus. The precise mechanisms of action of most of these agents are not well understood.

HYPERMAGNESEMIA

Elevated plasma Mg^{2+} is seen in patients with AKI and CKD, during the administration of pharmacologic doses of magnesium, in some infants born to mothers who received magnesium for eclampsia, and with the use of oral laxatives or rectal enemas containing magnesium (Fig. 10-23). Mild hypermagnesemia may also be present in patients with adrenal insufficiency, acromegaly, or FHH.

Clinical Manifestations

Symptoms and signs are the result of the pharmacologic effects of increased $[Mg^{2+}]$ on the nervous and cardiovascular systems. At $[Mg^{2+}]$ up to 1.5 mmol/l (3.6 mg/dl), hypermagnesemia is asymptomatic. Deep tendon reflexes are usually lost when plasma $[Mg^{2+}]$ is greater than 3 mmol/l (7.2 mg/dl). Respiratory paralysis, hypotension, abnormal cardiac conduction, and loss of consciousness may occur as plasma levels of magnesium approach 5 mmol/l (12 mg/dl).

Treatment

Treatment consists of cessation of magnesium administration and IV infusion of calcium salts, which is thought to counteract Mg blockade of calcium channels at the neuromuscular junction. For the management of symptomatic hypermagnesemia, calcium gluconate may be given, 1 g in 10 ml IV over 5 to 10 minutes (each gram calcium gluconate is approximately 90 mg elemental calcium).

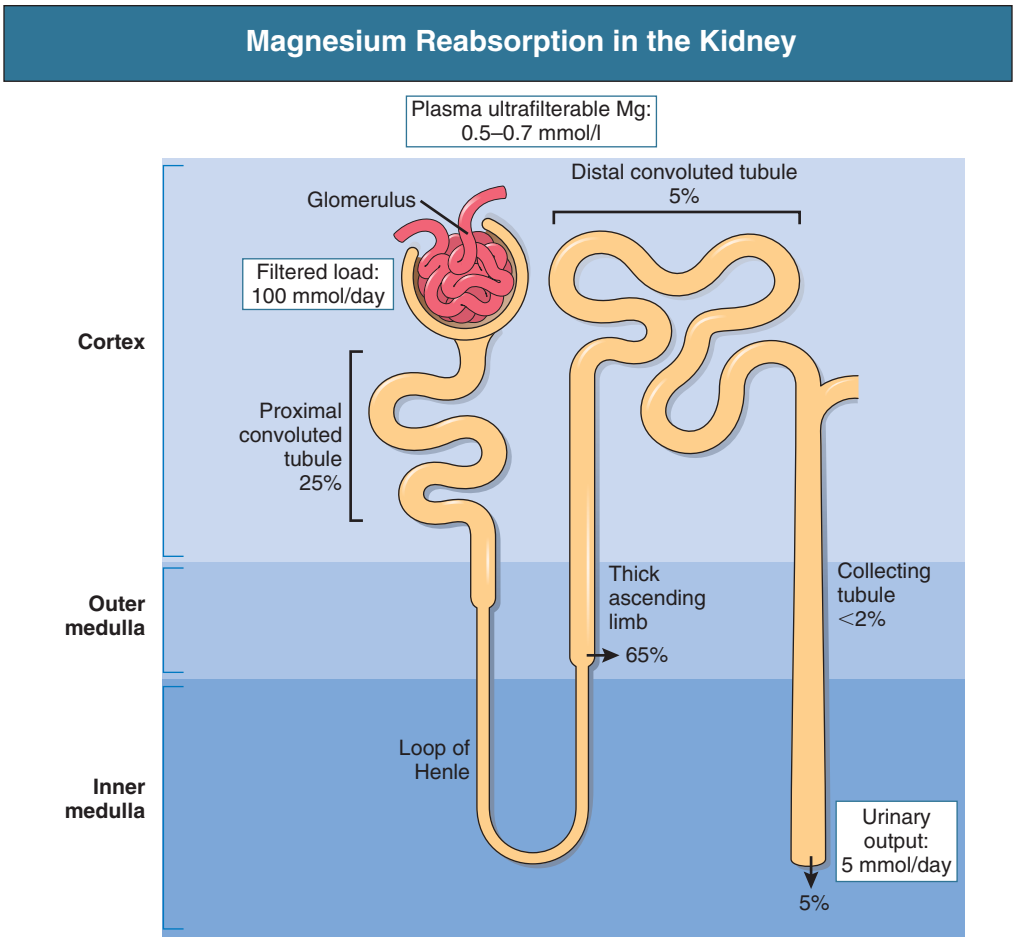

Figure 10-22 Sites of magnesium reabsorption in various segments. Percentage absorbed in various segments of the renal tubule from the glomerular ultrafiltrate. *(Redrawn from reference 35.)*

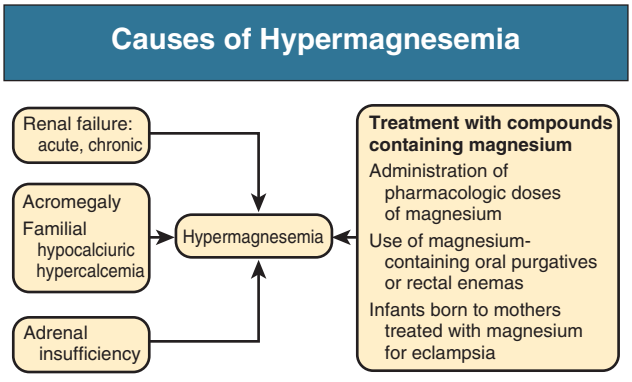

Figure 10-23 Causes of hypermagnesemia.

HYPOMAGNESEMIA AND MAGNESIUM DEFICIENCY

Magnesium deficiency is defined as a decrease in total body magnesium content. Poor dietary intake of magnesium is usually not associated with marked magnesium deficiency because of the ability of the intestine to increase Mg^{2+} absorption and the kidney to conserve Mg^{2+}. However, prolonged and severe dietary magnesium restriction of less than 0.5 mmol/day can produce symptomatic magnesium deficiency. Severe hypomagnesemia is usually associated with magnesium deficiency. About 10% of patients admitted to a large U.S. city hospital were hypomagnesemic. The incidence may be as high as 65% in medical intensive care units.

Underlying causes are usually GI diseases, in particular malabsorption syndromes such as nontropical sprue (celiac disease) and massive resection of the small intestine. Hypomagnesemia can also be induced by prolonged tube feeding without magnesium supplements and excessive use of non-magnesium-containing laxatives (Fig. 10-24).

Hypomagnesemia occurs in 25% to 35% of patients with acute pancreatitis, is frequently observed in chronic alcoholism, and can also occur in poorly controlled diabetes mellitus. Hypomagnesemia may be observed in patients with hypercalcemic disorders and primary aldosteronism, and magnesium deficiency can contribute to the metabolic syndrome.[37]

Excessive urinary loss of magnesium leads to hypomagnesemia and magnesium deficiency, even with normal dietary intake. It may result from the overzealous use of diuretics, and therefore it is important to monitor plasma Mg^{2+} levels in patients with congestive heart failure who are treated with diuretic agents. Other drugs that may cause hypomagnesemia, as previously described, include gentamicin, cisplatin, cyclosporine, and tacrolimus.

Several familial diseases are associated with hypermagnesuria, with or without hypomagnesemia. These are caused by inactivating mutations of genes whose abnormal products are responsible for

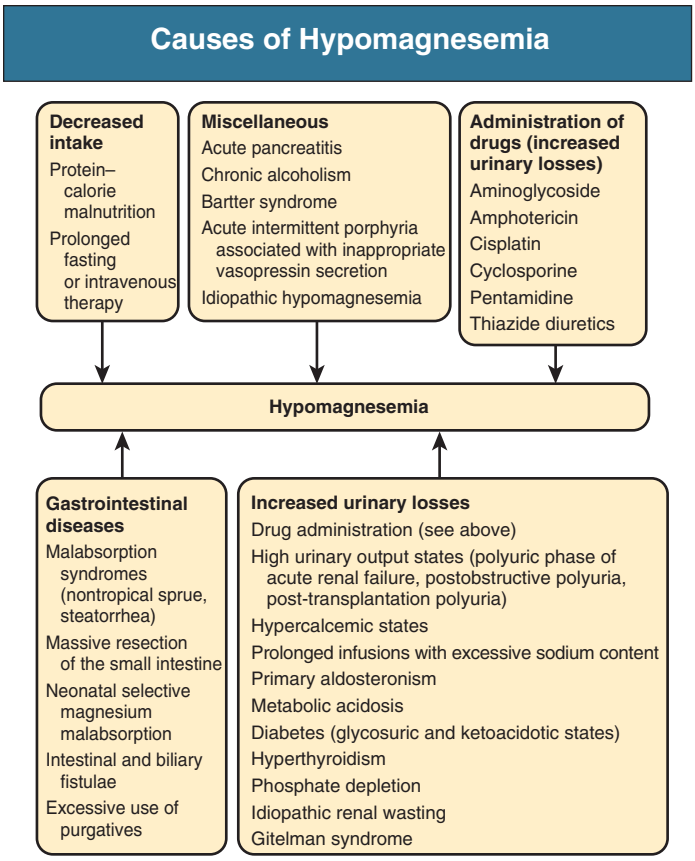

Figure 10-24 Causes of hypomagnesemia.

disturbed Mg^{2+} reabsorption in the TAL or distal nephron. Inactivating mutations of the genes of the Na^+-K^+-$2Cl^-$ cotransporter, rectifying K^+ channel (ROMK), or basolateral Cl^- channel in Bartter syndrome are responsible for the abolition of the driving force for Mg^{2+} reabsorption. This results in hypermagnesuria, which, however, is not always associated with hypomagnesemia. Inactivating mutations of the CaR_G gene, whose protein product is a key regulator of NaCl reabsorption in the TAL through extracellular $[Ca^{2+}]$, lead to hypermagnesuria and hypomagnesemia. Mutation of the claudin-16 gene reportedly induces recessive diseases characterized by hypomagnesemia, hypermagnesuria, hypercalciuria, and nephrocalcinosis. Mutations in the TRPM6 gene induce profound hypomagnesemia from impaired intestinal Mg^{2+} absorption and renal Mg^{2+} wasting, with secondary hypocalcemia.[38]

In the distal convoluted tubule, inactivating mutations of the thiazide-sensitive, electroneutral NaCl cotransporter gene (NCCT) in Gitelman syndrome are also responsible for selective renal magnesium wasting and hypomagnesemia.

Hypomagnesemia associated with inappropriate magnesuria has been reported in an autosomal-dominant, isolated familial hypomagnesemia syndrome, apparently caused by misrouting of the Na^+, K^+-ATPase γ subunit.

Clinical Manifestations

Specific clinical manifestations of hypomagnesemia may be difficult to appreciate because of concomitant hypocalcemia and hypokalemia. The main clinical manifestations of moderate to severe magnesium depletion include general weakness and neuromuscular hyperexcitability with hyperreflexia, carpopedal spasm, seizure, tremor, and rarely tetany. Cardiac findings include a prolonged QT interval and ST depression. There is a predisposition to ventricular arrhythmias and potentiation of digoxin toxicity. The role of magnesium deficiency in the clinical development of seizures and cardiac arrhythmias is demonstrated by the treatment of these conditions with magnesium. In mothers with pregnancy-related hypertension, IV magnesium was more effective than phenytoin for preventing eclamptic seizures. In patients with acute myocardial infarction and hypomagnesemia, magnesium repletion reduced the frequency of cardiac arrhythmias.

Magnesium deficiency can also be associated with hypocalcemia (decreased PTH release and end-organ responsiveness) and hypokalemia (urinary loss). In addition, intracellular K^+ is frequently decreased. Magnesium deficit constitutes a cardiovascular risk factor and also a risk factor in pregnancy for the mother and the fetus.

The diagnosis of moderate degrees of magnesium deficiency is not easy because clinical manifestations may be absent and serum Mg^{2+} levels may not reflect the state of body magnesium. Severe magnesium deficits, however, are associated with hypomagnesemia.

Treatment

Magnesium deficiency is managed with the administration of magnesium salts. Magnesium sulfate is generally used for parenteral therapy, 1500 to 3000 mg (150 to 300 mg elemental Mg) daily. A variety of magnesium salts are available for oral administration, including oxide, hydroxide, sulfate, lactate, chloride, carbonate, and pidolate. Oral magnesium salts often are not well tolerated, at least at high dosage. All may induce gastrointestinal intolerance, in particular diarrhea.

CHAPTER 11

Normal Acid-Base Balance

Biff F. Palmer

DEFINITION

The acid-base status of the body is carefully regulated to maintain the arterial pH between 7.35 and 7.45 and the intracellular pH between 7.0 and 7.3. This regulation occurs in the setting of continuous production of acidic metabolites and is accomplished by intracellular and extracellular buffering processes in conjunction with respiratory and renal regulatory mechanisms. This chapter reviews the normal physiology of acid-base homeostasis.

NET ACID PRODUCTION

Both acid and alkali are generated from the diet. Lipid and carbohydrate metabolism results in production of carbon dioxide (CO_2), a volatile acid, at the rate of approximately 15,000 mmol/day. Protein metabolism yields amino acids, which can be metabolized to form nonvolatile acid and alkali. Amino acids such as lysine and arginine yield acid on metabolism, whereas the amino acids glutamate and aspartate as well as organic anions such as acetate and citrate generate alkali. Sulfur-containing amino acids (methionine, cysteine) are metabolized to sulfuric acid (H_2SO_4), and organophosphates are metabolized to phosphoric acid (H_3PO_4). In general, animal foods are high in proteins and organophosphates, thereby providing a net acid diet; plant foods are higher in organic anions and provide a net alkaline load. In addition to acid and alkali generated from the diet, there is a small daily production of organic acids, including acetic acid, lactic acid, and pyruvic acid. Also, a small amount of acid is generated by the excretion of alkali into the stool. Under normal circumstances, daily net nonvolatile acid production is approximately 1 millimole (mmol) of hydrogen ions (H^+) per kilogram (kg) of body weight (Fig. 11-1).

BUFFER SYSTEMS IN REGULATION OF pH

Intracellular and extracellular buffer systems minimize the change in pH during the addition of acid or base equivalents but do not remove acid or alkali from the body. The most important buffer system is that of the bicarbonate ion and carbon dioxide (HCO_3^--CO_2). In this system, carbon dioxide concentration, [CO_2], is maintained at a constant level set by respiratory control. Addition of acid (HA) leads to conversion of HCO_3^- to CO_2 according to the reaction HA + $NaHCO_3$ → NaA + H_2O + CO_2. HCO_3^- is consumed, but [CO_2] does not change because this is maintained by respiration. The net result is that the acid load has been buffered and pH changes are minimal.

Whereas the HCO_3^--CO_2 buffer system is the most important of the buffers in extracellular fluid (ECF), other buffers such as plasma proteins and phosphate ions also participate in the maintenance of a stable pH. During metabolic acidosis, the skeleton becomes a major buffer source as acid-induced dissolution of bone apatite releases alkaline Ca^{2+} salts and HCO_3^- into the ECF. With chronic metabolic acidosis, this can result in osteomalacia and osteoporosis. The calcium released can result in hypercalciuria and an increased likelihood of renal stones. Within the intracellular fluid (ICF) compartment, pH is maintained by intracellular buffers such as hemoglobin, cellular proteins, organophosphate complexes, and HCO_3^- as well as by the H^+-HCO_3^- mechanisms that transport acid and alkali in and out of the cell.

RESPIRATORY SYSTEM IN REGULATION OF pH

Removal of acid or alkali from the body is accomplished by the lungs and kidneys. The lungs regulate the CO_2 tension (P_{CO_2}), and the kidneys regulate the serum bicarbonate concentration, [HCO_3^-]. Although the HCO_3^--CO_2 buffer system is not the only buffer system, all extracellular buffer systems are in equilibrium. Because serum [HCO_3^-] is much greater than that of other buffers, changes in the HCO_3^--CO_2 buffer pair can easily titrate other buffer systems and thus set pH. The following Henderson-Hasselbalch equation explains how the lungs and kidneys function in concert:

$$pH = 6.1 + \log\left[\frac{HCO_3^-}{(0.03 \times Pa_{CO_2})}\right]$$

As can be seen, pH is determined by the ratio of HCO_3^- to CO_2. Conditions associated with similar fractional changes in [HCO_3^-] and [CO_2], such as when both are halved, will not change blood pH.

The lungs defend pH by altering alveolar ventilation, which alters the CO_2 excretion rate and thereby controls the arterial CO_2 tension (Pa_{CO_2}) of body fluids. Systemic acidosis stimulates the respiratory center, resulting in increased respiratory drive that lowers the Pa_{CO_2}. As a result, the fall in blood pH is less than would have occurred in the absence of respiratory compensation. If the fractional change in P_{CO_2} were similar to that in serum [HCO_3^-], blood pH would not change. However, respiratory compensation rarely normalizes blood pH, and thus the fractional change in P_{CO_2} is less than the change in serum [HCO_3^-]. Quantitatively, the normal respiratory response in metabolic acidosis is a 1.2 mm Hg decrease in Pa_{CO_2} for every 1 mmol/l decrease in HCO_3^-; the increase in Pa_{CO_2} in response to metabolic alkalosis averages 0.7 mm Hg for every 1 mmol/l increase in HCO_3^- above baseline.[1]

RENAL REGULATION OF pH

Buffer systems and respiratory excretion of CO_2 help maintain normal acid-base balance, but the kidneys provide a critical role in acid-base homeostasis. The kidneys normally generate sufficient net

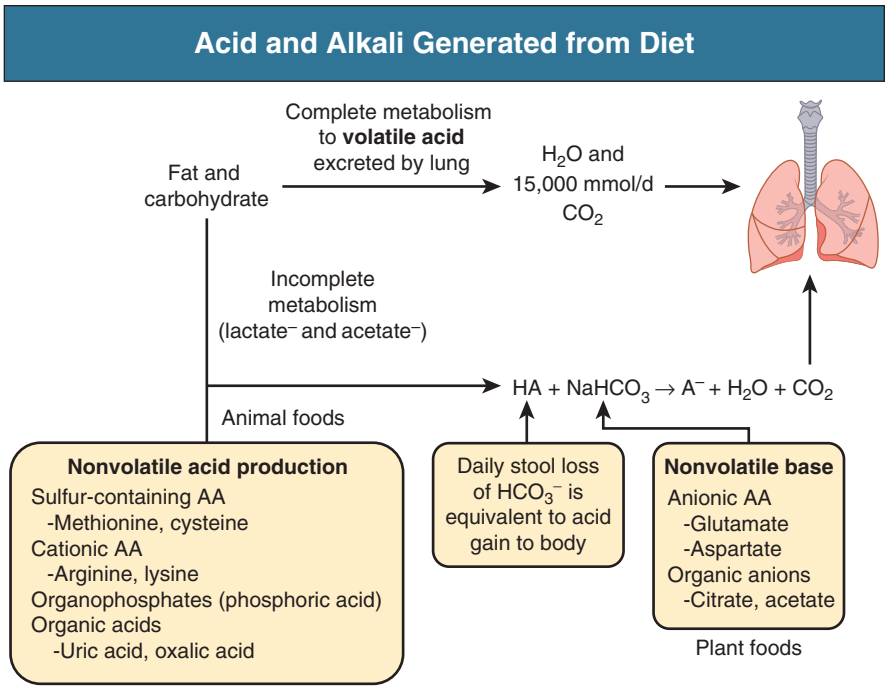

Figure 11-1 Acid and alkali generated from the diet. A nonvolatile acid is an acid produced from sources other than CO_2 and is not excreted by the lungs. Nonvolatile acids are produced from incomplete metabolism of carbohydrates, fats, and proteins and from metabolism of animal foods. Plant foods tend to produce an alkali load. *AA,* Amino acids.

acid excretion (NAE) to balance nonvolatile acid produced from normal metabolism. NAE has three components, titratable acids, ammonium (NH_4^+), and bicarbonate, and is calculated by the following formula:

$$NAE = U_{Am}V + U_{TA}V - U_{HCO_3^-}V$$

where $U_{Am}V$ is the rate of NH_4^+ excretion, $U_{TA}V$ is the rate of titratable acid excretion, and $U_{HCO_3^-}V$ is the rate of HCO_3^- excretion. Under basal conditions, approximately 40% of NAE is in the form of titratable acids and 60% is in the form of ammonia (NH_3); urinary bicarbonate concentrations and excretion are essentially zero under normal conditions. When acid production increases, the increase in acid excretion is almost entirely caused by an increase in excretion of NH_4^+.

RENAL TRANSPORT MECHANISMS OF HYDROGEN AND BICARBONATE IONS

Glomerulus

The glomerulus is not normally considered as participating in acid-base regulation. However, the glomerulus filters an amount of HCO_3^- equivalent to serum [HCO_3^-] multiplied by the glomerular filtration rate (GFR). Under normal circumstances, the filtered load of HCO_3^- averages approximately 4000 mmol/day. Normal acid-base homeostasis requires both the reabsorption of this filtered bicarbonate and the generation of "new" bicarbonate; the latter replenishes bicarbonate and other alkaline buffers consumed in the process of titrating endogenous acid production. From the standpoint of prevention of or correction of acidosis, GFR is not regulated by alterations in acid or base and therefore does not contribute to acid-base homeostasis.

Proximal Tubule

The proximal tubule reabsorbs approximately 80% of the filtered load of HCO_3^-. In addition, by titration of luminal pH from 7.4 down to approximately 6.7, the majority of phosphate, the major form of titratable acid, is titrated to its acid form. Lastly, ammonia synthesis occurs in the proximal tubule.

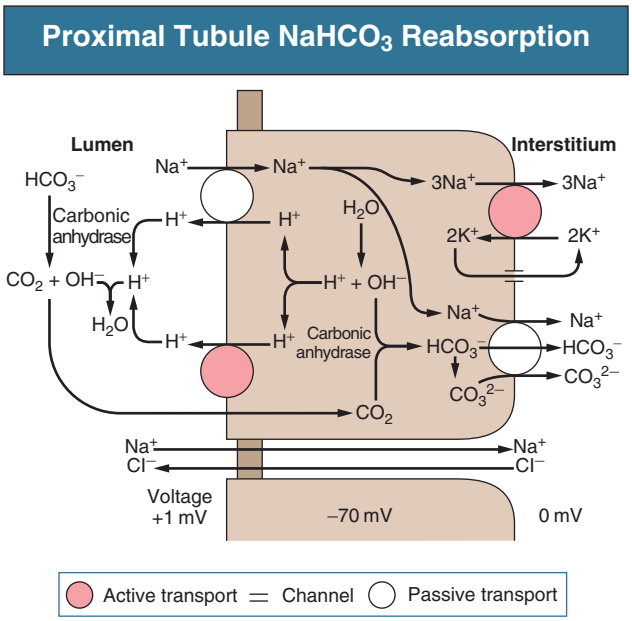

Figure 11-2 Proximal tubule sodium bicarbonate ($NaHCO_3$) reabsorption. The secretion of H^+ into the proximal tubule lumen involves a Na^+-H^+ antiporter and an H^+-ATPase. Apical membrane H^+ secretion generates OH^-, which reacts with CO_2 to form HCO_3^- and CO_3^{2-}, and these exit with a Na^+ on the basolateral membrane Na^+-HCO_3^--CO_3^{2-} cotransporter. The Na^+ absorbed by the Na^+-H^+ antiporter exits the cell on the basolateral membrane Na^+,K^+-ATPase and the Na^+-HCO_3^--CO_3^{2-} cotransporter. The K^+ that enters the cell on the Na^+,K^+-ATPase exits on a basolateral membrane K^+ channel. Carbonic anhydrase catalyzes the conversion of HCO_3^- to CO_2 and OH^- in the lumen and the reverse reaction in the cell. Electrogenic H^+ secretion generates a small, lumen-positive voltage that generates a current flow across the paracellular pathway.

Figure 11-2 shows the acid-base transport mechanisms of the proximal tubule cell. HCO_3^- absorption from the tubular lumen is mediated by H^+ secretion across the membrane.[2] This H^+ secretion

is active in that the electrochemical gradient favors H^+ movement from lumen to cell. Two mechanisms mediate active apical H^+ secretion. Approximately two thirds occurs through the apical membrane Na^+-H^+ antiporter NHE3.[3] This protein uses the inward Na^+ gradient to drive H^+ secretion. The Na^+-H^+ exchanger has a 1 : 1 stoichiometry and is electroneutral. In parallel with the Na^+-H^+ antiporter, there is an apical membrane H^+-ATPase that mediates approximately one third of basal proximal tubular HCO_3^- absorption.

Both these H^+ transporters generate base in the cell, which must exit across the basolateral membrane to effect transepithelial transport. This primarily occurs through a basolateral Na^+-HCO_3^--CO_3^{2-} cotransporter. Because this protein transports the equivalent of two net negative charges, the negative cell voltage generated by the basolateral Na^+,K^+-ATPase provides a strong favorable driving force for base efflux. The Na^+ that is carried on this transporter is moved out of the cell energy free in that ATP is not required. The Na^+-$3HCO_3^-$ cotransporter NBC1, encoded by the gene *SLC4A4,* mediates the majority of proximal tubule basolateral base exit.[4]

Carbonic anhydrase II is present in the proximal tubular cell cytoplasm, and carbonic anhydrase IV is on the apical and basolateral membranes. Carbonic anhydrase (carbonate dehydratase) has a number of functions in the proximal tubule. Apical membrane carbonic anhydrase allows secreted H^+ ions to react with luminal HCO_3^-, forming H_2CO_3, which rapidly dissociates to $CO_2 + H_2O$. This CO_2 diffuses across the apical plasma membrane into the cell. There the process is reversed, with use of cytoplasmic carbonic anhydrase, generating intracellular H^+ and HCO_3^-. This H^+ "replenishes" the H^+ secreted across the apical membrane, resulting in net movement of the HCO_3^- from the luminal solution to the cell cytoplasm. The intracellular HCO_3^- is then secreted across the basolateral plasma membrane, as described previously.

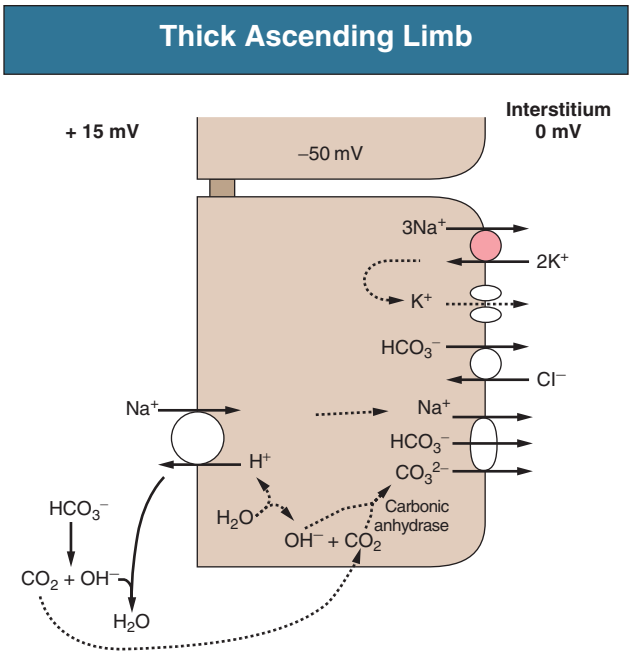

Figure 11-3 Hydrogen (H^+) and bicarbonate (HCO_3^-) ion transport in thick ascending limb. Apical H^+ secretion is mediated by a Na^+-H^+ antiporter. The low intracellular Na^+ concentration, maintained by the basolateral Na^+,K^+-ATPase, provides the primary driving force for the antiporter. Both Cl^--HCO_3^- exchange and Na^+-HCO_3^--CO_3^{2-} cotransport mediate base exit across the basolateral membrane.

Thick Ascending Limb of Henle Loop

Tubular fluid arriving at the early distal tubule has a pH and serum [HCO_3^-] similar to that in the late proximal tubule. Because there is significant water extraction in the loop of Henle, maintenance of a constant serum HCO_3^- concentration requires reabsorption of HCO_3^-. The majority of this HCO_3^- absorption occurs in the thick ascending limb (TAL) through mechanisms similar to those present in the proximal tubule (Fig. 11-3). The majority of apical membrane H^+ secretion is mediated by the Na^+-H^+ antiporter NHE3. As in the proximal tubule, the low intracellular Na^+ concentration maintained by the basolateral Na^+,K^+-ATPase provides the primary driving force for the antiporter. Base efflux across the basolateral membrane is mediated by a Cl^--HCO_3^- exchanger and a Na^+-HCO_3^--CO_3^{2-} cotransporter. These cells also possess an H^+-ATPase. The contribution of this pump to overall acidification in this segment is not clear.

Thick Distal Nephron

Approximately 80% of the filtered HCO_3^- is reabsorbed in the proximal tubule; most but not all of the remainder is absorbed in the TAL. One function of the distal nephron is to reabsorb the remaining 5% of filtered HCO_3^-. In addition, the distal nephron must secrete a quantity of H^+ equal to that generated systemically by metabolism to maintain acid-base balance.

The distal nephron is subdivided into several distinct portions that differ in their anatomy and acid secretory properties. Most of these segments transport H^+ and HCO_3^- into the luminal fluid, but the main segments appear to be in the collecting duct.[5] The segments of the collecting duct include the cortical collecting duct (CCD), the outer medullary collecting duct, and the inner medullary collecting duct. There are two distinct cell types in the CCD that can be distinguished histologically: the *principal* cell and the *intercalated* (IC) cell. The principal cell reabsorbs Na^+ and secretes K^+ and is discussed later. Depending on chronic acid-base status, the CCD is capable of either H^+ or HCO_3^- secretion. These functions are mediated by two types of IC cells: the acid-secreting α-intercalated cell and the base-secreting β-intercalated cell. Both IC cell types are rich in carbonic anhydrase II.

Reabsorption of HCO_3^- in the distal nephron is mediated by apical H^+ secretion by the α-intercalated cell. Two transporters secrete H^+: a vacuolar H^+-ATPase and an H^+,K^+-ATPase (Fig. 11-4). The vacuolar H^+-ATPase is an electrogenic pump related to the H^+ pump present within lysosomes, the Golgi apparatus, and endosomes. The H^+,K^+-ATPase uses the energy derived from adenosine triphosphate hydrolysis to secrete H^+ into the lumen and to reabsorb K^+ in an electroneutral fashion. The activity of the H^+,K^+-ATPase increases in K^+ depletion and thus provides a mechanism by which K^+ depletion enhances both collecting duct H^+ secretion and K^+ absorption.

Active H^+ secretion by the apical membrane generates intracellular base that must exit the basolateral membrane. A basolateral Cl^--HCO_3^- exchanger is the mechanism by which this base exit occurs. The Cl^- that enters the cell in exchange for HCO_3^- exits the cell through a basolateral membrane Cl^- conductance channel (Fig. 11-4).

The HCO_3^--secreting β-intercalated cell is a mirror image of the α-intercalated cell (Fig. 11-5). It possesses an H^+-ATPase on the basolateral membrane, which mediates active H^+ extrusion. Alkali that is generated within the cell then exits on an apical membrane Cl^--HCO_3^- exchanger. This Cl^--HCO_3^- exchanger is distinct from the basolateral Cl^--HCO_3^- exchanger present in the α-intercalated cell and functions as an anion exchanger or Cl^- channel in the luminal

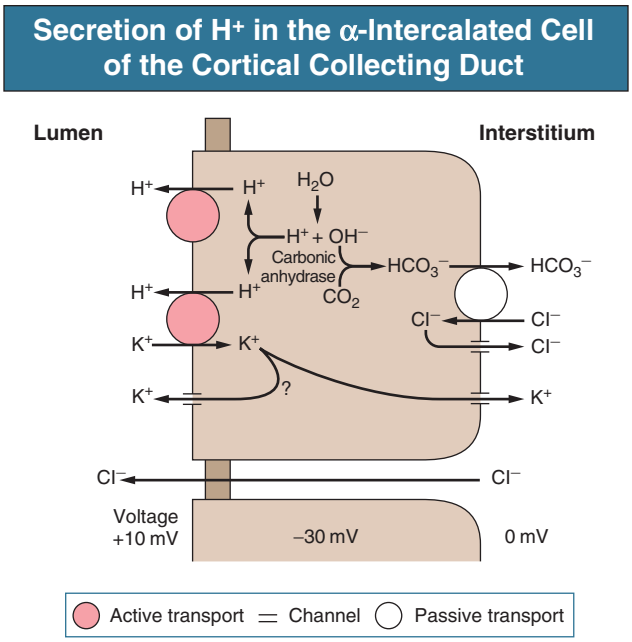

Figure 11-4 H^+ secretion in cortical collecting duct α-intercalated cell. Secretion of hydrogen ions into the lumen by an H^+-ATPase and an H^+,K^+-ATPase. Apical membrane H^+ secretion generates OH^-, which reacts with CO_2 to form HCO_3^-. This bicarbonate exits across the basolateral membrane on a Cl^--HCO3$^-$ exchanger, a member of the anion exchanger 1 (AE1) family and a truncated form of the red blood cell AE1 Cl^--HCO_3^- exchanger. The Cl^- that enters the cell on the exchanger recycles across a basolateral membrane Cl^- channel. The K^+ that enters the cell on the H^+,K^+-ATPase appears to be able either to recycle across the apical membrane or to exit across the basolateral membrane, depending on the potassium balance of the individual. Carbonic anhydrase catalyzes the conversion of CO_2 and OH^- to HCO_3^- in the cell. Electrogenic H^+ secretion generates a lumen-positive voltage that generates a current flow across the paracellular pathway.

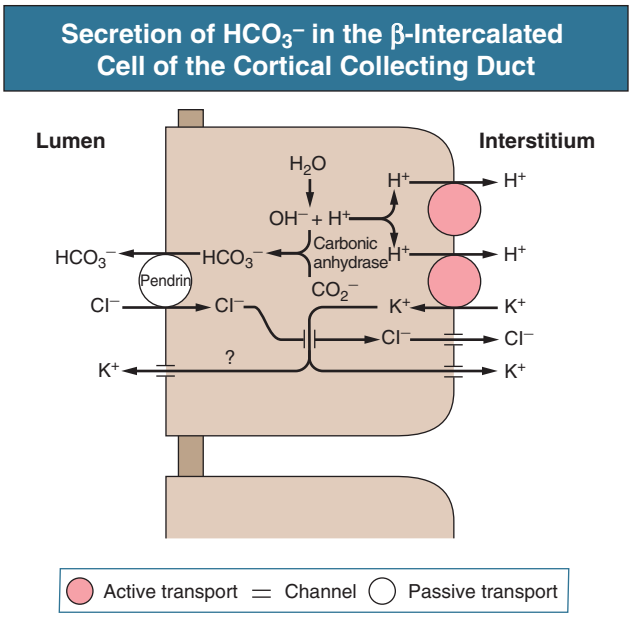

Figure 11-5 Bicarbonate secretion by cortical collecting duct β-intercalated cell. H^+ is secreted into the interstitium by an H^+-ATPase. The OH^- generated by basolateral membrane H^+ secretion reacts with CO_2 to form HCO_3^-, which exits across the apical membrane on a Cl^--HCO_3^- exchanger. The Cl^- that enters the cell on the exchanger exits across a basolateral membrane Cl^- channel. Carbonic anhydrase catalyzes the conversion of CO_2 and OH^- to HCO_3^- in the cell.

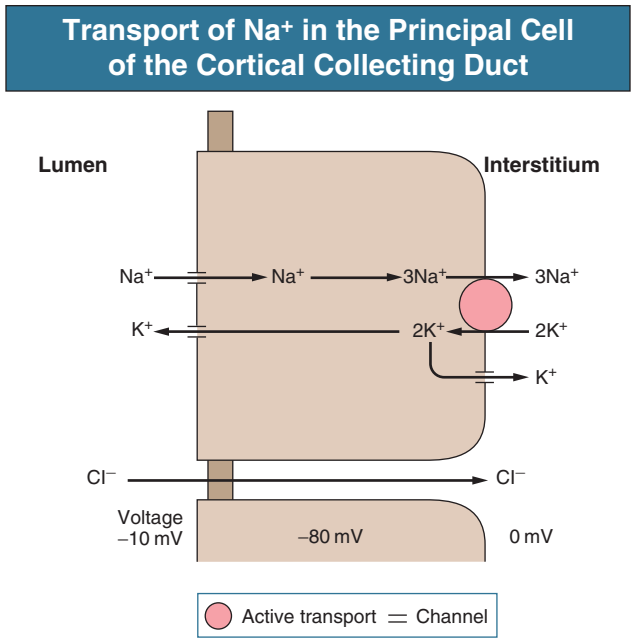

Figure 11-6 Sodium transport in cortical collecting duct principal cell. Electrogenic Na^+ absorption is mediated by an Na^+ channel. The Na^+ enters the cell across the apical membrane channel and exits the cell on the basolateral membrane Na^+,K^+-ATPase. The K^+ that enters the cell on the basolateral Na^+,K^+-ATPase can be secreted into the luminal fluid by an apical membrane K^+ channel. Electrogenic Na^+ absorption establishes a lumen-negative voltage that drives a paracellular current.

membrane of epithelial cells.[6] The SLC26A4 protein (pendrin) is a family member that mediates apical Cl^--HCO_3^- exchange in the β-intercalated cell of the kidney.

The other cortical collecting tubule cell type is the principal cell, which also regulates acid-base transport, although indirectly. Principal cells mediate electrogenic Na^+ reabsorption that results in a net negative luminal charge (Fig. 11-6). The greater this negative charge, the lesser is the electrochemical gradient for electrogenic proton secretion, and therefore the greater the rate of net proton secretion. Thus, factors that stimulate Na^+ reabsorption indirectly regulate the H^+ secretory rate.

The medullary collecting duct possesses mechanisms only for H^+ secretion. This H^+ secretion is mediated by α-intercalated cells but also by cells that appear morphologically distinct from IC cells but are functionally similar.

Net Acid Excretion

For the kidney to generate NAE, it must both reabsorb filtered HCO_3^- and excrete titratable acids and ammonia. Several weak acids, such as phosphate, creatinine, and uric acid, are filtered at the glomerulus and can buffer secreted protons. Of these, phosphate is the most important because of its favorable pK_a of 6.80 and its relatively high rate of urinary excretion (~25 to 30 mmol/day). However, the capacity of phosphate to buffer protons is maximized at a urine pH of 5.8, and acid-base disturbances do not, in general, induce substantial changes in urinary phosphate excretion. Other titratable acids, such as creatinine and uric acid, are limited by their lower excretion rate, which is not dramatically changed in response to acid-base disturbances. Titratable acid excretion is a minor component of the increase in NAE in response to metabolic acidosis (Fig. 11-7).

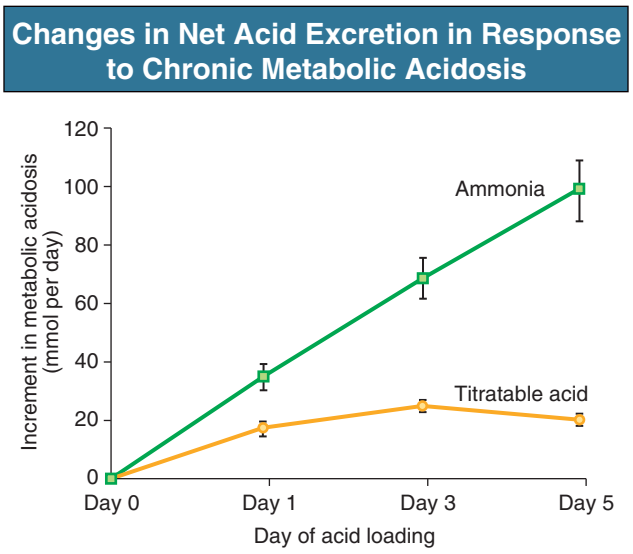

Figure 11-7 Changes in net acid excretion. Chronic metabolic acidosis increases net acid excretion dramatically during several days; shown quantitatively are the increases in the two major components of net acid excretion, titratable acids and ammonia. Titratable acid excretion increases slightly and predominantly in the first 24 to 48 hours. In contrast, urinary ammonia excretion progressively increases over 7 days and is responsible for most of the increase in net acid excretion in chronic metabolic acidosis. *(Plotted data redrawn from original data in reference 10.)*

Ammonia Metabolism

Quantitatively, the most important component of NAE is the NH_3/NH_4^+ system.[7] Unlike for titratable acids, the rate of ammonia (NH_3) production and excretion varies according to physiologic needs. Under normal circumstances, ammonia excretion accounts for approximately 60% of total NAE, and in chronic metabolic acidosis, almost the entire increase in NAE is caused by increased NH_3 metabolism. Ammonia metabolism involves an interplay among the proximal tubule, TAL, and collecting duct.

The proximal tubule is responsible for both ammonia production and luminal secretion. Ammonia is synthesized in the proximal tubule predominantly from glutamine metabolism through enzymatic processes in which phosphoenolpyruvate carboxykinase and phosphate-dependent glutaminase are the rate-limiting steps. This results in production of two ammonium (NH_4^+) and two HCO_3^- ions from each glutamine ion. Ammonia is then preferentially secreted into the lumen. The primary mechanism for this luminal secretion appears to be NH_4^+ transport by the apical Na^+-H^+ antiporter NHE3 (Fig. 11-8).

Metabolic acidosis increases the mobilization of glutamine from skeletal muscle and intestinal cells. Glutamine is preferentially taken up by the proximal tubular cell through the Na^+- and H^+-dependent glutamine transporter SNAT3. This transporter is a member of the *SCL38* gene family of Na^+-coupled neutral amino acid transporters. SNAT3 expression increases several-fold in metabolic acidosis, and

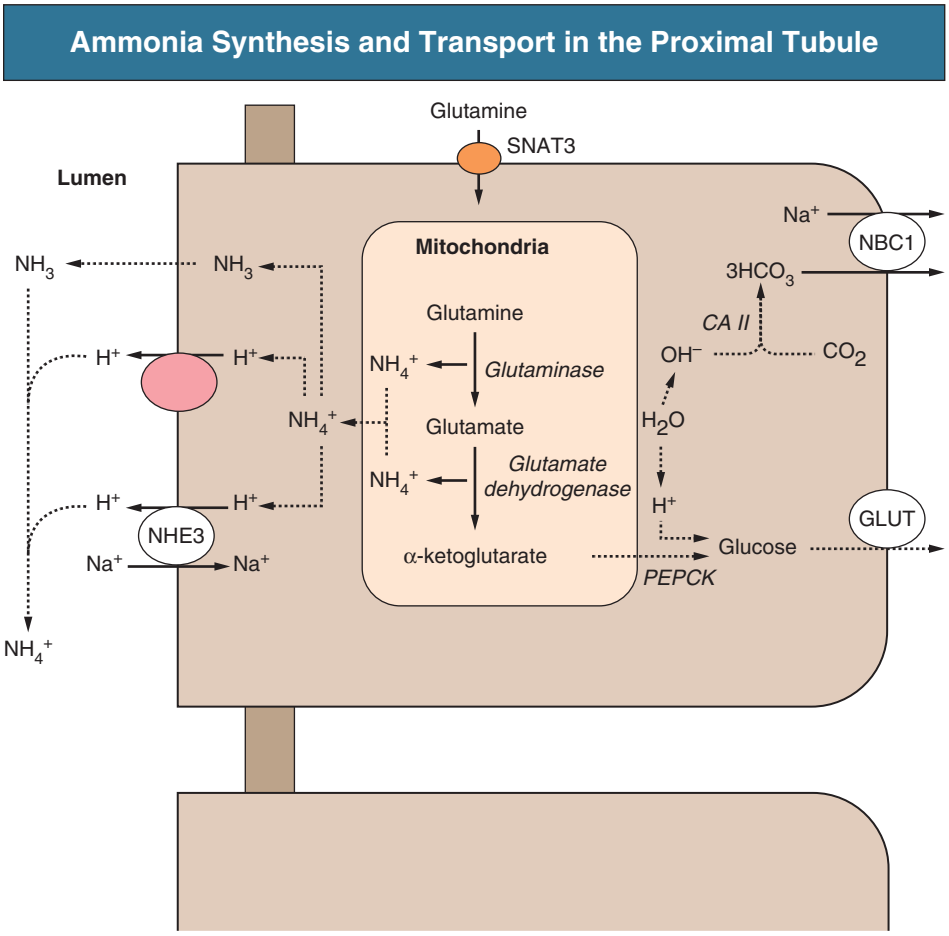

Figure 11-8 Ammonia synthesis and transport in proximal tubule. Metabolic acidosis and hypokalemia stimulate proximal ammonia synthesis by stimulating the uptake of glutamine through SNAT3.The generation of ammonia is the result of glutamine metabolism by enzymes closely linked to gluconeogenesis.

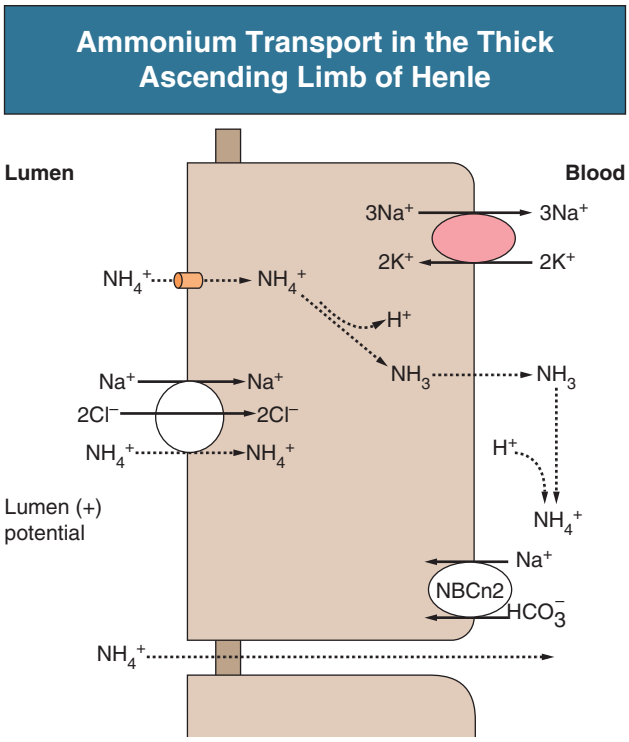

Figure 11-9 Ammonia transport in thick ascending limb of Henle loop. In addition to reabsorption through the paracellular pathway driven by the lumen-positive potential, ammonium can substitute for K^+ on the Na^+-K^+-$2Cl^-$ transporter and the apical membrane K^+ channel (ROMK). The basolateral Na^+-HCO_3^- cotransporter (NBCn2) is thought to play a housekeeping role to maintain cell pH given the large transcellular ammonium flux.

it is preferentially expressed on the cell's basolateral surface, where it is poised for glutamine uptake.[8] The increase in plasma cortisol that typically accompanies metabolic acidosis plays a role in this transporter's upregulation.[9] Metabolic acidosis also causes increased expression and activity of phosphate-activated glutaminase and glutamate dehydrogenase.

Most of the ammonia that leaves the proximal tubule does not return to the distal tubule. Thus, there is transport of ammonia out of the loop of Henle. This ammonia transport appears to occur predominantly in the TAL and is mediated by at least three mechanisms (Fig. 11-9). First, the lumen-positive voltage provides a driving force for passive paracellular NH_4^+ transport out of the TAL. Second, NH_4^+ can be transported out of the lumen by the furosemide-sensitive Na^+-K^+-$2Cl^-$ transporter. Third, NH_4^+ can leave the lumen across the apical membrane K^+ channel of the TAL cell. How NH_4^+ would then leave the cell across the basolateral membrane is largely unknown.

In addition, ammonia is secreted by the collecting duct. Although the traditional thought was that NH_3/NH_4^+ then enters the collecting duct by nonionic diffusion driven by the acid luminal pH, increasing evidence suggests that the nonerythroid glycoproteins Rhbg and Rhcg may be involved in collecting duct ammonia secretion.[11,12]

On the basis of the preceding discussion, ammonia excretion can be regulated by three mechanisms. First, ammonia synthesis in the proximal tubule can be regulated. Chronic acidosis and hypokalemia increase ammonia synthesis, whereas hyperkalemia suppresses ammonia synthesis. Second, ammonia delivery from the proximal tubule to the medullary interstitium can be regulated. In particular, chronic metabolic acidosis increases expression of both NHE3 and the loop of Henle Na^+-K^+-$2Cl^-$ cotransporter. Hyperkalemia can inhibit NH_4^+ reabsorption from the TAL. This may explain the low urinary $[NH_4^+]$ found in hyperkalemic distal renal tubular acidosis (in addition to decreased NH_3 synthesis by hyperkalemia). Also, any interstitial renal disease that destroys renal medullary anatomy may decrease medullary interstitial $[NH_3/NH_4^+]$. Third, mechanisms that regulate collecting duct H^+ secretion or ammonia transporter expression can regulate ammonia entry into the collecting duct and ammonia excretion. Importantly, the primary mechanisms require synthesis of new proteins to increase both ammonia production and transport. Accordingly, changes in ammonia excretion may be delayed, and the maximal renal response to chronic metabolic acidosis requires 4 to 7 days.

REGULATION OF RENAL ACIDIFICATION

The regulation of acid-base balance requires an integrated system that precisely regulates proximal tubular H^+-HCO_3^- transport, distal nephron H^+-HCO_3^- transport, and ammonia synthesis and transport.

Blood pH

The regulation of acid-base balance requires that net H^+ excretion increase in states of acidosis and decrease in states of alkalosis. This form of regulation involves both acute and chronic mechanisms. In the proximal tubule, acute decreases in blood pH increase the rate of HCO_3^- absorption, and acute increases in blood pH inhibit HCO_3^- absorption. These alterations in the rate of HCO_3^- absorption occur whether the change in pH is the result of changes in P_{CO_2} or serum $[HCO_3^-]$. Similarly, in the collecting duct, acute changes in peritubular serum $[HCO_3^-]$ and pH regulate the rate of H^+ secretion.

In addition to acute regulation, mechanisms exist for chronic regulation. Chronic acidosis or alkalosis leads to parallel changes in the activities of the proximal tubule apical membrane Na^+-H^+ antiporter and basolateral membrane Na^+-HCO_3^--CO_3^{2-} cotransporter. Metabolic acidosis acutely increases the kinetic activity of NHE3 through direct pH effects and by phosphorylation; chronic acidosis increases the number of NHE3 transporters.[13,14] In addition, chronic acidosis increases proximal tubular ammonia synthesis by increasing the activities of the enzymes involved in ammonia metabolism.

The CCD is also modified by chronic acid-base changes. Long-term increases in dietary acid lead to an increase in H^+ secretion, whereas long-term increases in dietary alkali lead to an increased capacity for HCO_3^- secretion.[15] This effect is mediated by changes in the relative number of α- and β-intercalated cells. For example, during metabolic acidosis, the number of α-intercalated cells increases while the number of β-intercalated cells decreases, without a change in the total number of IC cells. Recent evidence suggests that the extracellular protein hensin may be involved in the switch between the predominant IC cell types.[16]

Mineralocorticoids, Distal Sodium Delivery, and Extracellular Fluid Volume

Mineralocorticoid hormones are key regulators of distal nephron and collecting duct H^+ secretion. Two mechanisms appear to be involved. First, mineralocorticoid hormone stimulates Na^+ absorption in principal cells of the CCD (see Fig. 11-6). This leads to a more lumen-negative voltage that then stimulates H^+ secretion. This mechanism is indirect in that it requires the presence of Na^+ and of Na^+ transport. The second mechanism is the direct activation of H^+ secretion by mineralocorticoids. This effect is chronic, requiring long

exposure, and involves parallel increases in apical membrane H^+-ATPase and basolateral membrane Cl^--HCO_3^- exchanger activity.

Plasma Volume

Changes in plasma volume have important effects on acid-base homeostasis. This effect appears to be related to a number of factors. First, volume contraction is associated with a decreased GFR, which lowers the filtered load of HCO_3^- and decreases the load placed on the tubules, to maintain NAE. Volume contraction also acutely decreases the paracellular permeability of the proximal tubule. This will decrease HCO_3^- backleak around cells, thereby increasing net bicarbonate reabsorption by the proximal tubule. Third, chronic volume contraction is associated with an adaptive increase in the activity of the proximal tubule apical membrane Na^+-H^+ antiporter NHE3. Because this transporter contributes to both $NaHCO_3$ and NaCl absorption, both these capacities will be increased with chronic volume contraction. Further, volume contraction limits distal delivery of chloride. In the presence of chronic metabolic alkalosis, the CCD is poised for HCO_3^- secretion. However, collecting duct HCO_3^- secretion requires luminal Cl^- and is inhibited by Cl^- deficiency.

Potassium

Potassium deficiency is associated with an increase in renal NAE. This effect is multifactorial. First, chronic K^+ deficiency increases the proximal tubule apical membrane Na^+-H^+ antiporter and basolateral membrane Na^+-HCO_3^--CO_3^{2-} cotransporter activities. This effect is similar to that seen with chronic acidosis and may be caused by intracellular acidosis. Chronic K^+ deficiency also increases proximal tubular ammonia production. Last, chronic K^+ deficiency leads to an increase in collecting duct H^+ secretion. This appears to be related to increased activity of the apical membrane H^+,K^+-ATPase. Such an effect increases the rate of H^+ secretion and the rate of K^+ reabsorption in the collecting duct. In addition, ammonia, whose production is stimulated by hypokalemia, has direct effects that stimulate collecting duct H^+ secretion. Counterbalancing these effects is that K^+ deficiency decreases aldosterone secretion, which can inhibit distal acidification. Thus, in normal individuals, the net effect of K^+ deficiency is typically a minor change in acid-base balance. However, in patients with nonsuppressible mineralocorticoid secretion (e.g., hyperaldosteronism, Cushing syndrome), K^+ deficiency can greatly stimulate renal acidification and cause profound metabolic alkalosis.

Hyperkalemia appears to have opposite effects on renal acidification. The most notable effect of hyperkalemia is inhibition of ammonia synthesis in the proximal tubule and ammonia absorption in Henle loop, resulting in inappropriately low levels of urinary ammonia excretion. This contributes to the metabolic acidosis seen in patients with hyperkalemic distal (type 4) renal tubular acidosis.

CHAPTER 12

Metabolic Acidosis

Biff F. Palmer

DEFINITION

Metabolic acidosis is defined as a low arterial blood pH in conjunction with a reduced serum bicarbonate concentration, [HCO_3^-]. Respiratory compensation results in a decrease in arterial carbon dioxide tension ($Paco_2$). A low serum [HCO_3^-] alone is not diagnostic of metabolic acidosis because it also results from the renal compensation to chronic respiratory alkalosis. Measurement of the arterial pH differentiates between these two possibilities. Box 12-1 shows the expected compensatory responses for metabolic and respiratory acid-base disorders.[1]

After the diagnosis of metabolic acidosis is confirmed, the first step in the examination of the patient is to calculate the serum anion gap. The *anion gap* equals the difference between the plasma concentrations of the major cation, sodium ([Na^+]), and the major measured anions, chloride and bicarbonate ([Cl^-] and [HCO_3^-]), and is given by the following formula:

$$\text{Anion gap} = [Na^+] - ([Cl^-] + [HCO_3^-])$$

In healthy individuals, the normal value of the anion gap is approximately 12 ± 2 mmol/l. Because many of the unmeasured anions consist of albumin, the normal anion gap is decreased by approximately 4 mmol/l for each 1 g/dl decrease in the serum albumin concentration below normal. The total number of cations must equal the total number of anions, so a decrease in the serum HCO_3^- concentration must be offset by an increase in the concentration of other anions. If the anion accompanying excess H^+ is Cl^-, the decrease in serum [HCO_3^-] is matched by an equal increase in serum [Cl^-]. This acidosis is classified as a "normal anion gap" or a "non–anion gap" or a hyperchloremic metabolic acidosis. By contrast, if excess H^+ is accompanied by an anion other than Cl^-, the decreased [HCO_3^-] is balanced by an increase in the concentration of the unmeasured anion. [Cl^-] remains the same. In this setting, the acidosis is said to be a "high anion gap" or "anion gap" metabolic acidosis.

The normal value for the anion gap has tended to fall over time because of changes in how serum Na^+ and Cl^- are measured.[2] Flame photometry for Na^+ measurement and a colorimetric assay for Cl^- have been replaced by the use of ion-selective electrodes, with which the serum Na^+ values have largely remained the same, whereas the serum Cl^- values have tended to be higher. As a result, the normal value for the anion gap has decreased to as low as 6 mmol/l in some reports. Recognizing this change, some laboratories have adjusted the calibration set point for Cl^- to return the normal value for the anion gap to the 12 ± 2 mmol/l range. The clinician needs to be aware that the average anion gap and range of normal values will vary in different facilities.

Figure 12-1 provides a recommended approach to a patient with metabolic acidosis and lists the common causes of metabolic acidosis according to the anion gap.

NON–ANION GAP (NORMAL ANION GAP) METABOLIC ACIDOSIS

A non–anion gap metabolic acidosis can result from either renal or extrarenal causes. Renal causes of metabolic acidosis occur when renal bicarbonate generation, which results from net acid excretion, does not balance the loss of bicarbonate and other alkali buffers consumed in the buffering of normal endogenous acid production. This failure of net acid excretion is termed *renal tubular acidosis* (RTA). Extrarenal causes occur when exogenous acid loads, endogenous acid production, or endogenous bicarbonate losses are elevated and exceed renal net acid excretion. The most common extrarenal cause of non–anion gap metabolic acidosis is chronic diarrhea.

Renal and extrarenal causes of metabolic acidosis can be distinguished by measuring urinary ammonia excretion.[3] The primary response of the kidney to metabolic acidosis is to increase urinary ammonia excretion, each millimole of urinary ammonia excreted resulting in the generation of 1 mmol of "new" bicarbonate. Thus, renal causes of metabolic acidosis are characterized by low urinary ammonia excretion rates. In contrast, in extrarenal metabolic acidosis, urinary ammonia excretion is elevated. Because most laboratories do not measure urinary ammonia, one can indirectly assess ammonia excretion by measuring the *urinary anion gap* (UAG):

$$\text{UAG} = (U_{Na^+} + U_{K^+}) - U_{Cl^-}$$

The UAG is normally a positive value, ranging from +30 to +50 mmol/l. A negative value for the UAG suggests increased renal excretion of an unmeasured cation (i.e., cation other than Na^+ or K^+). One such cation is NH_4^+. With chronic metabolic acidosis due to extrarenal causes, urinary ammonia concentrations, in the form of NH_4Cl, can reach 200 to 300 mmol/l. As a result, the measured cation concentration will be less than the measured anion concentration, which includes the increased urinary Cl^-, and the UAG will be less than zero and frequently less than −20 mmol/l.

The UAG only indirectly reflects the urinary ammonia concentration and, if other unmeasured ions are excreted, can give misleading results. Examples include diabetic ketoacidosis, associated with substantial urinary excretion of sodium keto acid salts, and toluene exposure (discussed later), associated with increased urinary excretion of sodium hippurate and sodium benzoate. In these settings, the UAG value may remain positive despite an appropriate increase in urinary ammonia excretion because of the increased urinary excretion of Na^+ acid-anion salts. In most patients, these conditions are associated with an elevated–anion gap metabolic acidosis, not a non–anion gap metabolic acidosis, and thus are easily distinguishable from diarrhea-induced metabolic acidosis.

Urine pH, in contrast to the UAG, does not reliably differentiate acidosis of renal origin from that of extrarenal origin. For example, an acid urine pH does not necessarily indicate an appropriate

Compensation in Acid-Base Disorders

Acute respiratory acidosis
For every 10 mm Hg rise in P_{CO_2}, HCO_3^- increases by 1 mmol/l

Chronic respiratory acidosis
For every 10 mm Hg rise in P_{CO_2}, HCO_3^- increases by 3.5 mmol/l

Acute respiratory alkalosis
For every 10 mm Hg fall in P_{CO_2}, HCO_3^- decreases by 2 mmol/l

Chronic respiratory alkalosis
For every 10 mm Hg decrease in P_{CO_2}, HCO_3^- decreases by 5 mmol/l

Metabolic acidosis
1.2 mm Hg decrease in P_{CO_2} for each 1 mmol/l fall in HCO_3^-
$P_{CO_2} = HCO_3^- + 15$
P_{CO_2} = last digits of pH

Metabolic alkalosis
P_{CO_2} increases by 0.7 for each mmol/l HCO_3^-

Box 12-1 Expected compensatory responses to acid-base disorders. *P_{CO_2}*, Carbon dioxide tension; *HCO_3^-*, bicarbonate ions.

increase in net acid excretion. If renal ammonia metabolism is inhibited, as occurs with chronic hyperkalemia, there is decreased ammonia available in the distal nephron to serve as a buffer, and small amounts of distal H^+ secretion can lead to a significant urine acidification. In this setting, the urine pH is acid, but net acid excretion is low because of the low ammonia excretion. Similarly, alkaline urine does not necessarily imply a renal acidification defect. In conditions in which ammonia metabolism is stimulated, distal H^+ secretion can be massive and yet the urine remains relatively alkaline because of the buffering effects of ammonia.

Metabolic Acidosis of Renal Origin

An overall approach to patient assessment for workup of metabolic acidosis of renal origin is shown in Figure 12-2.

Proximal Renal Tubular Acidosis (Type 2)

Normally, 80% to 90% of the filtered load of HCO_3^- is reabsorbed in the proximal tubule. In proximal (type 2) RTA, the proximal tubule has a decreased capacity to reabsorb filtered bicarbonate. When serum bicarbonate concentration is normal or nearly normal, the amount of bicarbonate filtered by the glomerulus exceeds proximal tubule bicarbonate reabsorptive capacity. When this happens, there is increased bicarbonate delivery to the loop of Henle and distal nephron that exceeds their capacity to reabsorb bicarbonate. As a result, some filtered bicarbonate appears in the urine. The net effect is that serum [HCO_3^-] decreases. Eventually, the filtered bicarbonate load decreases to the point at which the proximal tubule is able to reabsorb sufficient filtered bicarbonate that the bicarbonate load to Henle loop and the distal nephron is within their reabsorptive capacity. When this occurs, no further bicarbonate is lost in the urine, net acid excretion normalizes, and a new steady-state serum [HCO_3^-] develops, although at a lower-than-normal level.

Hypokalemia is present in proximal RTA. Renal $NaHCO_3$ losses lead to intravascular volume depletion, which in turn activates the renin-angiotensin-aldosterone system. Distal Na^+ delivery is increased as a result of the impaired proximal reabsorption of $NaHCO_3$. Because of the associated hyperaldosteronism and increased distal nephron Na^+ reabsorption, there is increased K^+ secretion. The net result is renal potassium wasting and the development of hypokalemia. In the steady state, when virtually all the filtered HCO_3^- is reabsorbed in the proximal and distal nephron, renal potassium wasting is less, and the degree of hypokalemia tends to be mild.

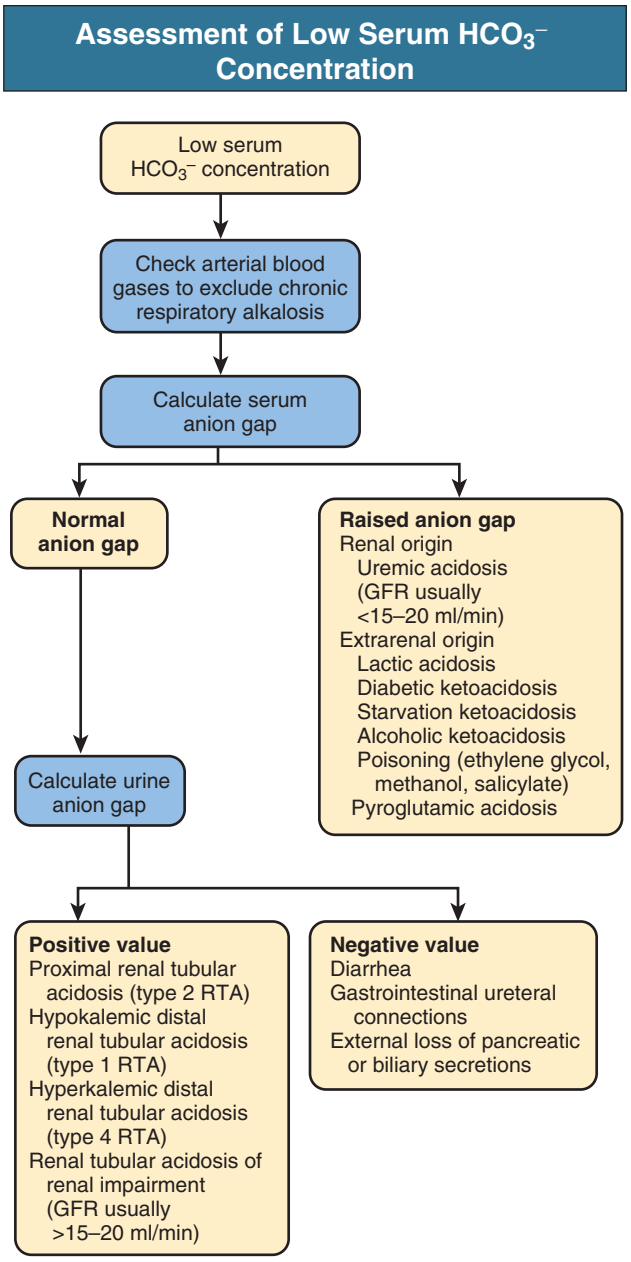

Figure 12-1 Approach to the patient with low serum HCO_3^- concentration.

Proximal RTA may occur as an isolated defect in acidification, but type 2 typically occurs in the setting of widespread proximal tubule dysfunction (Fanconi syndrome). In addition to decreased HCO_3^- reabsorption, patients with Fanconi syndrome have impaired reabsorption of glucose, phosphate, uric acid, amino acids, and low-molecular-weight proteins. Various inherited and acquired disorders have been associated with the development of Fanconi syndrome and proximal RTA (Box 12-2). The most common inherited cause in children is cystinosis (see Chapter 50). Most adults with Fanconi syndrome have an acquired condition that is related to an underlying dysproteinemic condition, such as multiple myeloma.

Skeletal abnormalities are common in these patients. Osteomalacia can develop from chronic hypophosphatemia caused by

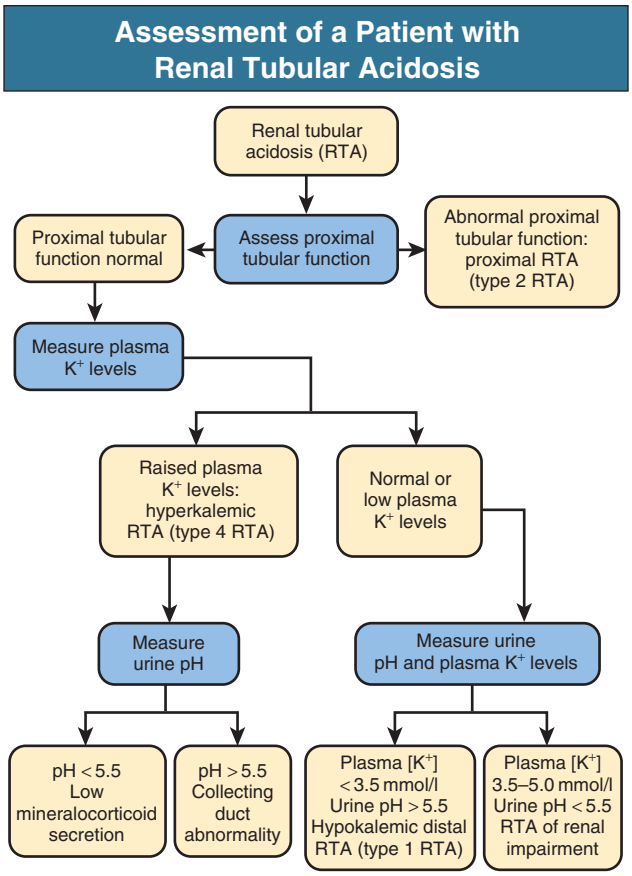

Figure 12-2 **Approach to the patient with renal tubular acidosis.**

renal phosphate wasting if Fanconi syndrome is present. These patients may also have a deficiency in the active form of vitamin D because of an inability to convert 25-hydroxyvitamin D_3 to 1,25-dihydroxyvitamin D in the proximal tubule.

In contrast to distal RTA, proximal RTA is not associated with nephrolithiasis or nephrocalcinosis. One exception is the use of topiramate,[4,5] an antiepileptic drug that is increasingly used to treat a variety of neurologic and metabolic disorders. The drug exerts an inhibitory effect on renal carbonic anhydrase activity, resulting in a proximal acidification defect similar to that observed with acetazolamide. Topiramate also is associated with hypocitraturia, hypercalciuria, and elevated urine pH, leading to an increased risk of kidney stone disease.

Proximal RTA should be suspected in a patient with a normal anion gap acidosis and hypokalemia who has an intact ability to acidify the urine to below 5.5 while in a steady state.[6] Proximal tubular dysfunction, such as euglycemic glycosuria, hypophosphatemia, hypouricemia, and mild proteinuria, helps support this diagnosis. The UAG is greater than zero, indicating the lack of increase in net acid excretion.

Treatment of proximal RTA is difficult. Administration of alkali increases serum [HCO_3^-], which increases urinary bicarbonate losses and thereby minimizes subsequent increases in the serum [HCO_3^-]. Moreover, the increased distal sodium load, in combination with increased circulating plasma aldosterone, results in increased renal potassium wasting and worsening hypokalemia. As a result, substantial amounts of alkali, often in the form of a potassium salt, such as potassium citrate, are required to prevent worsening hypokalemia. Children with proximal RTA should be aggressively treated to normalize their serum [HCO_3^-] to minimize growth retardation. These children may require large amounts of alkali therapy, typically 5 to 15 mmol/kg/day.

Adults with proximal RTA are frequently not treated as aggressively as children are because of the lack of systemic metabolic abnormalities or bone disease. Many clinicians administer alkali therapy if serum [HCO_3^-] is less than 18 mmol/l to prevent severe acidosis. Whether more aggressive therapy to normalize serum [HCO_3^-] is beneficial remains unknown. However, the large amounts

of alkali required, about 700 to 1000 mmol/day for a 70-kg individual, make this approach problematic.

Hypokalemic Distal Renal Tubular Acidosis (Type 1)

In contrast to proximal RTA, patients with distal RTA are unable to acidify their urine, either under basal conditions or in response to metabolic acidosis.[7,8] Type 1 RTA results from a reduction in net H^+ secretion in the distal nephron, which leads to continued urinary bicarbonate losses and prevents urinary acidification, thereby minimizing titratable acid excretion and urinary ammonia excretion. As a result, these patients are unable to match net acid excretion to endogenous acid production, and acid accumulation ensues. The subsequent metabolic acidosis stimulates reabsorption of bone matrix to release the calcium alkali salts present in bone. During prolonged periods, this can result in progressive osteopenia in adults and in osteomalacia in children.

Distal RTA can be caused by either impaired H^+ secretion (secretory defect) or an abnormally permeable distal tubule, resulting in increased backleak of normally secreted H^+ (gradient defect); it may be genetic or acquired. Certain medications, especially amphotericin, result in increased backleak of protons across the apical plasma membrane, leading to a gradient defect form of distal RTA.

For patients with a secretory defect, the inability to acidify the urine below pH 5.5 results from abnormalities in any of the proteins involved in collecting duct H^+ secretion. Some patients may have an isolated defect in the H^+,K^+-ATPase that impairs H^+ secretion and K^+ reabsorption.[9] A defect confined to the vacuolar H^+-ATPase also results in renal potassium wasting.[10] The development of systemic acidosis tends to diminish net proximal fluid reabsorption with an increase in distal delivery, resulting in volume contraction and activation of the renin-aldosterone system (RAS). Increased distal Na^+ delivery coupled to increased circulating levels of aldosterone then leads to increased renal K^+ secretion. Defects in the basolateral anion exchanger (AE1) can also cause distal RTA. In this case, the lack of basolateral HCO_3^- exit leads to intracellular alkalinization, which inhibits apical proton secretion.

Patients with distal RTA have low ammonia secretion rates. The decreased secretion is caused by the failure to trap ammonia in the tubular lumen of the collecting duct as a result of the inability to lower luminal fluid pH. In addition, there is often impaired medullary transfer of ammonia because of interstitial disease. Interstitial disease is frequently present in such patients through an associated underlying disease or as a result of nephrocalcinosis or hypokalemia-induced interstitial fibrosis.

In contrast to proximal RTA, nephrolithiasis and nephrocalcinosis are common.[11] Urinary Ca^{2+} excretion is high secondary to acidosis-induced bone mineral dissolution. Luminal alkalinization also inhibits calcium reabsorption, resulting in further increases in urinary calcium excretion.[12] Calcium phosphate solubility is also greatly lowered at alkaline pH, and calcium phosphate stone formation is accelerated. Stone formation is further enhanced as a result of low urinary citrate excretion. Citrate is metabolized to HCO_3^-, and its renal reabsorption is stimulated by metabolic acidosis, thereby minimizing the severity of metabolic acidosis. Urinary citrate also chelates urinary calcium, decreasing ionized calcium concentrations. Accordingly, the decreased citrate excretion that occurs in chronic metabolic acidosis due to distal RTA further contributes to both nephrolithiasis and nephrocalcinosis.

Distal RTA may be a primary disorder, either idiopathic or inherited, but it most often occurs in association with a systemic disease, one of the most common of which is Sjögren syndrome (Box 12-3). Hypergammaglobulinemic states as well as drugs and toxins may also cause this disorder.

Box 12-3 Causes of hypokalemic distal (type 1) renal tubular acidosis (RTA).

A common cause of acquired distal RTA is glue sniffing. Inhalation of toluene from the fumes of model glue, spray paint, and paint thinners can give rise to hypokalemic normal gap acidosis through multiple mechanisms. First, toluene inhibits collecting duct proton secretion. Second, metabolism of toluene produces the organic acids hippuric and benzoic acid. These are buffered by sodium bicarbonate, resulting in metabolic acidosis and the production of sodium hippurate and sodium benzoate. If plasma volume is normal, these salts are rapidly excreted in the urine, and a non–anion gap metabolic acidosis develops. If plasma volume is decreased, urinary excretion is limited, these salts accumulate, and an anion gap metabolic acidosis develops.

Distal RTA should be considered in all patients with a non–anion gap metabolic acidosis and hypokalemia who have an inability to lower the urine pH maximally. A urine pH above 5.5 in the patient with systemic acidosis suggests distal RTA, and a UAG value greater than zero is confirmatory. Depending on the duration of the distal RTA, the metabolic acidosis can be mild or very severe, with a serum [HCO_3^-] as low as 10 mmol/l. Urinary potassium losses lead to the development of hypokalemia. Severe hypokalemia (<2.5 mmol/l) may result in musculoskeletal weakness and nephrogenic diabetes insipidus. The latter occurs because hypokalemia decreases aquaporin 2 (AQP2) expression in the collecting duct, thereby minimizing the ability to concentrate urine. An abdominal ultrasound scan may reveal nephrocalcinosis.

In patients with minimal disturbances in blood pH and plasma [HCO_3^-], a test of urinary acidification is required. Traditionally, such a test involved oral NH_4Cl administration to induce metabolic acidosis with assessment of the renal response by serial measurement

of urine pH. Many patients poorly tolerate NH_4Cl ingestion because of gastric irritation, nausea, and vomiting. An alternative way to test the capacity for distal acidification is to administer furosemide and the mineralocorticoid fludrocortisone simultaneously.[13] The combination of both increased distal Na^+ delivery and mineralocorticoid effect will stimulate distal H^+ secretion by both an increase in the luminal electronegativity and a direct stimulatory effect on H^+ secretion. Normal individuals will lower urine pH to values below 5.5 with either maneuver.

Correction of the metabolic acidosis in distal RTA can be achieved by administration of alkali in an amount only slightly greater than daily acid production, usually 1 to 2 mmol/kg/day. In patients with severe K^+ deficits, correction of the acidosis with HCO_3^-, particularly if it is done with sodium alkali salts such as $NaHCO_3$, can lower serum potassium concentration to dangerous levels. In this setting, potassium replacement should begin before the acidosis is corrected. In general, a combination of sodium alkali and potassium alkali is required for long-term treatment of distal RTA. For the patient with recurrent renal stone disease caused by distal RTA, treatment of the acidosis increases urinary citrate excretion, which slows the rate of further stone formation and may even lead to stone dissolution.

Hyperkalemic Distal Renal Tubular Acidosis (Type 4)

Type 4 RTA is characterized by distal nephron dysfunction, resulting in impaired renal excretion of both H^+ and K^+ and causing a hyperchloremic normal gap acidosis and hyperkalemia.[14] The syndrome occurs most frequently with mild to moderate impairment in renal function; however, the magnitude of hyperkalemia and acidosis is disproportionately severe for the observed glomerular filtration rate (GFR). Whereas hypokalemic distal (type 1) RTA is also a disorder of distal nephron acidification, type 4 is distinguished from type 1 RTA on the basis of several important characteristics (Table 12-1). Type 4 RTA is also a much more common form of RTA, particularly in adults.

Hyperkalemic distal RTA results from deficient circulating aldosterone or abnormal cortical collecting duct (CCD) function, or it can be related to hyperkalemia. In either case, a defect in distal H^+ secretion develops. Impaired Na^+ reabsorption by the principal cell leads to a decrease in the luminal electronegativity of the CCD, which impairs distal acidification as a result of the decrease in driving force for H^+ secretion into the tubular lumen. The H^+ secretion is further impaired in this segment as well as in the medullary collecting duct as a result of either the loss of the direct stimulatory effect of aldosterone on H^+ secretion or an abnormality in the H^+-secreting cell.

A consequence of the decrease in luminal electronegativity in the CCD is impaired renal K^+ excretion. In addition, a primary abnormality in CCD transport can also impair K^+ secretion. The development of hyperkalemia adds to the defect in distal acidification by decreasing the amount of ammonia available to act as a urinary buffer. Some studies suggest that hyperkalemia itself, through its effects on ammonia metabolism, is the primary mechanism by which the metabolic acidosis develops in type 4 RTA.

The etiology of type 4 RTA includes disorders associated with decreased circulating levels of aldosterone and conditions associated with impaired CCD function. The most common disease associated with type 4 RTA in adults is diabetes mellitus. In these patients, primary NaCl retention leads to volume expansion and suppression and atrophy of the renin-secreting juxtaglomerular apparatus. Several common drugs, such as nonsteroidal anti-inflammatory agents (NSAIDs), angiotensin-converting enzyme (ACE) inhibitors, and high doses of heparin, as used for systemic anticoagulation, can lead to decreased mineralocorticoid synthesis. Impaired function of the CCD can be a feature of structural damage to the kidney, as in interstitial renal diseases such as sickle cell nephropathy, urinary tract obstruction, and lupus. CCD function also may be impaired from use of drugs such as amiloride, triamterene, and spironolactone.[15]

Type 4 RTA should be suspected in a patient with a normal gap metabolic acidosis associated with hyperkalemia. The typical patient is in the fifth to seventh decade of life with a longstanding history of diabetes mellitus with a moderate reduction in the GFR. Plasma $[HCO_3^-]$ is usually 18 to 22 mmol/l and serum $[K^+]$ between 5.5 and 6.5 mmol/l. Most patients are asymptomatic; however, the hyperkalemia may occasionally be severe enough to cause muscle weakness or cardiac arrhythmias. The UAG value is slightly positive, indicating minimal ammonia excretion in the urine. When the disorder is caused by a defect in mineralocorticoid activity, patients typically have urine pH below 5.5, reflecting a more severe defect in ammonia availability than in H^+ secretion (Fig. 12-3). In patients with structural damage to the collecting duct, the urine pH may be alkaline, reflecting both impaired H^+ secretion and decreased urinary ammonia excretion.

Treatment of patients with type 4 RTA is directed at both the hyperkalemia and the metabolic acidosis. In many patients, lowering serum $[K^+]$ will simultaneously correct the acidosis.[16] Correction of the hyperkalemia allows renal ammonia production to increase, thereby increasing the buffer supply for distal acidification. The first consideration in the treatment of patients is to discontinue any nonessential medication that might interfere in either the synthesis or activity of aldosterone or the ability of the kidneys to excrete potassium (Box 12-4). ACE inhibitors and angiotensin receptor blockers (ARBs) should usually be continued because of the beneficial effects on cardiovascular disease and their renoprotective benefits in patients with chronic kidney disease (CKD). In patients with aldosterone deficiency who are neither hypertensive nor fluid overloaded, administration of a synthetic mineralocorticoid such as fludrocortisone (0.1 mg/day) can be effective. In patients with hypertension or volume overload, particularly in association with CKD, administration of either a thiazide or a loop diuretic is frequently effective. Loop diuretics are required in patients with an estimated GFR below 30 ml/min. Loop and thiazide diuretics increase distal Na^+ delivery and thus stimulate K^+ and H^+ secretion in the collecting duct. Alkali therapy (e.g., $NaHCO_3$) can also be used to treat the acidosis and

Factors Differentiating Types 1, 2, and 4 Renal Tubular Acidosis

Factor	Type 1	Type 2	Type 4
Serum K^+	Low	Low	High
Renal function	Normal or near normal	Normal or near normal	Stage 3, 4, or 5 chronic kidney disease
Urine pH during acidosis	High	Low	Low or high
Serum HCO_3^- (mmol/l)	10–20	16–18	16–22
Urine P_{CO_2} (mm Hg)	<40	<40	>70
Urine citrate	Low	High	Low
Fanconi syndrome	No	May be present	No

Table 12-1 Differentiation of RTA types. Factors distinguishing hypokalemic distal (type 1), proximal (type 2), and hyperkalemic distal (type 4) renal tubular acidosis.

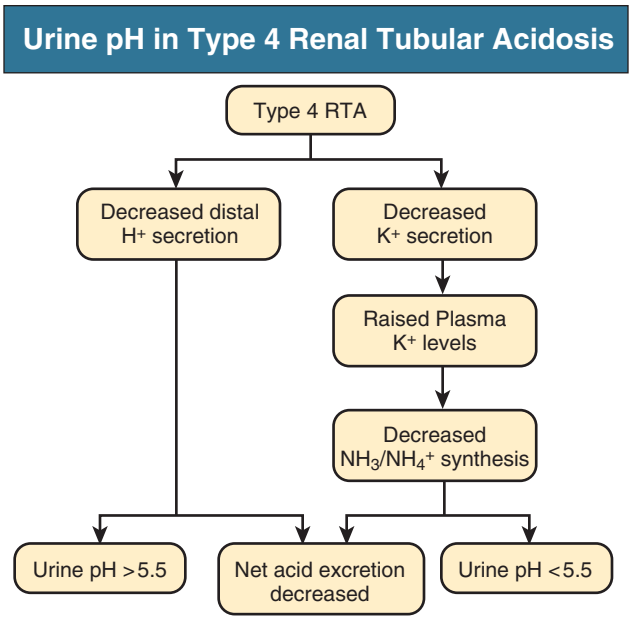

Figure 12-3 Urine pH in hyperkalemic distal (type 4) renal tubular acidosis. Net acid excretion is always decreased; however, the urine pH can be variable. In structural disease of the kidney, the predominant defect is usually decreased distal H^+ secretion, and the urine pH is above 5.5. In disorders associated with decreased mineralocorticoid activity, urine pH is usually below 5.5.

Causes of Type 4 Renal Tubular Acidosis

Mineralocorticoid Deficiency

Low Renin, Low Aldosterone

Diabetes mellitus

Drugs

- Nonsteroidal anti-inflammatory drugs (NSAIDs)
- Cyclosporine, tacrolimus
- β-Blockers

High Renin, Low Aldosterone

Adrenal destruction

Congenital enzyme defects

Drugs

- Angiotensin-converting enzyme (ACE) inhibitors
- Angiotensin II receptor blockers (ARBs)
- Heparin
- Ketoconazole

Abnormal Cortical Collecting Duct

Absent or defective mineralocorticoid receptor

Drugs

- Spironolactone, eplerenone
- Triamterene
- Amiloride
- Trimethoprim
- Pentamidine

Chronic tubulointerstitial disease

Box 12-4 Causes of hyperkalemic distal (type 4) renal tubular acidosis.

hyperkalemia, but the patient must be closely monitored to avoid volume overload and worsening hypertension.

Renal Tubular Acidosis in Chronic Kidney Disease

Metabolic acidosis in advanced CKD is caused by failure of the tubular acidification process to excrete the normal daily acid load. As functional renal mass is reduced by disease, there is an adaptive increase in ammonia production and H^+ secretion by the remaining nephrons. Despite increased production of ammonia from each remaining nephron, overall production may be decreased secondary to the decrease in total renal mass. In addition, less ammonia is delivered to the medullary interstitium secondary to a disrupted medullary anatomy.[17] The ability to lower the urinary pH remains intact, reflecting the fact that the impairment in distal nephron H^+ secretion is less than that in ammonia secretion. Quantitatively, however, the total amount of H^+ secretion is small, and the acidic urine pH is the consequence of very little buffer in the urine. The lack of ammonia in the urine is reflected by a positive value for the UAG. Differentiation of RTA from type 4 RTA can be difficult as it is based on the clinician's determination of whether the severity of metabolic acidosis is out of proportion to the degree of renal dysfunction.

Patients with CKD may develop a hyperchloremic normal gap metabolic acidosis associated with normokalemia or mild hyperkalemia as GFR decreases to less than 30 ml/min. With more advanced CKD (GFR <15 ml/min), the acidosis may change to an anion gap metabolic acidosis, reflecting a progressive inability to excrete phosphate, sulfate, and various organic acids. At this stage, the acidosis is commonly referred to as "uremic acidosis."

Correction of the metabolic acidosis in patients with CKD is achieved by treatment with $NaHCO_3$, 0.5 to 1.5 mmol/kg/day, beginning when the HCO_3^- level is less than 22 mmol/l. In some patients, non–sodium citrate formulations can be used. Loop diuretics are often used in conjunction with alkali therapy to prevent volume overload. If the acidosis becomes refractory to medical therapy, dialysis needs to be initiated. Recent evidence suggests that metabolic acidosis in the patient with CKD needs to be aggressively treated because chronic acidosis is associated with metabolic bone disease and may lead to an accelerated catabolic state in patients with CKD.[18,19]

Metabolic Acidosis of Extrarenal Origin

Diarrhea

Intestinal secretions from sites distal to the stomach are rich in HCO_3^-. Accelerated loss of this HCO_3^--rich solution can result in metabolic acidosis. The resultant volume loss signals the kidney to increase NaCl reabsorption; this combined with the intestinal $NaHCO_3$ losses generates a normal anion gap metabolic acidosis. The renal response is to increase net acid excretion by increasing urinary excretion of ammonia.[20] Hypokalemia, as a result of gastrointestinal losses, and the low serum pH both stimulate the synthesis of ammonia in the proximal tubule. The increase in availability of ammonia to act as a urinary buffer allows a maximal increase in H^+ secretion by the distal nephron.

The increase in urinary ammonia excretion associated with an extrarenal normal anion gap acidosis results in a negative UAG value. Urine pH can be misleading and in chronic diarrhea may be above 6.0 because of substantial increases in renal ammonia metabolism that result in increased urine pH from the buffering ability of the ammonia. Although the clinical history should distinguish between these two possibilities, in a patient with surreptitious laxative abuse, this may not be helpful because diarrhea may not be

reported. Colonoscopy may be required to demonstrate characteristic findings of laxative abuse (e.g., melanosis coli) if this diagnosis is being considered.

Treatment of diarrhea-associated metabolic acidosis is based on treatment of the underlying diarrhea. If this is not possible, alkali treatment, possibly including potassium alkali to treat hypokalemia and metabolic acidosis simultaneously, is indicated.

Ileal Conduits

Surgical diversion of the ureter into an ileal pouch is used in the treatment of the patient with neurogenic bladder or after cystectomy. The procedure may be associated rarely with development of a hyperchloremic normal anion gap metabolic acidosis. Acidosis in part is caused by reabsorption of urinary NH_4Cl by the intestine. The ammonia is transported through the portal circulation to the liver or is metabolized to urea to prevent hyperammonemic encephalopathy. This metabolic process consumes equimolar amounts of bicarbonate and therefore can result in the development of metabolic acidosis. Metabolic acidosis may also develop because urinary Cl^- can be exchanged for HCO_3^- through activation of a Cl^--HCO_3^- exchanger on the intestinal lumen. In some patients, a renal defect in acidification can develop and exacerbate the degree of acidosis. Such a defect may result from tubular damage caused by pyelonephritis or high colonic pressures, secondarily causing urinary obstruction.

The severity of acidosis relates to the length of time the urine is in contact with the bowel and the total surface area of bowel exposed to urine. In patients with a ureterosigmoid anastomosis, these factors are increased and the acidosis tends to be more common and more severe than in patients with an ileal conduit. The ileal conduit was designed to minimize the time and area of contact between urine and intestinal surface. Patients with surgical diversion of the ureter who develop metabolic acidosis should be examined for an ileal loop obstruction because this would lead to an increase in contact time between the urine and intestinal surface.

ANION GAP METABOLIC ACIDOSIS

Lactic Acidosis

Lactic acid is the end product in the anaerobic metabolism of glucose and is generated by the reversible reduction of pyruvic acid by lactic acid dehydrogenase and NADH (reduced nicotinamide adenine dinucleotide), as shown in the following formula:

$$\text{Pyruvate} + \text{NADH} + H^+ \leftrightarrow \text{Lactate} + NAD^+$$

Under normal conditions, the reaction is shifted toward the right, and the normal lactate to pyruvate ratio is approximately 10:1. The reactants in this pathway are interrelated, as shown in the following equation:

$$\text{Lactate} = K[(\text{pyruvate})(\text{NADH})(H^+)]/(NAD^+)$$

where K is the equilibrium constant.

On the basis of this relationship, it is evident that lactate can increase for three reasons.[21] First, lactate can increase because of increased pyruvate production alone. In this situation, the normal 10:1 lactate-pyruvate ratio will be maintained. An isolated increase in pyruvate production can be seen in the setting of intravenous (IV) glucose infusions, IV administration of epinephrine, and respiratory alkalosis. Lactate levels in these conditions are minimally elevated, rarely exceeding 5 mmol/l. Second, lactate can increase as a result of an increased NADH-NAD^+ ratio. Under these conditions, the lactate-pyruvate ratio can increase to very high values. Third, lactate can increase with a combination of increased pyruvate production and increased NADH/NAD^+. This is common in severe lactic acidosis.

Lactic acidosis occurs whenever there is an imbalance between the production and the use of lactic acid. The net result is an accumulation of serum lactate and development of metabolic acidosis. The accumulation of the non–chloride anion lactate accounts for the increase in anion gap. Severe exercise and grand mal seizures are examples of lactic acidosis developing as a result of increased production. The short-lived nature of the acidosis in these conditions suggests that a concomitant defect in lactic acid use is present in most conditions of sustained and severe lactic acidosis.

Some of the disorders associated with the development of lactic acidosis are listed in Box 12-5. Type A lactic acidosis is characterized by underperfusion of tissue or acute hypoxia, such as hypotension, sepsis, acute tissue hypoperfusion, cardiopulmonary failure, severe anemia, hemorrhage, and carbon monoxide poisoning. Type B lactic acidosis occurs in the absence of overt hypoperfusion or hypoxia, such as with congenital defects in glucose or lactate metabolism, diabetes mellitus, liver disease, effects of drugs and toxins, and neoplastic diseases.[22-27] In clinical practice, many patients will often exhibit features of type A and type B lactic acidosis simultaneously.

Therapy is aimed at correction of the underlying disorder. Restoration of tissue perfusion and oxygenation is attempted if these are compromised. The role of alkali in the treatment of patients with lactic acidosis is controversial; some experimental models and clinical observations suggest that administration of HCO_3^- may depress cardiac function and exacerbate the acidemia. In addition, such therapy may be complicated by volume overload, hypernatremia, and rebound alkalosis after the acidosis has resolved. In general, HCO_3^- should be given when the systemic pH decreases to below 7.1, because hemodynamic instability becomes much more likely with severe acidemia. In such patients, alkali therapy should be directed at increasing the pH above 7.1; attempts to normalize the

Causes of Lactic Acidosis

Type A (Tissue Underperfusion or Hypoxia)
- Cardiogenic shock
- Septic shock
- Hemorrhagic shock
- Acute hypoxia
- Carbon monoxide poisoning
- Anemia

Type B (Absence of Hypotension and Hypoxia)
- Hereditary enzyme deficiency (glucose 6-phosphatase)
- Drugs or toxins
  - Phenformin, metformin
  - Cyanide
  - Salicylate, ethylene glycol, methanol
  - Propylene glycol[25]
  - Linezolid[22]
  - Propofol[24]
  - Nucleoside reverse transcriptase inhibitors: stavudine, didanosine[23]
  - Clenbuterol[26]
  - Isoniazid
- Systemic disease
  - Liver failure
  - Malignancy

Box 12-5 Causes of lactic acidosis.

pH or [HCO_3^-] should be avoided. Acute hemodialysis is rarely beneficial for lactic acidosis induced by tissue hypoperfusion. The hemodynamic instability that can occur with hemodialysis in these critically ill patients may worsen the underlying difficulty in tissue oxygenation.

Diabetic Ketoacidosis

Diabetic ketoacidosis results from the accumulation of acetoacetic acid and β-hydroxybutyric acid. The development of ketoacidosis is the result of insulin deficiency and a relative or absolute increase in glucagon.[28] These hormonal changes lead to increased fatty acid mobilization from adipose tissue and alter the oxidative machinery of the liver such that delivered fatty acids are primarily metabolized into keto acids. In addition, peripheral glucose use is impaired, and the gluconeogenic pathway in the liver is maximally stimulated. The resultant hyperglycemia causes an osmotic diuresis and volume depletion.

Ketoacidosis results when the rate of hepatic keto acid generation exceeds renal excretion, causing increased blood keto acid concentrations. The H^+ accumulation in the extracellular fluid (ECF) decreases HCO_3^- concentration, whereas the keto acid anion concentration increases. An anion gap metabolic acidosis is the more common finding in the patient with diabetic ketoacidosis, but a normal gap metabolic acidosis can also be seen. In early stages of ketoacidosis, when the ECF volume is almost normal, keto acid anions that are produced are rapidly excreted by the kidney as Na^+ and K^+ salts. Excretion of these salts is equivalent to the loss of potential HCO_3^-. This loss of potential HCO_3^- in the urine at the same time that the kidney is retaining NaCl results in a normal gap metabolic acidosis. As volume depletion develops, renal keto acid excretion cannot match production rates, and keto acid anions are retained within the body, thus increasing the anion gap.

During treatment, the anion gap metabolic acidosis transforms once again into a normal gap acidosis. Treatment leads to a termination in keto acid production. As the ECF volume is restored, there is increased renal excretion of the Na^+ salts of the keto acid anions. The loss of this potential HCO_3^-, combined with the retention of administered NaCl, accounts for the redevelopment of the hyperchloremic normal gap acidosis. In addition, K^+ and Na^+ administered in solutions containing NaCl and KCl enter cells in exchange for H^+. The net effect is infusion of HCl into the ECF. The reversal of the hyperchloremic acidosis takes several days as the HCO_3^- deficit is corrected by the kidney.

Diabetic ketoacidosis can result in a severe metabolic acidosis with serum bicarbonate levels below 5 mmol/l. This diagnosis should be considered in patients with simultaneous metabolic acidosis and hyperglycemia. Diagnosis is confirmed by demonstration of retained keto acids with nitroprusside tablets or reagent strips. However, these tests detect only acetone and acetoacetate and not β-hydroxybutyrate. In the patient with lactic acidosis or alcoholic ketoacidosis, acetoacetate may be converted to β-hydroxybutyrate to an extent that depends on the NADH-NAD^+ ratio. With treatment of the diabetic ketoacidosis, acetoacetate is generated as this ratio falls, and the nitroprusside test result may suddenly become strongly positive.

The limitations of the nitroprusside test can be prevented by direct measurement of β-hydroxybutyrate. With uncontrolled diabetes, a serum β-hydroxybutyrate level above 3.0 mmol/l in adults and above 3.8 mmol/l in children confirms diabetic ketoacidosis.[29] Compared with urinary ketone measurements, capillary blood levels of β-hydroxybutyrate better correlate with both the degree of acidosis and the response to therapy.[30]

Treatment consists of insulin and IV fluids to correct volume depletion. Deficiencies in K^+, Mg^{2+}, and phosphate are common; therefore, these electrolytes are typically added to IV solutions. However, diabetic ketoacidosis typically presents with hyperkalemia due to the insulin deficiency. Potassium should be administered only as hypokalemia develops, usually during insulin treatment of diabetic ketoacidosis. If there is significant hypokalemia at presentation, potassium supplementation may be needed before insulin administration to avoid life-threatening worsening of hypokalemia. Alkali therapy is generally not required because administration of insulin leads to the metabolic conversion of keto acid anions to HCO_3^- and allows partial correction of the acidosis. However, HCO_3^- therapy may be indicated in those patients who present with severe acidemia (pH < 7.1).[31]

D-Lactic Acidosis

D-Lactic acidosis is a unique form of metabolic acidosis that can occur in the patient with small bowel resections or in patients with a jejunoileal bypass. Such short bowel syndromes create a situation in which carbohydrates that are normally extensively reabsorbed in the small intestine are delivered in large amounts to the colon. In the presence of colonic bacterial overgrowth, these substrates are metabolized into D-lactate and absorbed into the systemic circulation. Accumulation of D-lactate produces an anion gap metabolic acidosis in which the serum lactate concentration is normal because the standard test for lactate is specific for L-lactate. These patients typically present after ingestion of a large, high-carbohydrate meal, with neurologic abnormalities including confusion, slurred speech, and ataxia. Ingestion of low-carbohydrate meals and antimicrobial agents to decrease the degree of bacterial overgrowth are the principal treatments.

Starvation Ketosis

Abstinence from food can lead to a mild anion gap metabolic acidosis secondary to increased production of keto acids. The pathogenesis of this disorder is similar to that of diabetic ketoacidosis in that starvation leads to relative insulin deficiency and glucagon excess. As a result, there is increased mobilization of fatty acids while the liver is set to oxidize fatty acids to keto acids. With prolonged starvation, the blood keto acid level can reach 5 to 6 mmol/l. The serum [HCO_3^-] is rarely less than 18 mmol/l. More fulminant ketoacidosis is aborted because ketone bodies stimulate the pancreatic islets to release insulin, and lipolysis is held in check. This break in the ketogenic process is notably absent in patients with insulin-dependent diabetes. No specific therapy is indicated in starvation ketosis.

Alcoholic Ketoacidosis

Ketoacidosis develops in patients with a history of chronic ethanol abuse, decreased food intake, and often a history of nausea and vomiting. As with starvation ketosis, a decrease in the insulin to glucagon ratio leads to accelerated fatty acid mobilization and alters the enzymatic machinery of the liver to favor keto acid production. However, features unique to this disorder differentiate alcoholic ketoacidosis from simple starvation ketosis. First, the alcohol withdrawal combined with volume depletion and starvation greatly increases the levels of circulating catecholamines. As a result, the peripheral mobilization of fatty acids is much greater than typically found with starvation alone. This sometimes massive mobilization of fatty acids can lead to marked keto acid production and severe metabolic acidosis. Second, the metabolism of ethanol leads to

accumulation of NADH. The increase in NADH/NAD^+ is reflected by a higher β-hydroxybutyrate–acetoacetate ratio. As mentioned previously, the nitroprusside reaction may be diminished by this redox shift despite the presence of severe ketoacidosis. Treatment of patients with alcoholic ketoacidosis focuses on glucose administration, which leads to the rapid resolution of the acidosis; stimulation of insulin release leads to diminished fatty acid mobilization from adipose tissue, as well as decreased hepatic output of keto acids.

Ethylene Glycol and Methanol Intoxications

Ethylene glycol and methanol intoxications are characteristically associated with the development of a severe anion gap metabolic acidosis. Metabolism of ethylene glycol by alcohol dehydrogenase generates various acids, including glycolic, oxalic, and formic acids. Ethylene glycol is present in antifreeze and solvents and is ingested by accident or as a suicide attempt. The initial effects of intoxication are neurologic and begin with drunkenness but can quickly progress to seizures and coma. If left untreated, cardiopulmonary symptoms such as tachypnea, noncardiogenic pulmonary edema, and cardiovascular collapse may appear. From 24 to 48 hours after ingestion, patients may develop flank pain and acute kidney injury, often accompanied by abundant calcium oxalate crystals in the urine (Box 12-6). A fatal dose of ethyl glycol is approximately 100 ml.

Methanol is also metabolized by alcohol dehydrogenase and forms formaldehyde, which is then converted to formic acid. Methanol is found in a variety of commercial preparations, such as shellac, varnish, and de-icing solutions, and is also known as wood alcohol.

Ethylene Glycol and Methanol Poisoning

Time course of clinical symptoms and signs after ingestion

Ethylene glycol

- 0–12 hours: inebriation progressing to coma
- 12–24 hours: tachypnea, noncardiogenic pulmonary edema
- 24–36 hours: flank pain, renal failure, urinary calcium oxalate crystals

Methanol

- 0–12 hours: inebriation followed by asymptomatic period
- 24–36 hours: pancreatitis, retinal edema progressing to blindness, seizures
- >48 hours: putamen and white matter hemorrhage leading to Parkinson-like state

Increased anion gap metabolic acidosis

Increased osmolar gap

Treatment

Supportive care

Fomepizole (4-methylpyrazole) is agent of choice (competitor of alcohol dehydrogenase): 15 mg/kg IV loading dose, then 10 mg/kg every 12 hours for 48 hours. After 48 hours, increase dose to 15 mg/kg every 12 hours; increase frequency of dosing to 4 hours during hemodialysis.

Intravenous ethanol (5% or 10% solution) if fomepizole unavailable: loading dose of 0.6 g/kg, followed by hourly maintenance dose of 66 mg/kg. Increase maintenance dose when the patient has history of chronic alcohol use and during hemodialysis.

Hemodialysis to accelerate removal of parent compound and metabolites

Bicarbonate therapy to treat acidosis

Box 12-6 Ethylene glycol and methanol poisoning.

As with ethylene glycol, methanol can be ingested either by accident or as a suicide attempt. Clinically, methanol ingestion is associated with an acute inebriation followed by an asymptomatic period lasting 24 to 36 hours. Abdominal pain caused by pancreatitis, seizures, blindness, and coma may develop. The blindness is caused by direct toxicity of formic acid on the retina. Methanol intoxication is also associated with hemorrhage in the white matter and putamen, which can lead to the delayed onset of a Parkinson disease–like syndrome (Box 12-6). The lethal dose of methanol is 60 to 250 ml.

Lactic acidosis is also a feature of methanol and ethylene glycol poisoning and contributes to the elevated anion gap. Together with an elevated anion gap, an osmolar gap is an important clue to the diagnosis of ethylene glycol and methanol poisoning. The osmolar gap is the difference between the measured and calculated osmolality. The formula for the calculated osmolality is as follows:

$$\text{Calculated osmolality} = 2 \times Na^+ + BUN/2.8 + \text{glucose}/18 + EtOH/4.6$$

where the blood urea nitrogen (BUN), glucose, and ethanol concentrations are in milligrams per deciliter. Inclusion of the ethanol concentration in this calculation is important because many patients ingest ethylene glycol or methanol while inebriated from ethanol ingestion. The normal value for the osmolar gap is less than 10 mOsm/kg. Each 100 mg/dl (161 mmol/l) of ethylene glycol will increase the osmolar gap by 16 mOsm/kg. Methanol contributes 32 mOsm/kg for each 100 mg/dl (312 mmol/l).

In addition to supportive measures, the patient with ethylene glycol and methanol poisoning is treated with fomepizole (4-methylpyrazole), which inhibits alcohol dehydrogenase and prevents formation of toxic metabolites[32] (Box 12-6). If fomepizole is unavailable, IV ethanol can be used to prevent the formation of toxic metabolites. Ethanol has more than a 10-fold greater affinity for alcohol dehydrogenase than that of other alcohols. Ethanol has its greatest efficacy when levels of 100 to 200 mg/dl are obtained. In addition to both fomepizole and ethanol therapy, the patient should receive hemodialysis to remove both the parent compound and its metabolites. Correction of the acidosis is accomplished with an HCO_3^--containing dialysate or by IV infusion of $NaHCO_3$.

Salicylate

Aspirin (acetylsalicylic acid) is associated with a large number of accidental or intentional poisonings. At toxic concentrations, salicylate uncouples oxidative phosphorylation and, as a result, leads to increased lactic acid production. In children, keto acid production may also be increased. The accumulation of lactic, salicylic, keto, and other organic acids leads to the development of an anion gap metabolic acidosis. At the same time, salicylate has a direct stimulatory effect on the respiratory center. Increased ventilation lowers the carbon dioxide tension (P_{CO_2}), contributing to the development of a respiratory alkalosis. Children primarily manifest an anion gap metabolic acidosis with toxic salicylate levels; a respiratory alkalosis is most evident in adults.

In addition to conservative management, the initial goals of therapy for salicylate poisoning are to correct systemic acidemia and increase the urine pH. By increasing systemic pH, the ionized fraction of salicylic acid will increase, resulting in less accumulation of the drug in the central nervous system. Similarly, an alkaline urine pH favors increased urinary excretion because the ionized fraction of the drug is poorly reabsorbed by the tubule. At serum concentrations above 80 mg/dl or in the setting of severe clinical toxicity, hemodialysis can be used to accelerate drug elimination.

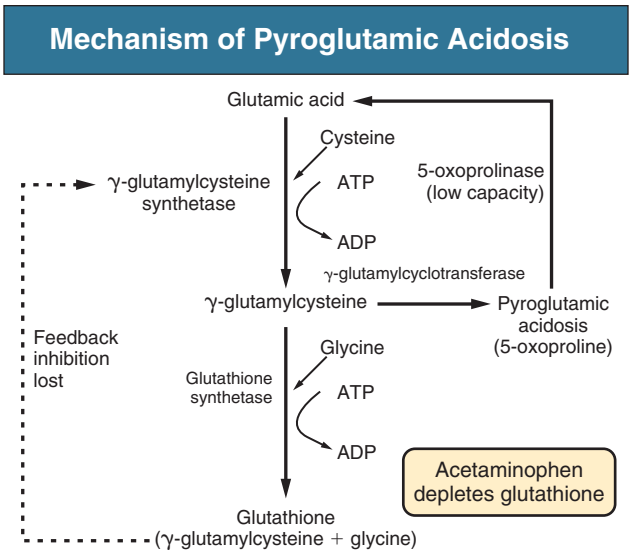

Figure 12-4 Mechanism of pyroglutamic acidosis. Glutathione is formed from γ-glutamylcysteine and glycine in the presence of glutathione synthetase. Glutathione normally regulates the activity of γ-glutamylcysteine synthetase through feedback inhibition. Depletion of glutathione results in increased formation of γ-glutamylcysteine, which in turn is metabolized to pyroglutamic acid (5-oxoproline) and cystine through γ-glutamylcyclotransferase. Pyroglutamic acid accumulates because the enzyme responsible for its metabolism (5-oxoprolinase) is low capacity. *ADP,* Adenosine diphosphate; *ATP,* adenosine triphosphate.

Pyroglutamic Acidosis

Pyroglutamic acid, also known as 5-oxoproline, is an intermediate in glutathione metabolism. An anion gap acidosis caused by pyroglutamic acid has been described rarely in critically ill patients receiving therapeutic doses of acetaminophen[33,34] (Fig. 12-4). Patients present with severe anion gap metabolic acidosis accompanied by alterations in mental status ranging from confusion to coma. High concentrations of pyroglutamic acid are found in the blood and urine. In this setting, glutathione levels are reduced because of the oxidative stress associated with critical illness and by the metabolism of acetaminophen. The reduction in glutathione secondarily leads to increased production of pyroglutamic acid. The diagnosis of pyroglutamic acidosis should be considered in patients with unexplained anion gap metabolic acidosis and recent acetaminophen ingestion.

ALKALI TREATMENT OF METABOLIC ACIDOSIS

Treatment of metabolic acidosis usually involves either sodium bicarbonate or citrate[31] (Table 12-2). $NaHCO_3$ can be taken orally as tablets or powder or given intravenously as a hypertonic bolus or an isotonic infusion, which can be created by adding 150 mmol $NaHCO_3$ to 1 liter of 5% dextrose in water (D5W). This solution is useful if treatment requires both volume expansion and alkali administration.

Citrate may be taken orally as a liquid, as sodium citrate, potassium citrate, or citric acid, or a combination. Many patients find citrate-containing solutions more palatable than oral $NaHCO_3$ as a source of oral alkali therapy. Oral citrate therapy should not be combined with medications that include aluminum. Citrate, which has a −3 charge under normal conditions, can complex with aluminum (Al^{3+}) in the intestinal tract, resulting in an uncharged moiety that is rapidly absorbed across the intestinal tract and then can dissociate

Alkali Treatment Options

Therapy	Route	Usual Dose per Unit	Comments
Sodium bicarbonate tablet	PO	650 mg = 8 mmol	May cause gastric gas
Sodium bicarbonate	IV	50 mmol in 50 ml	Hypertonic, may cause hypernatremia
D5W with $NaHCO_3$	IV	150 mmol/l	Useful for simultaneous intravascular volume expansion and alkali administration
Sodium citrate/ citric acid (liquid)	PO	1 mmol of Na^+ and citrate per milliliter	1 mmol citrate equivalent to 1 mmol HCO_3^- Avoid concomitant aluminum-containing medications such as antacids and sucralfate.
Potassium citrate (tablet)	PO	5 and 10 mmol per tablet	Useful for simultaneous K^+ and alkali therapy
Citric acid/ potassium citrate/sodium citrate (liquid)	PO	1 mmol of Na^+ and K^+ and 2 mmol of citrate per milliliter	Avoid concomitant aluminum-containing medications.
Potassium citrate (liquid)	PO	2 mmol of K^+ and 2 mmol of citrate per milliliter	Avoid concomitant aluminum-containing medications.

Table 12-2 Alkali treatment options. *D5W,* 5% Dextrose in water; *IV,* intravenous; *PO,* oral.

to release free aluminum. This can increase the rate of aluminum absorption dramatically and in some patients, particularly those with severe CKD, has resulted in acute aluminum encephalopathy.

The dose of alkali therapy administered is based on both the total body bicarbonate deficit and the desired rapidity of treatment. Under normal circumstances, the volume of distribution (V_D) for bicarbonate is approximately 0.5 l/kg total body weight. Thus, the bicarbonate deficit, in millimoles, can be estimated from the following formula:

$$\text{Bicarbonate deficit} = (0.5 \times \text{LBW}_{kg}) \times (24 - \text{HCO}_3^-)$$

where LBW_{kg} is the lean body weight in kilograms and 24 is the desired resultant bicarbonate concentration.

Several caveats regarding this equation should be understood. First, edema fluid contributes to the volume of distribution of bicarbonate. Accordingly, an estimation of the amount of edema fluid should be included in this calculation. Second, the volume of distribution for bicarbonate increases as the severity of the metabolic acidosis worsens. When serum [HCO_3^-] is 5 mmol/l or less, the volume of distribution may increase to 1 l/kg or more.

When acute treatment is desired, 50% of the bicarbonate deficit should be replaced during the first 24 hours. If hypertonic $NaHCO_3$ is administered, the increase in serum [HCO_3^-] will be mirrored by an increase in serum [Na^+]. After the initial 24 hours of therapy, the response to therapy and the patient's current clinical condition are reevaluated before future therapy is decided. Acute hemodialysis solely for the treatment of metabolic acidosis, other than that associated with renal failure, is rarely beneficial.

CHAPTER 13

Metabolic Alkalosis

F. John Gennari

DEFINITION

Metabolic alkalosis is caused by retention of excess alkali and is defined by a venous total carbon dioxide concentration ([total CO_2]) greater than 30 mmol/l or an arterial bicarbonate concentration ($[HCO_3^-]$) greater than 28 mmol/l. The increase in pH that results from the elevation in $[HCO_3^-]$ induces hypoventilation, producing a secondary increase in arterial CO_2 tension ($Paco_2$). Thus, metabolic alkalosis is characterized by coexisting elevations in serum $[HCO_3^-]$, arterial pH, and $Paco_2$. Because the kidney normally responds to an increase in $[HCO_3^-]$ by rapidly excreting excess alkali, sustained metabolic alkalosis occurs *only* when some additional factor impairs bicarbonate excretion. This chapter reviews the normal process of bicarbonate reabsorption by the kidney and how it is impaired in metabolic alkalosis, the various clinical settings in which this disorder occurs, and its diagnosis and management.

BICARBONATE TRANSPORT IN THE KIDNEY

Bicarbonate ions are freely filtered across the glomerulus and under normal conditions must be completely recaptured from the tubule urine to conserve body alkali stores. In addition, acid excretion must occur to regenerate any HCO_3^- consumed in buffering of endogenously produced acids. Both tasks are accomplished by secretion of hydrogen ions (H^+) into the renal tubules.[1] Bicarbonate ions are recaptured when secreted H^+ combines with filtered HCO_3^- to produce CO_2 and water, removing HCO_3^- from the urine. Acid excretion occurs in the collecting duct when secreted H^+ combines with filtered phosphate, converting HPO_4^{2-} to $H_2PO_4^-$, or with ammonia (NH_3) to form ammonium (NH_4^+), and these ions are excreted. Whenever excess alkali is ingested or administered, HCO_3^- is secreted into the tubule urine as well as being filtered, and acid excretion decreases, all changes that result in rapid bicarbonate excretion.

Figure 13-1 illustrates the key epithelial transporters and channels that participate in HCO_3^- reabsorption and secretion. In the proximal tubule, where most of the filtered HCO_3^- is reabsorbed, H^+ is secreted into the tubule urine both by a Na^+-linked transporter (Na^+-H^+ exchanger, NHE3) and an H^+-ATPase (not shown in figure). In the thick ascending limb of Henle loop (TAL), H^+ is secreted via NHE3, and in the collecting duct, H^+ secretion is accomplished primarily by an apical membrane H^+-ATPase. The activity of this collecting duct proton transporter is regulated by aldosterone and by the rate of Na^+ delivery to and reabsorption at this site in the nephron. When body K^+ stores are low, an apical membrane H^+,K^+-ATPase is activated in the cortical collecting duct, further promoting H^+ secretion linked to K^+ reabsorption.[2] Excretion of excess bicarbonate is facilitated by secretion of HCO_3^- into the tubule urine in the cortical collecting duct through an apical membrane Cl^--HCO_3^- exchanger (pendrin).[3] This transporter is activated by alkalemia and requires Cl^- reabsorption in exchange for secreted HCO_3^-. The HCO_3^- secreted into the urine by this transporter can be recaptured again by H^+ secretion further along in the collecting duct, so that excretion of excess alkali requires both stimulation of the Cl^--HCO_3^- exchanger and suppression of the normally active collecting duct H^+-ATPase.

PATHOPHYSIOLOGY OF METABOLIC ALKALOSIS

With the exception of alkali administration in the setting of severe impairment of kidney function (GFR <30 ml/min), sustained metabolic alkalosis is always the result of dysregulation of the transporters that control bicarbonate reabsorption and acid excretion by the kidney. A key feature of this dysregulation is abnormal stimulation of collecting duct ion transport[4] (Box 13-1). This stimulation usually is secondary to abnormalities in Na^+ and Cl^- reabsorption that occur before the urine reaches the collecting duct. More rarely, metabolic alkalosis is the result of primary stimulation of collecting duct ion transport resulting from abnormal signaling or genetic abnormalities.

Secondary Stimulation of Collecting Duct Ion Transport

Chloride Depletion

The most common clinical presentation of metabolic alkalosis is generated by Cl^- depletion. Although the term *contraction alkalosis* is sometimes used as a synonym for Cl^- depletion alkalosis, this phrase is confusing because it implies that volume contraction is responsible for the disorder. The term refers specifically to the increase in serum $[HCO_3^-]$ that follows *only one type* of extracellular fluid (ECF) volume contraction, that caused by selective Cl^- losses. Moreover, volume contraction is neither necessary nor instrumental in inducing this change in serum $[HCO_3^-]$.[5]

Selective Cl^- depletion, induced by vomiting or nasogastric suction, increases serum $[HCO_3^-]$.[6] The degree of alkalosis generated is greater when H^+ loss also occurs, as shown in the example in Figure 13-2, but it may occur even when H^+ loss is minimized by administration of a proton pump inhibitor. In either setting, maintenance of the metabolic alkalosis depends on sustained depletion of body Cl^- stores. Serum $[HCO_3^-]$ returns to normal when sufficient Cl^- is given to replenish losses. Chloride-depletion metabolic alkalosis always causes concomitant K^+ depletion through renal K^+ losses, but Cl^- administration can correct the alkalosis even if the K^+ deficit is deliberately maintained.[7] Despite this experimental finding, secondary K^+ depletion plays a key role in maintaining alkalosis. When K^+ depletion is maintained, much larger amounts of Cl^- are needed to correct the disorder completely.[8] The metabolic alkalosis induced by gastrointestinal Cl^- losses can be very severe, with reports of

Key Apical Membrane Ion Transporters Along the Nephron

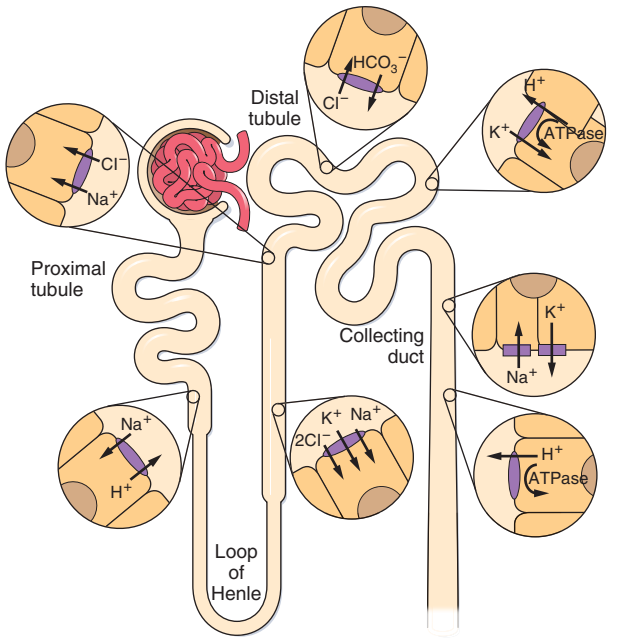

Figure 13-1 Key apical membrane ion transporters along the nephron. Bicarbonate ions (HCO_3^-) are recaptured by H^+ secretion throughout the renal tubules. In the proximal tubule and loop of Henle, H^+ secretion is directly linked to Na^+ reabsorption through the Na^+/H^+ exchanger. In addition, H^+ secretion occurs in the proximal tubule through an apical membrane H^+-ATPase (not shown). In the collecting duct, H^+ secretion is indirectly coupled to Na^+ uptake through a Na^+ channel and parallel H^+-ATPase. Chloride-linked Na^+ reabsorption in the loop of Henle and early distal tubule affects H^+ secretion by determining Na^+ delivery to the collecting duct. Bicarbonate secretion occurs in the distal tubule and cortical collecting duct under conditions of alkalemia through a Cl^--linked exchanger (pendrin). Potassium reabsorption in states of K^+ depletion is linked to H^+ secretion through a H^+/K^+-ATPase.

Pathophysiologic Classification of Causes of Metabolic Alkalosis

- Primary stimulation of collecting duct ion transport (Na^+ uptake, H^+ and K^+ secretion)
  - Mineralocorticoid induced
  - Activating genetic mutations of ENaC or its signal pathway
- Secondary stimulation of collecting duct ion transport (Na^+ uptake, H^+ and K^+ secretion)
  - Extrarenal Cl^- losses and secondary K^+ losses
  - Renal Cl^- losses and secondary K^+ losses
    - Pharmacologic (diuretics)
    - Inactivating gene mutations of Cl^--linked Na^+ cotransporters
- Alkali administration in settings in which HCO_3^- excretion is impaired (e.g., kidney failure)

Box 13-1 Pathophysiologic classification of causes of metabolic alkalosis. *ENaC,* Epithelial sodium channel in collecting duct.

serum [HCO_3^-] greater than 60 mmol/l.[9,10] A less severe Cl^--dependent metabolic alkalosis, without evident H^+ loss, is generated by administration of thiazide or loop diuretics and by two genetic abnormalities in Cl^- reabsorption, Bartter and Gitelman syndromes, as discussed later.

Effects of Gastric Drainage with NaCl-Restricted Diet

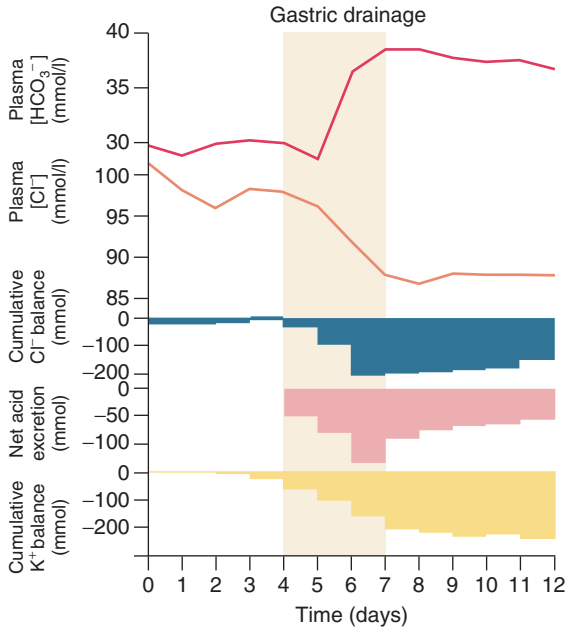

Figure 13-2 Effect of gastric drainage with salt-restricted diet. Effect on plasma [HCO_3^-] and [Cl^-] and on the net balance of [Cl^-] and [K^+] in the body in a normal individual ingesting a NaCl-restricted diet. Changes in net acid excretion are also shown. Gastric drainage on three consecutive nights in this patient increased plasma [HCO_3^-] by 9 mmol/l, a change that persisted after gastric drainage was stopped. Potassium depletion results from renal K^+ losses during the period of gastric drainage. These losses are not regained, however, after the drainage is discontinued, despite the continued daily ingestion of 70 mmol of K^+. Net acid excretion decreases transiently during drainage but then returns to control levels despite sustained metabolic alkalosis. Chloride depletion is maintained by the low dietary intake of this ion.

When metabolic alkalosis is induced by Cl^- depletion and dietary Cl^- intake is restricted, a characteristic sequence of changes in electrolyte excretion occurs (see Fig. 13-2).[6] Sodium and HCO_3^- excretion increase transiently, then decrease rapidly to low levels, accompanied by an abnormal increase in K^+ excretion. The increase in K^+ excretion is also transient but still induces significant K^+ depletion. In the new steady state, urinary K^+ excretion matches intake despite depletion of body K^+ stores (see Fig. 13-2). As a result, hypokalemia is a cardinal feature of Cl^--depletion alkalosis. Potassium depletion stimulates H^+ secretion in the collecting duct (through H^+,K^+-ATPase; see Fig. 13-1) and HCO_3^- reabsorption in the ascending limb of the loop of Henle.[11] Potassium depletion also downregulates both the Na^+-K^+-2Cl^- cotransporter and the Na^+- Cl^- cotransporter,[11] increasing Na^+ delivery to the collecting duct and further stimulating collecting duct H^+ secretion (Fig. 13-3). When K^+ deficiency is severe, this effect results in measurable Cl^- excretion despite Cl^- depletion and sustained metabolic alkalosis even when NaCl is administered.[12] Finally, K^+ depletion stimulates renal NH_4^+ production, facilitating the acid excretion needed to sustain metabolic alkalosis. Although the Cl^--HCO_3^- exchanger is activated by metabolic alkalosis, its activation in turn stimulates collecting duct H^+ secretion, resulting in reabsorption of all the secreted HCO_3^- and continued acid excretion.[13] In the steady state, acid excretion matches net acid production despite systemic alkalemia, indicating a failure of downregulation of collecting duct ion transport. The contribution of Cl^- and K^+ depletion to the maintenance of metabolic alkalosis is

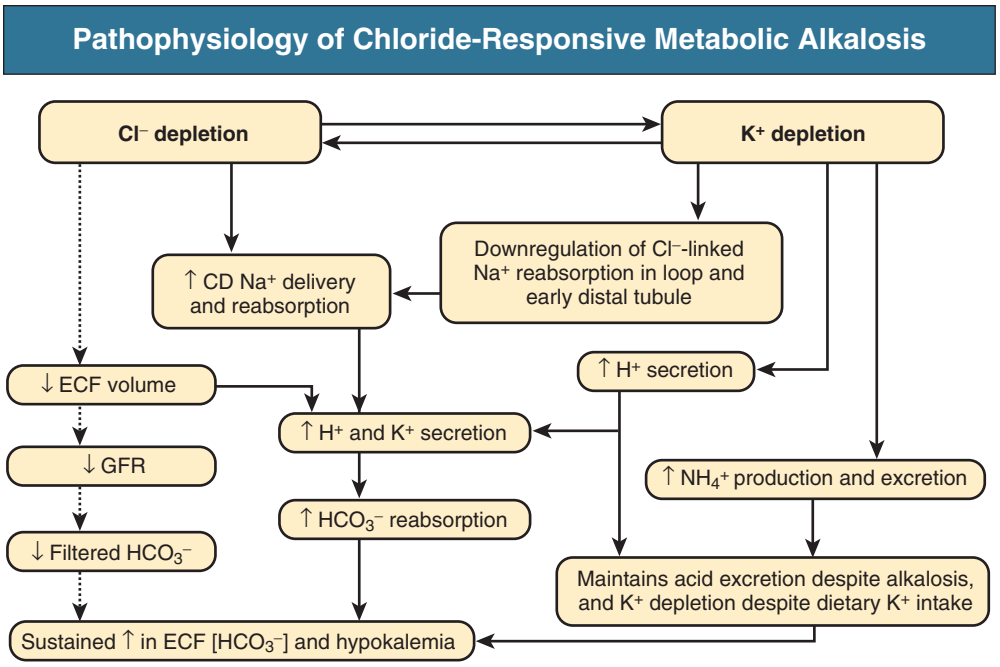

Figure 13-3 Pathophysiology of metabolic alkalosis caused by depletion of body chloride stores. Chloride depletion stimulates H^+ and K^+ secretion into the collecting duct *(CD)* as a result of disproportionate distal Na^+ delivery and reabsorption. The resultant K^+ depletion further stimulates H^+ secretion and promotes ammonium (NH_4^+) production and excretion, as well as downregulating Na^+ reabsorption in Henle loop. These events all contribute to a sustained increase in serum [HCO_3^-]. Chloride depletion also reduces glomerular filtration rate *(GFR)* and therefore HCO_3^- filtration, reducing potential alkali losses. As indicated by the *dashed lines,* the role of this effect in sustaining metabolic alkalosis remains controversial. *ECF,* Extracellular fluid.

of little importance in the clinic because treatment is dictated by the particular setting; some patients need NaCl to replenish ECF volume, and most need KCl to treat K^+ depletion.

Potassium Depletion

Induction of net K^+ loss by severe restriction of dietary K^+ intake produces a small but significant increase in serum [HCO_3^-].[8] When dietary Cl^- intake is concomitantly restricted, however, the resultant alkalosis is four times as great, illustrating the complementary roles of Cl^- and K^+ in regulating renal HCO_3^- reabsorption. Depletion of body K^+ stores is probably the most important factor in producing and sustaining the rarer forms of metabolic alkalosis induced by mineralocorticoid excess or apparent mineralocorticoid excess (see later discussion).

Primary Stimulation of Collecting Duct Ion Transport

Metabolic alkalosis produced by primary stimulation of collecting duct ion transport accounts for less than 1% of the clinical incidence of this disorder, and by far the most common cause is primary hyperaldosteronism.[14] Primary hyperaldosteronism is characterized by persistently high and unregulated aldosterone secretion, which activates both the epithelial sodium channel (ENaC) and H^+-ATPase, regardless of body fluid volume and acid-base status (Fig. 13-4; see also Fig. 13-1). As a result, Na^+ reabsorption and H^+ secretion are increased directly, and K^+ secretion is increased secondarily, depleting body K^+ stores. The resultant K^+ depletion promotes NH_4^+ production and activates H^+,K^+-ATPase activity, further facilitating acid excretion. Sodium retention leads to hypertension and also ensures continued Na^+ delivery to the collecting duct, sustaining the cycle of increased reabsorption and increased K^+ and H^+ secretion. As a result of all these events, metabolic alkalosis is sustained despite normal Cl^- intake. Not surprisingly, the degree of alkalosis induced by primary hyperaldosteronism is modulated by both Cl^- and K^+ intake. Much more rarely, metabolic alkalosis is caused by genetic mutations in the regulation and function of ENaC in the collecting duct (see Etiology and Chapter 49).

Exogenous Alkali

The kidney responds rapidly to excess alkali by increasing HCO_3^- excretion, and sustained metabolic alkalosis does not occur unless massive amounts are administered in individuals with normal kidney function. When lesser amounts of $NaHCO_3$ are ingested daily, serum [HCO_3^-] does not increase unless dietary Cl^- intake is severely restricted.[15] If HCO_3^- excretion is impaired as a result of kidney failure, even minimal daily alkali administration can cause a sustained metabolic alkalosis independent of Cl^- intake.[16] End-stage renal disease is the ultimate model of impaired HCO_3^- excretion, and any added alkali remains in the body until it is consumed by buffering the strong acids produced by protein metabolism (endogenous acid production).

Secondary Response to Alkalemia Induced by Bicarbonate Retention

Regardless of the cause, blood pH increases in patients with metabolic alkalosis and elicits secondary hypoventilation, increasing P_{CO_2}. The response is a potent one, occurring despite the concomitant development of hypoxemia. On average, P_{CO_2} increases by 0.7 mm Hg (0.1 kP) for each 1 mmol/l increase in serum [HCO_3^-]. Assuming a normal [HCO_3^-] of 24 mmol/l and P_{CO_2} of 40 mm Hg, the predicted P_{CO_2} for any given serum [HCO_3^-] in metabolic alkalosis can be calculated as follows:

$$P_{CO_2}(\text{mm Hg}) = 40 + 0.7 \times ([HCO_3^-](\text{mmol/l}) - 24)$$

Although this formula is helpful in determining whether the ventilatory response to metabolic alkalosis is appropriate, it implies a precision that does not exist in nature. Variations of up to 5 to 7 mm Hg between the observed and calculated P_{CO_2} may occur. When serum [HCO_3^-] exceeds 60 mmol/l, moreover, the formula is not a reliable predictor of the respiratory response. Even when metabolic alkalosis is severe (serum [HCO_3^-] >50 mmol/l), however, the P_{CO_2} (in mm Hg) virtually always exceeds the value for the serum [HCO_3^-] (in mmol/l).[10] Figure 13-5 illustrates the ameliorating effect of increasing P_{CO_2} on pH in metabolic alkalosis. While it mitigates the alkalemia, the increase in P_{CO_2}, when sustained, also directly

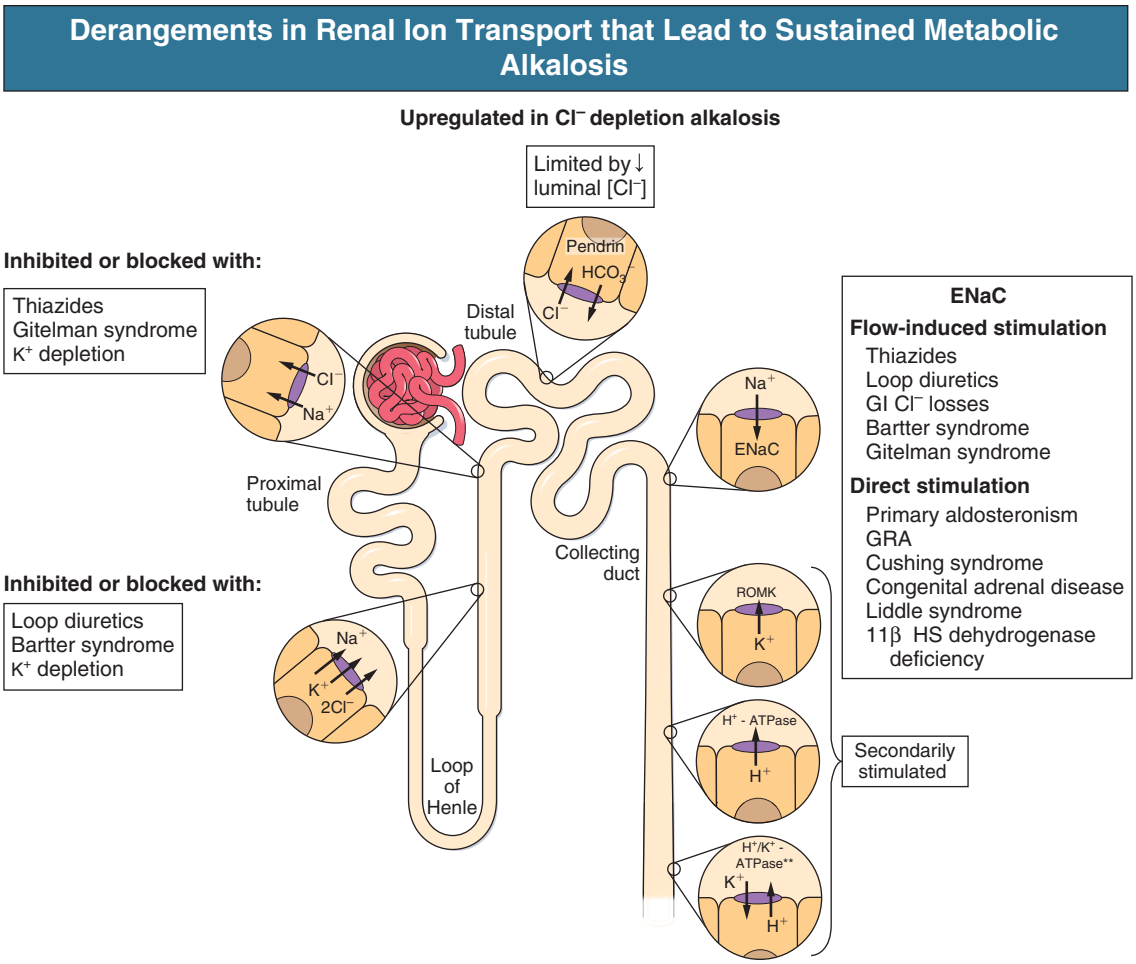

Figure 13-4 Sustained metabolic alkalosis from renal ion transport derangements. Schematic of key apical membrane transport proteins in the loop of Henle and distal nephron and the ways their function is altered to impair renal HCO_3^- excretion and sustain K^+ excretion in the face of K^+ depletion. Bartter and Gitelman syndromes are caused by genetic abnormalities that impede or inactivate Cl^--linked Na^+ reabsorption in Henle loop and early distal tubule, respectively. The epithelial Na^+ channel *(ENaC)* in the collecting duct is stimulated directly in primary hyperaldosteronism and in several genetic abnormalities. Glucocorticoid-remediable aldosteronism *(GRA)* causes aldosterone secretion to respond to corticotropin (ACTH) rather than to angiotensin II; Liddle syndrome blocks downregulation of the channel, and 11β-hydroxysteroid *(HS)* dehydrogenase deficiency allows cortisol to act as a mineralocorticoid. *ROMK,* Renal outer medulla K^+ (channel).

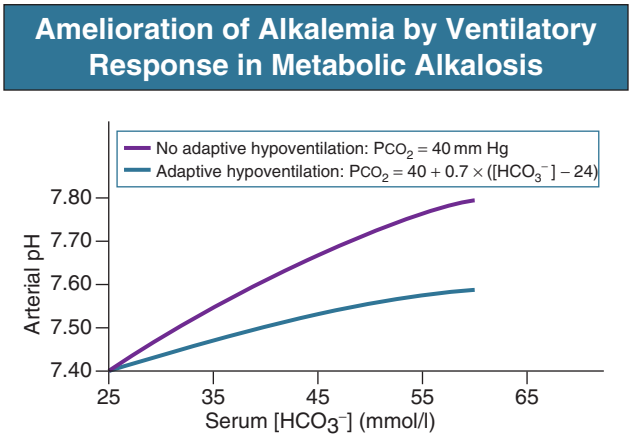

Figure 13-5 Alkalemia in metabolic alkalosis. Amelioration of alkalemia by the normal ventilatory response to increased serum $[HCO_3^-]$. *Upper line* in the graph illustrates the relationship between arterial pH and serum $[HCO_3^-]$ in the absence of adaptive hypoventilation (P_{CO_2} maintained at 40 mm Hg). *Lower line shows* the relationship when P_{CO_2} is increased by the expected level of hypoventilation.

stimulates renal HCO_3^- reabsorption, increasing serum $[HCO_3^-]$ further.[17] This effect is small and unimportant in the clinical setting.

ETIOLOGY

The major causes of metabolic alkalosis are subdivided into three groups based on pathophysiology[4] (see Box 13-1). The most common causes are induced and sustained by chloride depletion resulting from abnormal losses from the gut or the kidney. The second subgroup, much rarer, includes the metabolic alkaloses induced and sustained by excess corticosteroids, or by collecting duct transport abnormalities that mimic excess mineralocorticoid activity. The third subgroup includes the causes of metabolic alkalosis due to alkali administration or ingestion. This newer classification replaces the traditional separation of causes based on treatment response (chloride-responsive and chloride-resistant) with a more straightforward and inclusive grouping that logically combines the causes of metabolic alkalosis that have the same pathophysiology (e.g., Bartter and Gitelman syndromes and diuretic-induced metabolic alkalosis).

Metabolic Alkalosis from Secondary Stimulation of Ion Transport
Chloride loss from the stomach (common)
Vomiting
Nasogastric suction
Chloride-depleting diarrheas (rare)
Congenital chloridorrhea
Some villous adenomas of the colon
High-volume ileostomy losses
Diuretic administration (common)
Thiazides
Metolazone
Loop diuretics: furosemide, bumetanide, torsemide, ethacrynic acid
Impaired chloride-linked sodium transport (rare)
Bartter syndrome
Gitelman syndrome
Rare causes
Recovery from chronic hypercapnia
Gastrocystoplasty
Cystic fibrosis
Severe potassium deficiency

Box 13-2 Causes of metabolic alkalosis resulting from secondary stimulation of collecting duct ion transport.

Secondary Stimulation of Collecting Duct Ion Transport

Box 13-2 lists the causes of metabolic alkalosis resulting from stimulation of collecting duct ion transport by abnormal transport events occurring earlier in the nephron. Specific examples are discussed next.

Vomiting or Nasogastric Drainage

Loss of chloride from the upper gastrointestinal (GI) tract, often accompanied by concomitant H^+ losses, produces a metabolic alkalosis that is sustained until body Cl^- stores are replenished (see Fig. 13-2). With continued emesis or nasogastric suction and without replacement of Cl^- losses, serum [HCO_3^-] may rise to extremely high levels.[9,10]

Diuretic Administration

Diuretics that inhibit Cl^- transport proteins in the kidney are the most common cause of metabolic alkalosis (see Box 13-2). The thiazides and metolazone inhibit the Na^+-Cl^- cotransporter in the early distal tubule, and the loop diuretics inhibit the Na^+-K^+-$2Cl^-$ cotransporter in the TAL (see Fig 13-1). These agents all impair Cl^- reabsorption, causing selective Cl^- depletion, and stimulate K^+ excretion by increasing Na^+ delivery to the collecting duct. The alkalosis produced is typically mild (serum [HCO_3^-] <38 mmol/l), except in patients who continue to ingest excess salt and have extreme renal Na^+ avidity. Hypokalemia caused by K^+ depletion is more prominent and is the major management problem.[18]

Genetic Impairment of Cl^--Linked Na^+ Transport

Bartter and Gitelman syndromes are two hereditary disorders manifested by metabolic alkalosis and hypokalemia without hypertension (see Chapter 49). Bartter syndrome is caused by several mutations, all of which have the effect of impeding Cl^--associated Na^+ reabsorption in the TAL[19] (through Na^+-K^+-$2Cl^-$ cotransporter; see Fig. 13-4). Patients with Bartter syndrome usually become ill early in life with metabolic alkalosis and volume depletion, features similar to those seen in individuals abusing loop diuretic agents. Gitelman syndrome is caused by genetic mutations that inactivate the thiazide-sensitive Na^+-Cl^- cotransporter in the early distal tubule (see Fig. 13-3), leading to hypokalemia and metabolic alkalosis similar to that caused by thiazide diuretics. Gitelman syndrome becomes clinically apparent later in life and, unlike Bartter syndrome, has hypomagnesemia and hypocalciuria as prominent features.[20]

Recovery from Chronic Hypercapnia

The renal response to sustained hypercapnia results in an increase in HCO_3^- reabsorption and a decrease in Cl^- reabsorption (see Chapter 14). As a result, serum [HCO_3^-] increases and body Cl^- stores are reduced. When P_{CO_2} is restored to normal, renal excretion of excess HCO_3^- requires repletion of the Cl^- losses incurred during adaptation. If these losses are not replaced, recovery from hypercapnia can result in a persistent metabolic alkalosis.

Congenital Chloridorrhea

This rare form of diarrhea is caused by an inactivating mutation in the "downregulated in adenoma" *(DRA)* gene, an apical membrane Cl^--HCO_3^- exchanger in the small intestine.[21] The result is a large-volume diarrhea that is rich in Cl^-, causing selective loss of this ion as well as H^+ and K^+ losses. The resultant metabolic alkalosis is ameliorated by K^+ and Cl^- administration, but correction is difficult because of continuing losses. Interestingly, the volume of diarrhea is reduced dramatically by proton pump inhibition, which reduces gastric Cl^- secretion and presumably reduces Cl^- delivery to the small intestine.[22]

Other Causes of Excessive Chloride Losses

Villous adenomas occur in the distal colon and typically secrete 1 to 3 l/day of fluid that is rich in Na^+, Cl^-, and K^+. Because the volume of secreted fluid is relatively low, these tumors are only occasionally associated with metabolic alkalosis, which is usually mild when present.[23] Cystic fibrosis is characterized by high sweat [Cl^-] and, with excessive sweating, Cl^- losses can be large enough to cause metabolic alkalosis. In children and adolescents, this acid-base disorder can be the presenting symptom.[24] Patients with high-volume ileostomy losses can sometimes develop severe metabolic alkalosis,[25] and their fluid contains abnormally high [Na^+] and [Cl^-]. The use of gastric tissue to augment bladder size (gastrocystoplasty) can occasionally lead to transient metabolic alkalosis as a result of gastrin-induced Cl^- secretion into the urine.[26]

Severe Potassium Deficiency

In patients with severe K^+ depletion (serum [K^+] <2 mmol/l), metabolic alkalosis can be sustained despite Cl^- administration.[12] Chloride resistance in this setting is probably caused by impairment of renal Cl^- reabsorption induced by K^+ depletion (see earlier discussion). Even partial repletion of K^+ stores rapidly reverses this problem and makes the alkalosis Cl^- responsive.

Primary Stimulation of Collecting Duct Ion Transport

Box 13-3 lists the causes of metabolic alkalosis caused by primary stimulation of collecting duct ion transport. Specific examples are discussed next.

Metabolic Alkalosis from Primary Stimulation of Ion Transport

- Mineralocorticoid excess
  - Primary hyperaldosteronism: adenoma, hyperplasia
  - Cushing syndrome
  - Corticotropin-secreting tumor
  - Renin-secreting tumor
  - Glucocorticoid-remediable aldosteronism
  - Adrenogenital syndromes
  - Fludrocortisone treatment
  - 9α-Fluoroprednisolone (inhaled)
- Apparent mineralocorticoid excess
  - Licorice
  - Carbenoxolone
  - Liddle syndrome
  - 11β-Hydroxysteroid dehydrogenase deficiency
- Glucocorticoids (high dose)
  - Methylprednisolone

Box 13-3 Causes of metabolic alkalosis resulting from primary stimulation of collecting duct ion transport.

Mineralocorticoid Excess

Aldosterone and other mineralocorticoids cause metabolic alkalosis by directly stimulating both the H^+-ATPase and the ENaC in the collecting duct, promoting Na^+ retention, K^+ loss, and metabolic alkalosis (see Figs. 13-1 and 13-4). The metabolic alkalosis is typically mild (serum [HCO_3^-] 30 to 35 mmol/l) and is associated with more severe hypokalemia (K^+ often <3 mmol/l) than observed with Cl^- depletion alkalosis.[11,14] Primary hyperaldosteronism is by far the most common cause of this form of metabolic alkalosis (see Chapter 40), but it can also occur with rarer hereditary defects in cortisol synthesis or in the regulation of aldosterone secretion (Box 13-3). Glucocorticoid-remediable aldosteronism (GRA) is caused by a mutation that results in stimulation of aldosterone secretion by adrenocorticotropic hormone (ACTH) rather than by angiotensin.[27] The oral mineralocorticoid fludrocortisone, as well as inhaled 9α-fluoroprednisolone, can induce metabolic alkalosis if used inappropriately. Corticosteroids, when administered in high doses, increase renal K^+ excretion nonspecifically and produce a mild increase in serum [HCO_3^-].

Apparent Mineralocorticoid Excess Syndromes

Several inherited abnormalities produce a metabolic alkalosis that is clinically indistinguishable from hyperaldosteronism but without measurable aldosterone (see Chapter 49). Liddle syndrome results from a genetic mutation that prevents the removal of ENaCs from the urinary membrane of collecting duct epithelial cells[28] (see Fig. 13-3). As a result, Na^+ reabsorption cannot be downregulated, causing the same cascade of events seen in hyperaldosteronism. Because continuous stimulation of Na^+ reabsorption expands ECF volume, however, aldosterone levels are vanishingly low. In another rare familial disorder, confusingly termed "the syndrome of apparent mineralocorticoid excess," a mutation inactivates 11β-hydroxysteroid dehydrogenase, an enzyme adjacent to the mineralocorticoid receptor that rapidly converts cortisol to cortisone, minimizing cortisol binding to this receptor.[29] When this enzyme is inactivated, cortisol activates the receptor, stimulating Na^+ reabsorption and K^+ secretion and producing metabolic alkalosis and hypertension with low aldosterone levels. Glycyrrhizic acid (a component of natural licorice), carbenoxolone, and gossypol (an agent that inhibits spermatogenesis) inhibit the activity of 11β-hydroxysteroid dehydrogenase and can cause the same clinical picture.[11]

Metabolic Alkalosis from Alkali Administration

Renal Status	Causes
Normal renal function (only in association with K^+ depletion or low NaCl intake)	Alkali intake: $NaHCO_3$, citrate, lactate, acetate, amino acid anions
Renal failure	Milk-alkali syndrome Alkali intake Aluminum hydroxide with K^+ exchange resin

Table 13-1 Causes of metabolic alkalosis associated with alkali administration.

Potential Sources of Alkali

Alkali or Alkali Precursors	Source
Bicarbonate	$NaHCO_3$: pills, intravenous solutions Proprietary preparations (e.g., Alka-Seltzer), baking soda $KHCO_3$: pills, oral solutions
Lactate	Ringer solutions Peritoneal dialysis solutions
Acetate Glutamate Propionate	Parenteral nutrition solutions
Citrate	Blood products Plasma exchange, K^+ supplements Alkalinizing agents

Alkali Administration

Table 13-1 lists the causes of metabolic alkalosis induced by alkali administration. Exogenous alkali produces metabolic alkalosis in individuals with normal kidney function only when body K^+ or Cl^- stores are deficient, because these deficiencies impair HCO_3^- excretion by the kidney[15] (see Fig. 13-3). In acute or chronic kidney disease, alkali administration or ingestion can produce metabolic alkalosis independent of K^+ and Cl^- stores if the damage is severe enough to impair excretion of the excess alkali.[16] *Milk-alkali syndrome* is characterized by the concomitant presence of metabolic alkalosis and kidney damage, initiated by the ingestion of $NaHCO_3$ in combination with excess calcium (either in milk or as $CaCO_3$).[30,31] In this disorder, kidney damage is caused by calcium deposition, facilitated by an alkaline urine. The renal damage in turn facilitates the maintenance of metabolic alkalosis by limiting HCO_3^- excretion in the face of continued ingestion. Metabolic alkalosis is usually relatively mild in these patients unless they develop concomitant vomiting. In hospitalized patients with kidney failure, a wide variety of alkali sources or alkali precursors can cause metabolic alkalosis (Table 13-2). Although aluminum hydroxide is now administered only rarely, its use in combination with sodium polystyrene sulfonate (Kayexalate) can cause metabolic alkalosis because aluminum binds to the resin in exchange for Na^+. As a result, the HCO_3^- normally secreted into the duodenum is not titrated by H^+, which was

neutralized by the aluminum hydroxide, nor does bicarbonate form an insoluble salt with aluminum. Instead, it is completely reabsorbed from the gut, increasing serum [HCO_3^-].[32]

Other Causes

Refeeding after starvation causes an abrupt increase in serum [HCO_3^-] from the low concentrations characteristic of the fasting state. In some patients, serum [HCO_3^-] increases transiently above normal, causing a mild metabolic alkalosis. The causes are multiple, including HCO_3^- generation from metabolism of accumulated organic anions and K^+ and Cl^- depletion. Administration of either vitamin D or parathyroid hormone causes a small but significant increase in serum [HCO_3^-].[33,34] Despite this experimental finding, hyperparathyroidism is not associated with clinically significant metabolic alkalosis. Hypercalcemia and vitamin D intoxication have been associated with metabolic alkalosis, but in most cases, the alkalosis can be explained by the vomiting that characteristically accompanies these disorders. High aldosterone levels induced by hyperreninemia in renovascular or malignant hypertension are associated with hypokalemia and occasionally with very minor increases in serum [HCO_3^-].

CLINICAL MANIFESTATIONS

Mild to moderate metabolic alkalosis is well tolerated, with few clinically important adverse effects. Patients with serum [HCO_3^-] as high as 40 mmol/l are usually asymptomatic. The adverse effect of most concern is hypokalemia, which increases the likelihood of cardiac arrhythmias in patients with coronary heart disease.[33] With more severe metabolic alkalosis (serum [HCO_3^-] >45 mmol/l), arterial oxygen tension (Pa_{O_2}) often falls to less than 50 mm Hg (<6.6 kP) secondary to hypoventilation, and ionized calcium decreases (due to alkalemia). Patients with serum [HCO_3^-] greater than 50 mmol/l may develop seizures, tetany, delirium, or stupor. These changes in mental status are probably multifactorial in origin, resulting from alkalemia, hypokalemia, hypocalcemia, and hypoxemia.

DIAGNOSIS

Diagnosis of metabolic alkalosis involves three steps (Fig. 13-6). The first step, detection, is most often based on the finding of an elevated venous [total CO_2]. The second step is evaluation of the secondary response (hypoventilation), excluding the possibility that a respiratory acid-base abnormality is also present. This step requires measurement of arterial pH and $Paco_2$. The third step is determination of the cause.

Serum [total CO_2] greater than 30 mmol/l in association with hypokalemia is virtually pathognomonic of metabolic alkalosis. The only other cause of an elevated value is chronic respiratory acidosis, and hypokalemia is not a feature (see Chapter 14). Because the diagnosis is usually evident and metabolic alkalosis is almost always uncomplicated, measurement of arterial pH and $Paco_2$ is unnecessary in most patients. If the alkalosis is severe (serum [HCO_3^-]

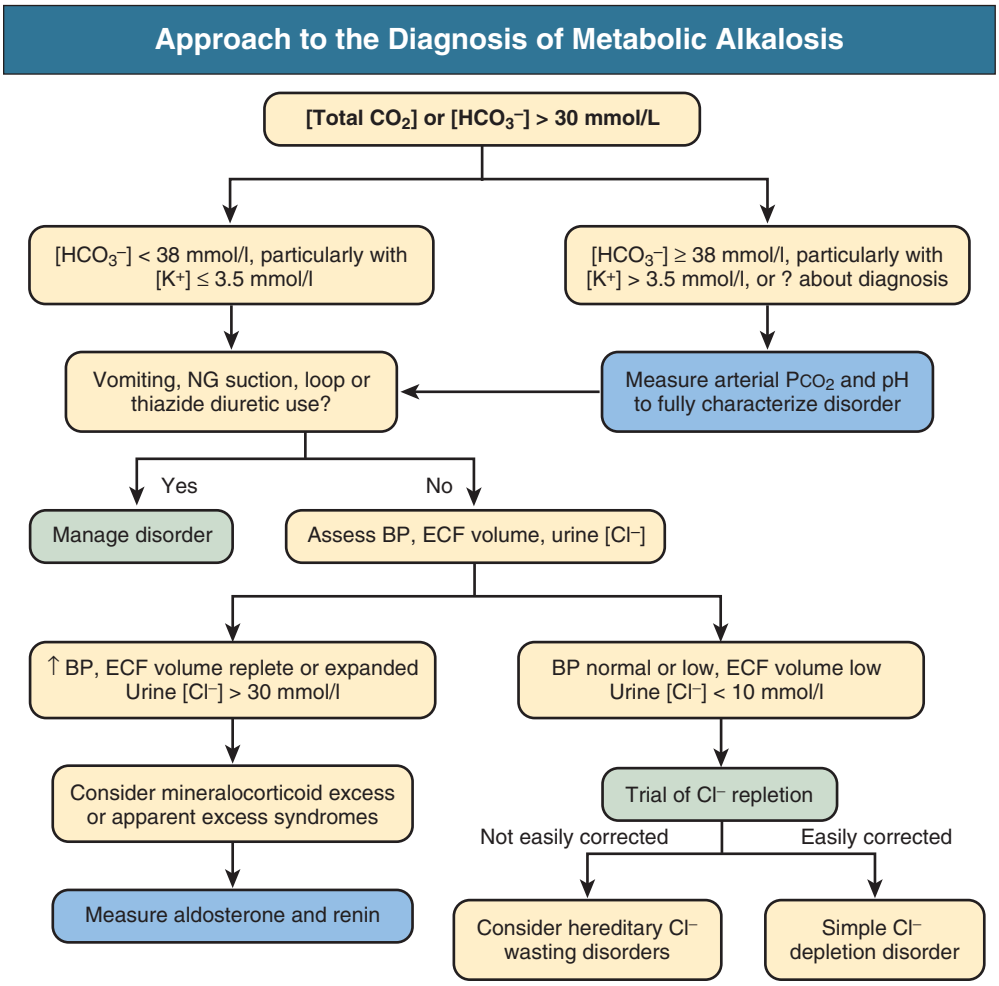

Figure 13-6 Approach to diagnosis of metabolic alkalosis. If the increase in [total CO_2] (or serum [HCO_3^-]) is mild and hypokalemia is present, arterial gas measurements are usually not necessary, and a simple algorithm can be used to diagnose the cause of the metabolic alkalosis. If hypokalemia is not present, if the increase in serum [total CO_2] is severe, or if there is a question about the diagnosis, arterial measurement of pH and Pco_2 is recommended to determine whether the condition is caused by metabolic alkalosis, respiratory acidosis, or a mixed disorder. *BP,* Blood pressure; *ECF,* extracellular fluid; *NG,* nasogastric.

>38 mmol/l), if the cause of the elevated [HCO_3^-] is unclear, or if a mixed acid-base disorder is suspected, however, the clinician should always measure pH and $Paco_2$ to characterize the disorder fully (see Fig. 13-6). These measurements confirm the presence of alkalosis and allow an estimation of whether the degree of hypoventilation is appropriate for the serum [HCO_3^-] (see earlier equation). A major deviation in $Paco_2$ from the expected value indicates the presence of a complicating respiratory acid-base disorder, either respiratory acidosis or respiratory alkalosis (see Chapter 14). The anion gap, [Na^+] – ([Cl^-] + [HCO_3^-]), is not increased in mild to moderate metabolic alkalosis, but it can be increased by as much as 3 to 5 mmol/l when alkalosis is severe. If the anion gap is more than 20 mmol/l, metabolic alkalosis is most likely complicated by superimposed metabolic acidosis (see Chapter 12).

The third step, elucidation of the cause, is straightforward in most patients. In more than 95%, metabolic alkalosis is caused either by diuretic use or by Cl^- losses from the GI tract. This information is usually easily obtained from the patient history, and attention can be directed toward the appropriate treatment. If the cause is unclear from the history, measurement of urine [Cl^-] can help. Unless the patient has recently taken a diuretic agent, urine [Cl^-] should be less than 10 mmol/l if the metabolic alkalosis is caused by Cl^- depletion. A confounding problem can be self-induced vomiting (bulimia) or the surreptitious use of diuretics, which presents the greater diagnostic dilemma because continued diuretic-induced Cl^- excretion may lead one to undertake an extensive workup for rarer forms of metabolic alkalosis. Urinary screens for specific diuretic compounds may be necessary to establish the correct diagnosis. In bulimic patients, urine Cl^- excretion should be low (spot urine [Cl^-] <10 mmol/l). If the cause is not apparent from this analysis, rarer forms of metabolic alkalosis caused by tubule transport abnormalities should be considered. In these forms of metabolic alkalosis, urine [Cl^-] is typically greater than 30 mmol/l.

In the patient with hypertension and adequate chloride intake who is not taking a diuretic agent, the most common cause of metabolic alkalosis is primary hyperaldosteronism. Measurement of serum renin and serum or urine aldosterone levels can distinguish mineralocorticoid excess syndromes from the rarer syndromes of apparent mineralocorticoid excess (see Box 13-3). The details of such a workup are presented in Chapter 40. In the normotensive or hypotensive patient who is not taking a diuretic agent, and who has metabolic alkalosis despite adequate chloride intake, the diagnosis of Bartter or Gitelman syndrome should be considered. Aldosterone and renin levels are not helpful in making these diagnoses because the levels can be low or high, depending on the patient's ECF volume at the time of measurement. Familial genetic studies can establish these diagnoses with high specificity.

TREATMENT

Chloride Depletion Alkalosis

In the patient with metabolic alkalosis caused by nasogastric drainage or vomiting, ECF volume depletion is virtually always a concomitant feature and treatment is straightforward. Administration of intravenous NaCl will correct both the alkalosis and the volume depletion. Potassium losses should also be replaced by oral or intravenous KCl. Typically the K^+ deficit is 200 to 400 mmol in patients with mild to moderate metabolic alkalosis induced by Cl^- losses in the upper GI tract. When nasogastric drainage must be continued, H^+ and Cl^- losses can be reduced by drugs that inhibit gastric acid secretion. In contrast to patients with GI losses, NaCl administration is not usually required in patients with metabolic alkalosis caused by diuretics, unless clinical signs of volume depletion are present. Potassium chloride supplements should be given to minimize K^+ depletion and mitigate the severity of the metabolic alkalosis. The addition of a potassium-sparing diuretic, such as amiloride, triamterene, spironolactone, or eplerenone, can assist in minimizing these abnormalities. Complete resolution of diuretic-induced metabolic alkalosis is often difficult because of continued Cl^- and K^+ losses. Fortunately, such a therapeutic goal is not necessary in most patients. A mild metabolic alkalosis is well tolerated, with no clinically significant adverse effects. If possible, the diuretic should be discontinued; the disorder then will resolve as long as the diet contains adequate K^+ and Cl^-.

The metabolic alkalosis and hypokalemia seen in Bartter and Gitelman syndromes is the most difficult to manage. In addition to oral KCl supplements (and magnesium supplements in Gitelman syndrome), nonsteroidal anti-inflammatory drugs have been used with moderate success. NSAIDs minimize renal Cl^- losses.

Corticosteroid and Apparent Corticosteroid-Induced Metabolic Alkalosis

Management of patients with metabolic alkalosis caused by corticosteroids or tubule transport abnormalities that mimic mineralocorticoid excess depends on the underlying cause. If the alkalosis is caused by an adrenal adenoma, the disorder is corrected by surgical removal of the tumor (see Chapter 40). In other forms of primary hyperaldosteronism, the alkalosis can be minimized by dietary NaCl restriction and by aggressive replacement of body K^+ stores with supplemental KCl. Spironolactone or eplerenone, competitive inhibitors of aldosterone, can also correct the disorder. In patients with GRA, the disorder is corrected by dexamethasone administration, which suppresses ACTH secretion and thereby reduces aldosterone secretion. In the hereditary forms of apparent mineralocorticoid excess (Liddle syndrome and 11β-hydroxysteroid dehydrogenase deficiency), amiloride is the most effective treatment.

Alkali Ingestion

Treatment for the patient ingesting alkali is directed at identification and discontinuation of the offending alkali (see Table 13-2). In the intensive care unit, sources of exogenous alkali should be carefully sought. A common offender is acetate used as a replacement for Cl^- in parenteral nutrition solutions.

SPECIAL PROBLEMS IN MANAGEMENT

Management of metabolic alkalosis is more difficult in patients with severe congestive heart failure or kidney failure. In patients with congestive heart failure and fluid overload who still have adequate kidney function, acetazolamide can be used to reduce serum [HCO_3^-]. This carbonic anhydrase inhibitor blocks H^+-linked Na^+ reabsorption, leading to excretion of both Na^+ and HCO_3^-. Acetazolamide decreases ECF volume and lowers serum [HCO_3^-] but stimulates K^+ excretion, exacerbating hypokalemia. When used, acetazolamide should be accompanied by aggressive K^+ replacement therapy.

In patients with kidney failure, serum [HCO_3^-] can be reduced in a timely manner by the appropriate form of renal replacement therapy. Continuous venovenous hemofiltration can remove as much as 20 to 30 l/day of an ultrafiltrate of plasma, and a bicarbonate-free replacement solution can be used to reduce serum [HCO_3^-] and increase serum [Cl^-]. Serum [HCO_3^-] can also be lowered by

continuous slow, low-efficiency dialysis, with the dialysate [HCO_3^-] adjusted to 23 mmol/l. Standard hemodialysis or peritoneal dialysis is less useful because these treatments are designed to add alkali to the blood, and the alkali concentration in the dialysate is set at 35 to 40 mmol/l. However, newer machines allow adjustment of the dialysate [HCO_3^-] to as low as 30 mmol/l, and this form of treatment has been used to successfully treat patients with severe metabolic alkalosis.[10]

If renal replacement therapy cannot be instituted, titration with hydrochloride is an alternative therapy. This approach is limited by the concentration of HCl that can be administered without producing hemolysis or venous coagulation. Although some have used higher concentrations, the recommended safe level of H^+ is 100 mmol/l (0.1N HCl). Even at this concentration, HCl must be administered through a central vein. Because the apparent space of distribution of HCO_3^- is approximately 50% of body weight, 350 mmol of H^+ is required to reduce serum [HCO_3^-] by 10 mmol/l in a 70-kg patient. The volume of fluid required for this titration using HCl, unfortunately, is 3.5 liters.

Ammonium chloride (NH_4Cl) and arginine monohydrochloride are not recommended for the treatment of metabolic alkalosis because of their life-threatening complications of NH_3 intoxication and severe hyperkalemia, respectively.[35]

CHAPTER 14

Respiratory Acidosis, Respiratory Alkalosis, and Mixed Disorders

Horacio J. Adrogué and Nicolaos E. Madias

Deviations of systemic acidity in either direction can have adverse consequences and, when severe, can be life threatening to the patient. Therefore, it is essential for the clinician to recognize and properly diagnose acid-base disorders, to understand their impact on organ function, and to be familiar with their treatment and the potential complications of treatment.[1,2]

RESPIRATORY ACIDOSIS (PRIMARY HYPERCAPNIA)

Definition

Respiratory acidosis is the acid-base disturbance initiated by an increase in carbon dioxide tension (P_{CO_2}) of body fluids and in whole-body CO_2 stores. The secondary increment in plasma bicarbonate ion concentration (plasma [HCO_3^-]) observed in acute and chronic hypercapnia is an integral part of the respiratory acidosis.[3] The level of arterial CO_2 tension (Pa_{CO_2}) is greater than 45 mm Hg in patients with simple respiratory acidosis, as measured at rest and at sea level. (To convert values from millimeters Hg to kilopascals [kP], multiply by 0.1333.) An element of respiratory acidosis may still occur with lower Pa_{CO_2} in patients residing at high altitude (e.g., 4000 m or 13,000 ft) or with metabolic acidosis, in whom a normal Pa_{CO_2} is inappropriately high for this condition.[4] Another special case of respiratory acidosis is the presence of arterial eucapnia, or even hypocapnia, occurring together with severe venous hypercapnia, in patients having an acute, profound decrease in cardiac output but relative preservation of respiratory function.[5,6] This disorder is known as pseudorespiratory alkalosis and is discussed under respiratory alkalosis.

Etiology and Pathogenesis

The ventilatory system is responsible for eucapnia by adjustment of alveolar minute ventilation ($\dot{V}_A$) to match the rate of CO_2 production. Its main elements are the respiratory pump, which generates a pressure gradient responsible for airflow, and the loads that oppose such action.

Carbon dioxide retention can occur from an imbalance between the strength of the respiratory pump and the extent of respiratory load (Fig. 14-1). When the respiratory pump is unable to balance the opposing load, respiratory acidosis develops. Respiratory acidosis may be acute or chronic (Tables 14-1 and 14-2). Life-threatening acidemia of respiratory origin can occur during severe, acute respiratory acidosis or during respiratory decompensation in patients with chronic hypercapnia.

A simplified form of the alveolar gas equation at sea level and on breathing of room air (Fi_{O_2}, 21%) is as follows:

$$Pa_{O_2} = 150 - 1.25\, Pa_{CO_2}$$

where P_{AO_2} is alveolar O_2 tension (mm Hg). This equation demonstrates that patients breathing room air cannot reach Pa_{CO_2} levels much greater than 80 mm Hg (10.6 kP) because the hypoxemia that would occur at greater values is incompatible with life. Therefore, extreme hypercapnia occurs only during O_2 therapy, and severe CO_2 retention is often the result of uncontrolled O_2 administration.

Secondary Physiologic Response

Adaptation to acute hypercapnia elicits an immediate increment in plasma [HCO_3^-] due to titration of non-HCO_3^- body buffers; such buffers generate HCO_3^- by combining with H^+ derived from the dissociation of carbonic acid, as follows:

$$CO_2 + H_2O \leftrightarrow H_2CO_3 \leftrightarrow HCO_3^- + H^+ \text{ and } H^+ + B^- \leftrightarrow HB$$

where B^- refers to the base component and HB refers to the acid component of non-HCO_3^- buffers. This adaptation is completed within 5 to 10 minutes from the increase in Pa_{CO_2}, and assuming a stable level of hypercapnia, no further change in acid-base equilibrium is detectable for a few hours.[7] Moderate hypoxemia does not alter the adaptive response to acute respiratory acidosis. However, preexisting hypobicarbonatemia (whether it is caused by metabolic acidosis or chronic respiratory alkalosis) enhances the magnitude of the HCO_3^- response to acute hypercapnia; this response is diminished in hyperbicarbonatemic states, whether caused by metabolic alkalosis or chronic respiratory acidosis.[8,9]

The adaptive increase in plasma [HCO_3^-] observed in acute hypercapnia is amplified greatly during chronic hypercapnia as a result of HCO_3^- generation by the kidney.[10] In addition, the renal response to chronic hypercapnia includes a reduction in the rate of Cl^- reabsorption, resulting in depletion of body Cl^- stores. Complete adaptation to chronic hypercapnia requires 3 to 5 days.[7] Table 14-3 provides quantitative aspects of the secondary physiologic responses to acute and chronic hypercapnia. More recently, a substantially steeper slope for the change in plasma [HCO_3^-] in chronic respiratory acidosis was reported (0.51 mmol/l for each 1 mm Hg chronic increase in Pa_{CO_2}), but the small number of arterial blood gas (ABG) measurements, one for each of 18 patients, calls in question the validity of the conclusion reached.[11] The renal response to chronic hypercapnia is not altered appreciably by dietary Na^+ or Cl^- restriction, moderate K^+ depletion, alkali loading, or moderate hypoxemia. However, recovery from chronic hypercapnia is crippled by a diet deficient in Cl^-; in this circumstance, despite correction of the level of Pa_{CO_2}, plasma [HCO_3^-] remains elevated as long as the state of Cl^- deprivation persists, leading to posthypercapnic metabolic alkalosis.

Clinical Manifestations

Because clinical hypercapnia almost always occurs in association with hypoxemia, it is often difficult to determine whether a specific

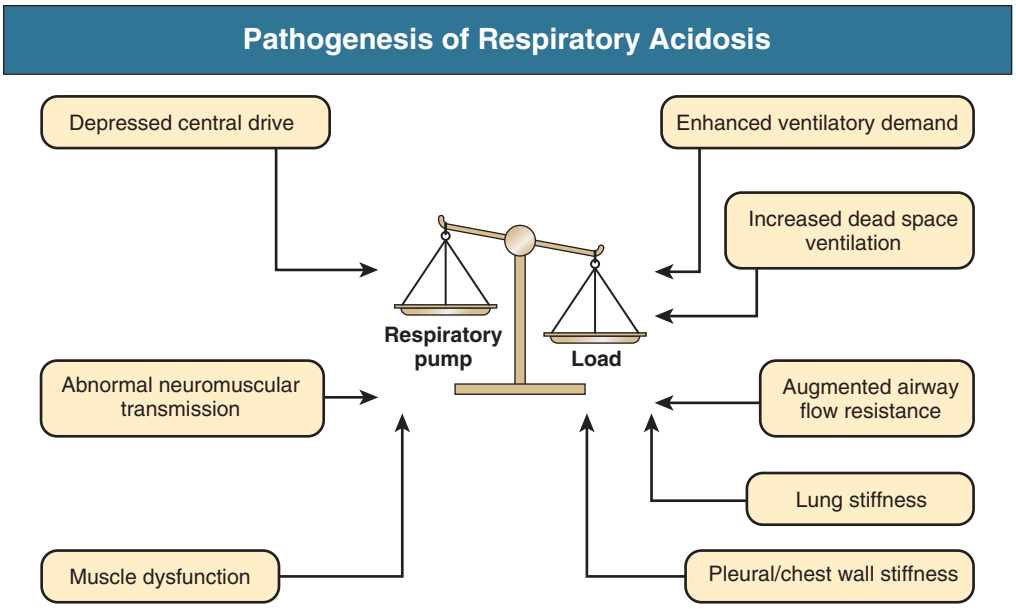

Figure 14-1 Pathogenesis of respiratory acidosis.

manifestation is the consequence of elevated $Paco_2$ or reduced Pao_2. Nevertheless, the clinician should bear in mind several characteristic manifestations of neurologic or cardiovascular dysfunction to diagnose the condition accurately and to treat it effectively.[4,7]

Neurologic Symptoms

Acute hypercapnia is often associated with marked anxiety, severe breathlessness, disorientation, confusion, incoherence, and combativeness. A narcotic-like effect can occur in patients with chronic hypercapnia, and drowsiness, decreased alertness, inattention, forgetfulness, loss of memory, irritability, confusion, and somnolence may be observed. Motor disturbances, including tremor, myoclonic jerks, and asterixis, are frequently observed with both acute and chronic hypercapnia. Sustained myoclonus and seizure activity can also develop. Signs and symptoms of increased intracranial pressure (ICP) such as pseudotumor cerebri are occasionally evident in patients with either acute or chronic hypercapnia and appear to be related to the vasodilating effects of CO_2 on cerebral blood vessels. Headache is a frequent complaint. Blurring of the optic discs and frank papilledema can be found when hypercapnia is severe. Hypercapnic coma characteristically occurs in patients with acute exacerbations of chronic respiratory insufficiency who are treated injudiciously with high-flow O_2.[12]

Cardiovascular Symptoms

Acute hypercapnia of mild to moderate degree is usually characterized by warm and flushed skin, bounding pulse, sweating, increased cardiac output, and normal or increased blood pressure. By comparison, severe hypercapnia might be attended by decreases in both cardiac output and blood pressure. Cardiac arrhythmias occur frequently in patients with either acute or chronic hypercapnia, especially those receiving digoxin.

Renal Symptoms

Mild to moderate hypercapnia results in renal vasodilation, but acute increments in $Paco_2$ to levels above 70 mm Hg (9.3 kP) can induce renal vasoconstriction and hypoperfusion. Salt and water retention typically attend sustained hypercapnia, especially in the presence of cor pulmonale. In addition to the effects of heart failure on the kidney, multiple other factors might be at play, including the prevailing stimulation of the sympathetic nervous system and the renin-angiotensin-aldosterone axis, the increased renal vascular resistance, and the elevated levels of antidiuretic hormone (ADH) and cortisol.[12]

Diagnosis

Whenever CO_2 retention is suspected, ABG values should be obtained.[12] If the patient's acid-base profile reveals hypercapnia in association with acidemia, at least an element of respiratory acidosis must be present. However, hypercapnia can be associated with a normal or even an alkaline pH if certain additional acid-base disorders are also present. Information from the patient history, physical examination, and ancillary laboratory data should be used to assess whether part or all of the increase in $Paco_2$ reflects an adaptive response to metabolic alkalosis rather than being primary in origin.

Treatment

As previously noted, CO_2 retention, whether acute or chronic, is always associated with hypoxemia in patients breathing room air. Consequently, O_2 administration represents a critical element in the management of respiratory acidosis.[1,13] However, supplemental O_2 may lead to worsening hypercapnia, especially in patients with chronic obstructive pulmonary disease (COPD). Although a depressed respiratory drive in CO_2 retention seems to play a role, other factors might account for the worsening hypercapnia in response to supplemental O_2 therapy. These include an increase in dead space ventilation and ventilation/perfusion ($\dot{V}/\dot{Q}$) mismatch caused by the loss of hypoxic pulmonary vasoconstriction and the Haldane effect (decreased hemoglobin affinity for CO_2 in the presence of increased O_2 saturation), which mandates an increase in ventilation to eliminate the excess CO_2.[7]

Figures 14-2 and 14-3 outline the management of acute respiratory acidosis and chronic respiratory acidosis. Whenever possible, treatment must be directed at removal or amelioration of the underlying cause. Immediate therapeutic efforts should focus on securing a patent airway and restoring adequate oxygenation by delivery of an O_2-rich inspired mixture. Supplemental oxygen can be administered to the spontaneously breathing patient with nasal cannulas,

Causes of Acute Respiratory Acidosis	
Increased Load	**Depressed Pump**
Enhanced Ventilatory Demand	**Depressed Central Drive**
High-carbohydrate diet High-carbohydrate dialysate (peritoneal dialysis) Sorbent-regenerative hemodialysis	General anesthesia Sedative overdose Head trauma Cerebrovascular accident Obesity-hypoventilation syndrome Cerebral edema Brain tumor Encephalitis Brainstem lesion

Venturi masks, or non-rebreathing masks. Oxygen flow rates up to 5 l/min can be used with nasal cannulas; each increment of 1l/min increases the fraction of inspired O_2 concentration (Fio_2) by approximately 4%. Venturi masks, calibrated to deliver Fio_2 between 24% and 50%, are most useful in patients with COPD because the Po_2 can be titrated, thus minimizing the risk of CO_2 retention. Oxygen saturation of hemoglobin of approximately 80% to 90% can be achieved with nonbreathing masks.

If the target Po_2 is not achieved with these measures and the patient is conscious, cooperative, hemodynamically stable, and able to protect the lower airway, a method of noninvasive ventilation through a mask can be used, including bilevel positive airway pressure (BiPAP). With BiPAP, the inspiratory-pressure support decreases the work of breathing, and the expiratory-pressure support improves gas exchange by preventing alveolar collapse.

Endotracheal intubation and mechanical ventilatory support should be initiated if adequate oxygenation cannot be secured by noninvasive measures, if progressive hypercapnia or obtundation

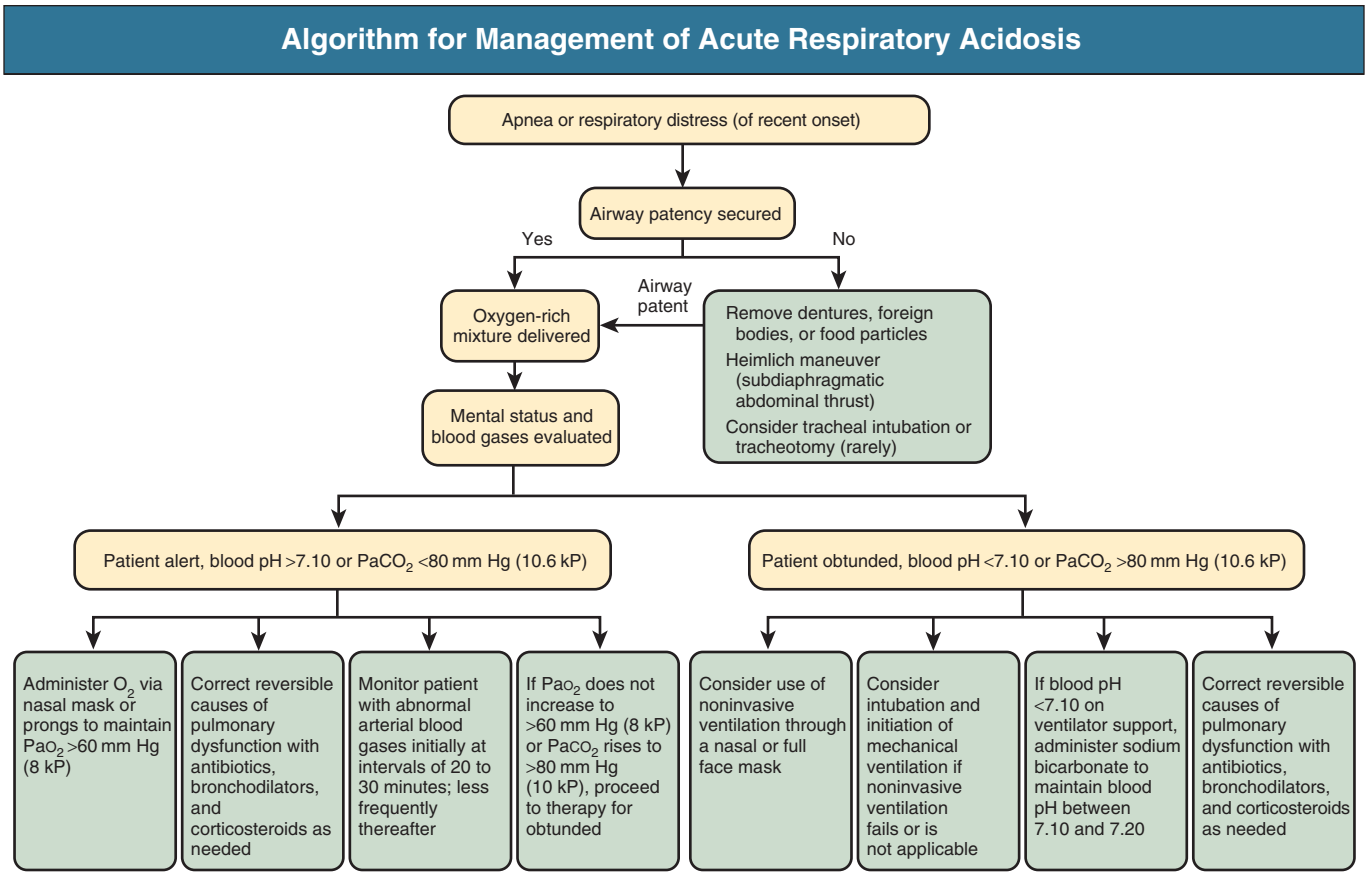

Figure 14-2 **Algorithm for management of the patient with acute respiratory acidosis.**

develops, or if the patient is unable to cough and clear secretions. Minute ventilation should be raised so that the $Paco_2$ gradually returns to near its long-term baseline and excretion of excess HCO_3^- by the kidneys is accomplished (assuming that Cl^- is provided). By contrast, overly rapid reduction in the $Paco_2$ risks the development of posthypercapnic alkalosis, with potentially serious consequences. If it develops, posthypercapnic alkalosis can be ameliorated by providing Cl^-, usually as the potassium salt, and administering the HCO_3^--wasting diuretic acetazolamide at doses of 250 to 500 mg once or twice daily. Vigorous treatment of pulmonary infections, bronchodilator therapy, and removal of secretions can offer considerable benefit. Naloxone will reverse the suppressive effect of narcotic agents on ventilation. Avoidance of tranquilizers and sedatives, gradual reduction of supplemental oxygen, aiming at a Pao_2 of about 60 mm Hg (8 kP), and treatment of a superimposed metabolic alkalosis will optimize the ventilatory drive.

Mechanical ventilation with tidal volumes of 10 to 15 ml/kg body weight often leads to alveolar overdistention and volutrauma. Therefore, an alternative approach called *permissive hypercapnia* (or controlled mechanical hypoventilation) has been successfully applied to prevent barotrauma and cardiovascular collapse.[4,14] In this form of treatment, lower tidal volumes of less than 6 ml/kg and lower peak inspiratory pressures are used. Further, $Paco_2$ is allowed to increase, but rarely exceeds 80 mm Hg, and blood pH can decrease to as low as 7.00 to 7.10, while adequate oxygenation is maintained. Because the patient usually requires neuromuscular blockade as well, accidental disconnection from the ventilator can cause sudden death. Contraindications to permissive hypercapnia include cerebrovascular disease, brain edema, increased ICP, convulsions, depressed cardiac function, arrhythmias, and severe pulmonary hypertension. Correction of acidemia attenuates the adverse hemodynamic effects of permissive hypercapnia.[15] It appears prudent, although still controversial, to keep the blood pH at approximately 7.30 by the administration of intravenous alkali when controlled hypoventilation is prescribed.[1,16]

RESPIRATORY ALKALOSIS (PRIMARY HYPOCAPNIA)

Definition

Respiratory alkalosis is the acid-base disturbance initiated by a reduction in CO_2 tension of body fluids. The secondary decrease in plasma $[HCO_3^-]$ observed in acute and chronic hypocapnia is an integral part of the respiratory alkalosis. Whole-body CO_2 stores are decreased and $Paco_2$ is less than 35 mm Hg (4.7 kP) in patients with simple respiratory alkalosis (at rest and at sea level). An element of respiratory alkalosis may still occur with higher levels of $Paco_2$ in patients with metabolic alkalosis, in whom a normal $Paco_2$ is inappropriately low for this primary metabolic disorder.

Etiology and Pathogenesis

Respiratory alkalosis is the most frequent acid-base disorder encountered because it occurs in normal pregnancy and with high-altitude residence.[2,17,18] It is also the most common acid-base abnormality in critically ill patients, occurring either as the simple disorder or as a component of mixed disturbances; indeed, in such patients, its

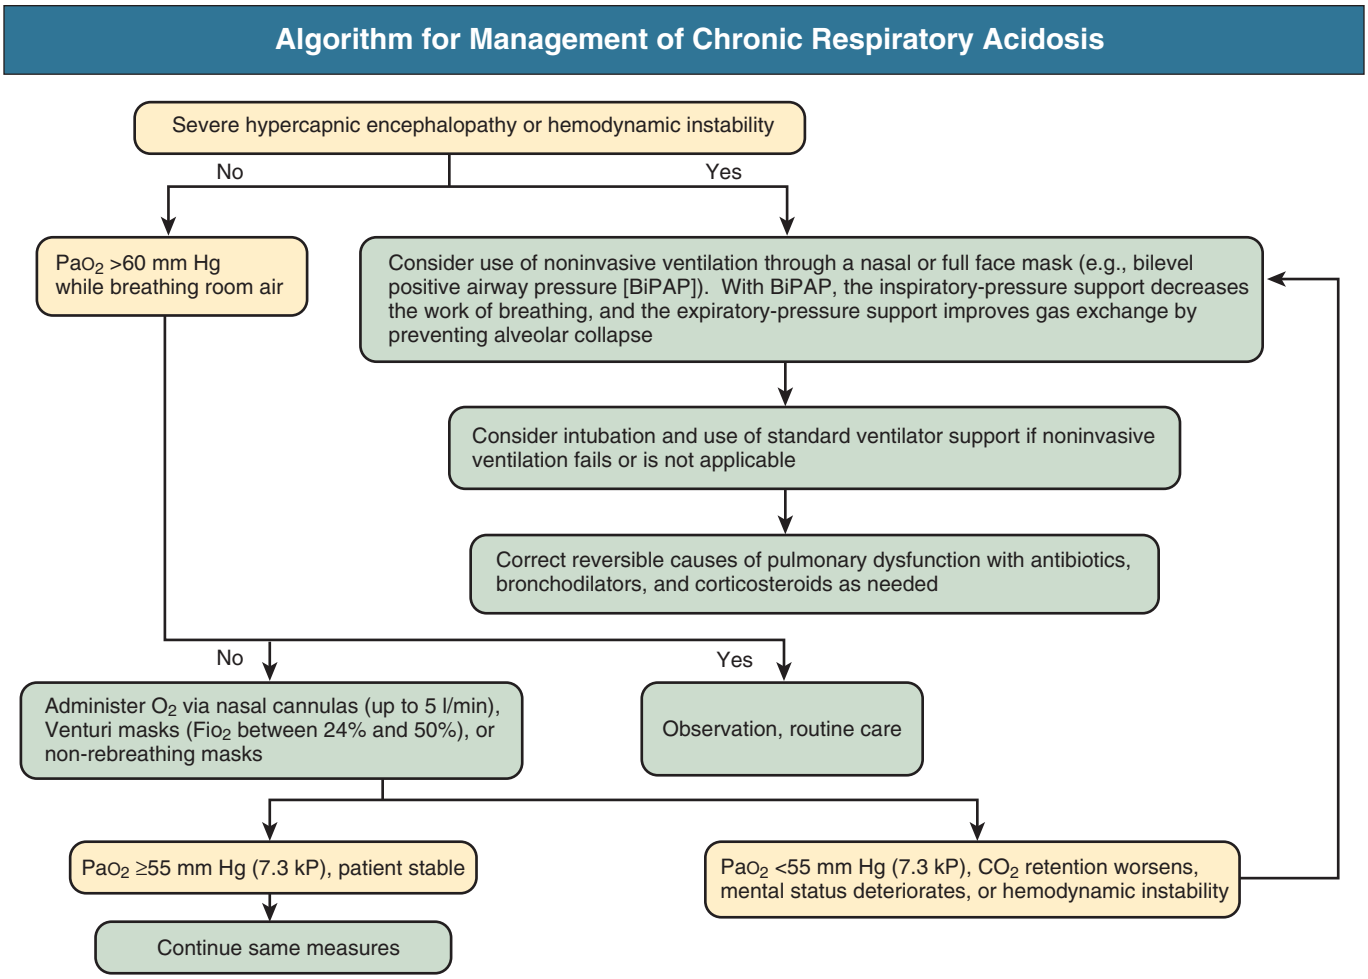

Figure 14-3 **Algorithm for management of the patient with chronic respiratory acidosis.**

presence may constitute a serious prognostic sign, especially if P_{aCO_2} level is below 20 to 25 mm Hg (2.7 to 3.3 kP). The presence of hypocapnia signifies transient or persistent alveolar hyperventilation relative to the prevailing CO_2 production, thus leading to negative CO_2 balance. Primary hypocapnia might also originate from the extrapulmonary elimination of CO_2 by dialysis or other extracorporeal circulation (e.g., heart-lung machine).

Table 14-4 provides the major causes of respiratory alkalosis.[12] In most patients, primary hypocapnia reflects alveolar hyperventilation caused by increased ventilatory drive. This is a result of signals arising from the lung, the peripheral chemoreceptors (carotid and aortic), or the brainstem chemoreceptors, or signals originating in other brain centers.

The response of the brainstem chemoreceptors to CO_2 can be augmented by systemic diseases (e.g., liver disease, sepsis), pharmacologic agents, and volition. Hypoxemia is a major stimulus of alveolar ventilation, but P_{AO_2} values below 60 mm Hg (8 kP) are required to elicit this effect consistently. Alveolar hyperventilation can be the result of maladjusted mechanical ventilators, psychogenic hyperventilation, and lesions involving the central nervous system.

In states of severe circulatory failure, arterial hypocapnia may coexist with venous and therefore tissue hypercapnia; under these conditions, the body CO_2 stores have been enriched so that there is respiratory acidosis rather than respiratory alkalosis. This entity, which we have termed *pseudorespiratory alkalosis,* develops in patients with profound depression of cardiac function and pulmonary perfusion but relative preservation of alveolar ventilation, including patients with advanced circulatory failure and those undergoing cardiopulmonary resuscitation (CPR). The severely reduced pulmonary blood flow limits the CO_2 delivered to the lungs for excretion, thereby increasing the venous P_{CO_2}. However, the increased ventilation-perfusion ratio causes a larger than normal removal of CO_2 per unit of blood traversing the pulmonary circulation, thereby giving rise to arterial eucapnia or frank hypocapnia. A progressive widening of the arteriovenous difference in pH and P_{CO_2} develops in two settings of cardiac dysfunction, circulatory failure and cardiac arrest (Fig. 14-4). In both situations, there is severe tissue O_2 deprivation, and it can be completely disguised by the reasonably preserved arterial O_2 values. Appropriate monitoring of acid-base composition and oxygenation in patients with advanced cardiac dysfunction requires mixed (or central) venous blood sampling in addition to the sampling of arterial blood.

Secondary Physiologic Response

Adaptation to acute hypocapnia is characterized by an immediate decrement in plasma [HCO_3^-] that results totally from nonrenal mechanisms and is explained principally by alkaline titration of the non-HCO_3^- body buffers (see second equation under Respiratory Acidosis). This adaptation is completed within 5 to 10 minutes of the

Causes of Respiratory Alkalosis

onset of hypocapnia, and if there is no further change in P_{aCO_2}, no additional detectable changes in acid-base equilibrium occur for several hours.[7]

Adaptation to chronic hypocapnia entails an additional, larger decrease in plasma [HCO_3^-] as a consequence of renal adjustments that reflect a dampening of H^+ secretion by the renal tubule.[10] Approximately 2 to 3 days are required for completion of the adaptation to chronic hypocapnia. Quantitative aspects of the secondary physiologic responses to acute and chronic hypocapnia are shown in Table 14-3.

Clinical Manifestations

A rapid decrease in P_{aCO_2} to half-normal values or lower is typically accompanied by numbness and paresthesias of the extremities, chest discomfort (especially in patients manifesting increased airway resistance), circumoral numbness, lightheadedness, and mental confusion. Muscle cramps, increased deep tendon reflexes, carpopedal spasm, and generalized seizures occur infrequently. Cerebral vasoconstriction and reduced cerebral blood flow have been well documented during acute hypocapnia; in severe cases, cerebral blood flow might decrease to below 50% of normal values. Hypocapnia can have deleterious effects on the brain of premature infants; in patients with traumatic brain injury, acute stroke, or general anesthesia; and after sudden exposure to very high altitude.[19] Long-term neurologic sequelae can develop when immature brains are exposed to P_{aCO_2} levels below 15 mm Hg (2 kP) for even short periods. Furthermore, abrupt correction of hypocapnia in these patients leads to cerebral vasodilation, which might cause reperfusion injury or intraventricular hemorrhage.

Brain injury caused by hypocapnia probably results from cerebral ischemia. Other factors include hypocapnia itself, alkalemia, pH-induced shift of the oxyhemoglobin (HbO_2) dissociation curve, decreased levels of ionized calcium and potassium, depletion of the antioxidant glutathione by cytotoxic excitatory amino acids, increases in anaerobic metabolism, cerebral oxygen demand, neuronal dopamine, and seizure activity. If sepsis is present, brain damage worsens with the release of lipopolysaccharide, interleukin-1β, and tumor necrosis factor α.[19]

The cardiovascular manifestations of respiratory alkalosis differ in passive and active hyperventilation. The induction of acute hypocapnia in anesthetized patients (i.e., passive hyperventilation) results in a decrease in cardiac output, an increase in peripheral resistance, and a decrease in the systemic blood pressure. By contrast, active hyperventilation does not change or might even increase cardiac output and leaves systemic blood pressure virtually unchanged. The discrepant response of cardiac output during hyperventilation probably reflects the decrease in venous return caused by mechanical ventilation in passive hyperventilation and the reflex tachycardia consistently observed in active hyperventilation. Sustained hypocapnia induced by exposure to high altitude for several weeks results in a cardiac output within control values or higher. Although it does not lead to cardiac arrhythmias in normal individuals, acute

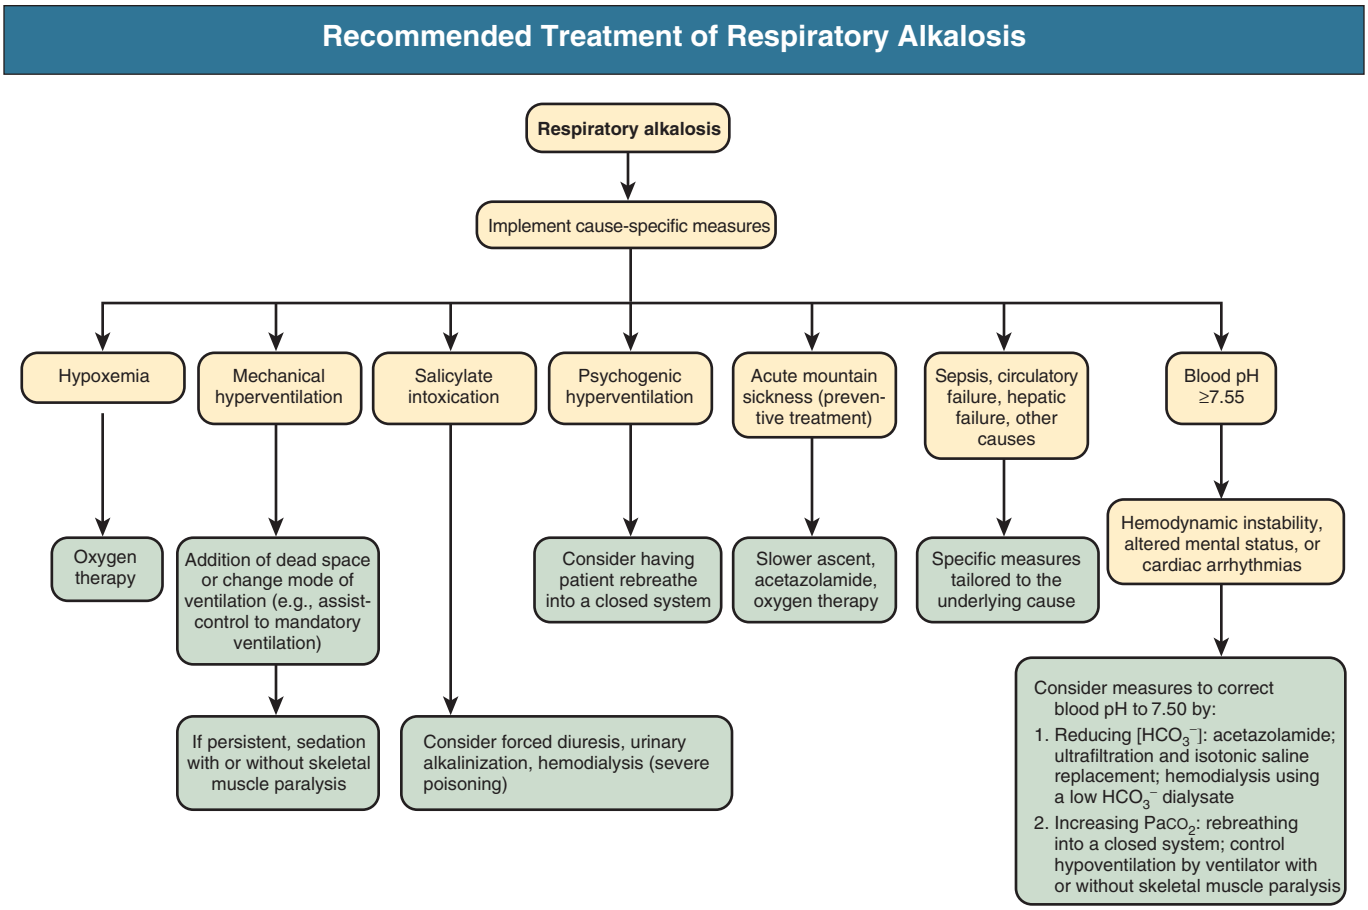

Figure 14-5 **Recommended management of the patient with respiratory alkalosis.**

hypocapnia appears to contribute to the generation of both atrial and ventricular tachyarrhythmias in patients with ischemic heart disease; such arrhythmias are frequently resistant to standard forms of therapy. Chest pain and ischemic ST-T wave changes have been observed in acutely hyperventilating patients with no evidence of fixed lesions on coronary angiography.

Diagnosis

Evaluation of the patient history, physical examination, and ancillary laboratory data are required to establish the diagnosis of respiratory alkalosis.[12,17] Careful observation can detect abnormal patterns of breathing in some patients, although marked hypocapnia can occur without a clinically evident increase in respiratory effort. ABG determinations are required to confirm the presence of hyperventilation.

The diagnosis of respiratory alkalosis, especially the chronic form, is frequently missed; physicians often misinterpret the electrolyte pattern of hyperchloremic hypobicarbonatemia as indicative of normal anion gap metabolic acidosis. If the patient's acid-base profile reveals hypocapnia in association with alkalemia, at least an element of respiratory alkalosis must be present. However, hypocapnia might be associated with a normal or an acidic pH because of the concomitant presence of additional acid-base disorders. The clinician should also note that mild degrees of chronic hypocapnia leave blood pH within the high-normal range. The diagnosis of respiratory alkalosis can have important clinical implications; it often provides a clue to the presence of an unrecognized, serious disorder or signals the threat of a known underlying disease.

Treatment

Figure 14-5 provides a synopsis of the management of patients with respiratory alkalosis. The view that hypocapnia poses minimal risk to health under most conditions is not accurate. Substantial hypocapnia in hospitalized patients, whether spontaneous or deliberately induced, may result in transient or permanent damage in the brain as well as the respiratory and cardiovascular systems.[19] Furthermore, rapid correction of severe hypocapnia leads to vasodilation of ischemic areas, resulting in reperfusion injury in the brain and lung. Consequently, severe hypocapnia in hospitalized patients must be prevented whenever possible, and if it is present, abrupt correction should be avoided. Severe alkalemia caused by acute primary hypocapnia requires corrective measures that depend on whether serious clinical manifestations are present. Such measures can be directed at reducing plasma [HCO_3^-], increasing $Paco_2$, or both. Even if baseline plasma [HCO_3^-]is moderately decreased, reducing it further can be particularly rewarding in these patients because this maneuver combines effectiveness with relatively little risk. For patients with the anxiety-hyperventilation syndrome, in addition to reassurance or sedation, rebreathing into a closed system (e.g., paper bag) might prove helpful by interrupting the vicious cycle that can result from the reinforcing effects of the symptoms of hypocapnia.

Respiratory alkalosis resulting from severe hypoxemia requires O_2 therapy. The oral administration of 250 to 500 mg acetazolamide twice daily can be beneficial in the management of signs and symptoms of high-altitude sickness, a syndrome characterized by hypoxemia and respiratory alkalosis.[17] Patients undergoing mechanical ventilation can facilitate effective correction of hypocapnia, whether from maladjusted ventilator or other factors, by resetting the device.

MIXED ACID-BASE DISTURBANCES

Definition

Mixed acid-base disturbances are defined as the simultaneous presence of two or more acid-base disorders. Such association might include two or more simple acid-base disorders (e.g., metabolic acidosis and respiratory alkalosis), two or more forms of a simple disturbance having different time course or pathogenesis (e.g., acute and chronic respiratory acidosis or high anion gap and hyperchloremic metabolic acidosis, respectively), or a combination of these two forms.[20] The secondary or adaptive response to a simple acid-base disorder cannot be taken as one of the components of a mixed disorder.

Etiology and Pathogenesis

Mixed acid-base disturbances are usually observed in hospitalized patients, especially those in critical care units.[21] Characterization of these disorders and proper identification of their pathogenesis can be challenging and are a prerequisite for taking sound corrective action. Certain clinical settings are often associated with mixed acid-base disorders, including cardiorespiratory arrest, sepsis, drug intoxications, diabetes mellitus, and organ failure (especially renal, hepatic, and pulmonary failure). Patients with severe renal impairment or end-stage renal disease (ESRD) are prone to mixed acid-base disturbances of great complexity and severity.[22] In these conditions, metabolic acidosis of the high anion gap type is frequently accompanied by a component of hyperchloremic acidosis, inability to mount an appropriate secondary response to chronic respiratory acidosis or alkalosis, inability to respond to a load of fixed acids (e.g., lactic acid) or a primary loss of alkali (e.g., diarrhea) with the expected increase in net acid excretion, and inability to respond to an alkali load with bicarbonaturia despite the presence of increased plasma [HCO_3^-]. As a result, these patients are particularly vulnerable to the development of both extreme acidemia and extreme alkalemia.

A practical classification of mixed acid-base disorders recognizes three main groups of disturbances in accordance with the preceding definition (Fig. 14-6). Representative examples are depicted in Table 14-5, and some of these mixed disorders are reviewed next.

Metabolic Acidosis and Respiratory Acidosis

The expected hypocapnia secondary to metabolic acidosis is estimated by $\Delta Pa_{CO_2}/\Delta[HCO_3^-]$ = 1.2 mm Hg/mEq/l (Δ indicates change). If measured Pa_{CO_2} exceeds 5 mm Hg of the estimated value, respiratory acidosis is also present. Clinical examples of metabolic acidosis combined with respiratory acidosis include untreated cardiopulmonary arrest, circulatory failure in patients with COPD, severe renal failure associated with hypercapnic respiratory failure, various intoxications, and hypokalemic (or less frequently hyperkalemic) paralysis of respiratory muscles in patients with diarrhea or renal tubular acidosis (RTA) (Fig. 14-7 and Table 14-5, example 4).

Metabolic Alkalosis and Respiratory Alkalosis

Metabolic alkalosis combined with respiratory alkalosis might be encountered in patients with primary hypocapnia associated with chronic liver disease who develop metabolic alkalosis from a variety of causes, including vomiting, nasogastric drainage, diuretics, profound hypokalemia, and alkali administration (e.g., absorption of antacids; infusion of lactated Ringer solution, alimentation solutions, citrated blood products), especially in the patient with renal impairment. Mixed metabolic/respiratory alkalosis also occurs in critically ill patients, particularly those undergoing mechanical ventilation, and in patients with respiratory alkalosis, caused by either pregnancy or heart failure, who experience metabolic alkalosis attributable to diuretics or vomiting (Fig. 14-8 and Table 14-5, example 6).

Metabolic Alkalosis and Respiratory Acidosis

Metabolic alkalosis with respiratory acidosis is one of the most frequently encountered mixed acid-base disorders. The usual clinical setting involves COPD in conjunction with diuretic therapy, but it can occur with other causes of metabolic alkalosis (e.g., vomiting, administration of corticosteroids) (Fig. 14-9 and Table 14-5, example 5). Critically ill patients with respiratory failure caused by acute respiratory distress syndrome and occasionally those with profound hypokalemia with diaphragmatic muscle weakness also might develop mixed metabolic alkalosis and respiratory acidosis.

Metabolic Acidosis and Respiratory Alkalosis

As with respiratory acidosis and metabolic alkalosis, the combination of metabolic acidosis and respiratory alkalosis is characterized

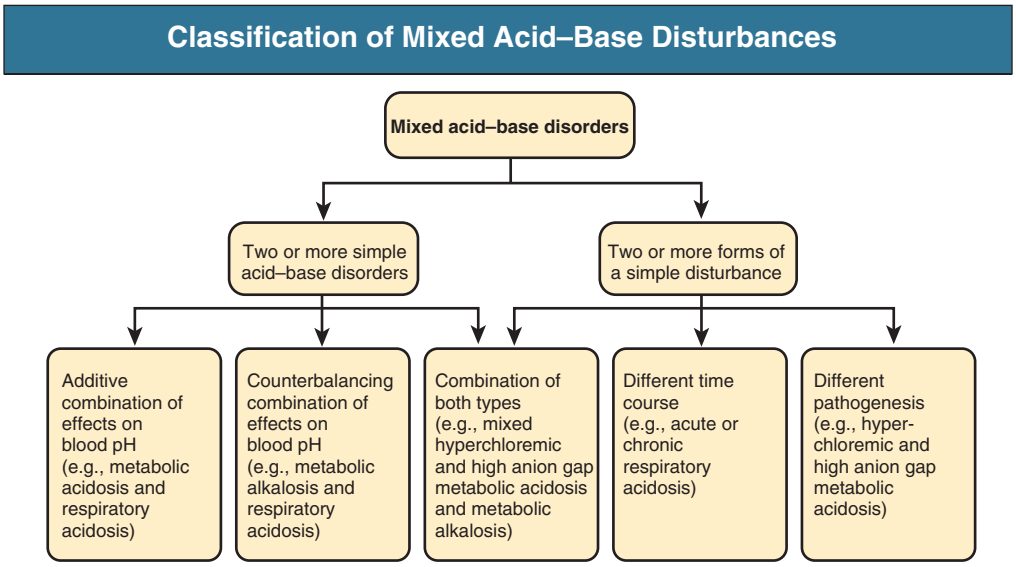

Figure 14-6 Classification of mixed acid-base disturbances.

Representative Examples of Mixed Acid-Base Disorders

Type of Mixed Disorder	No.*	pH	$Paco_2$† (mm Hg)	HCO_3^- (mmol/l)	Na^+ (mmol/l)	K^+ (mmol/l)	Cl^- (mmol/l)	Anion gap (mmol/l)	Clinical Circumstances

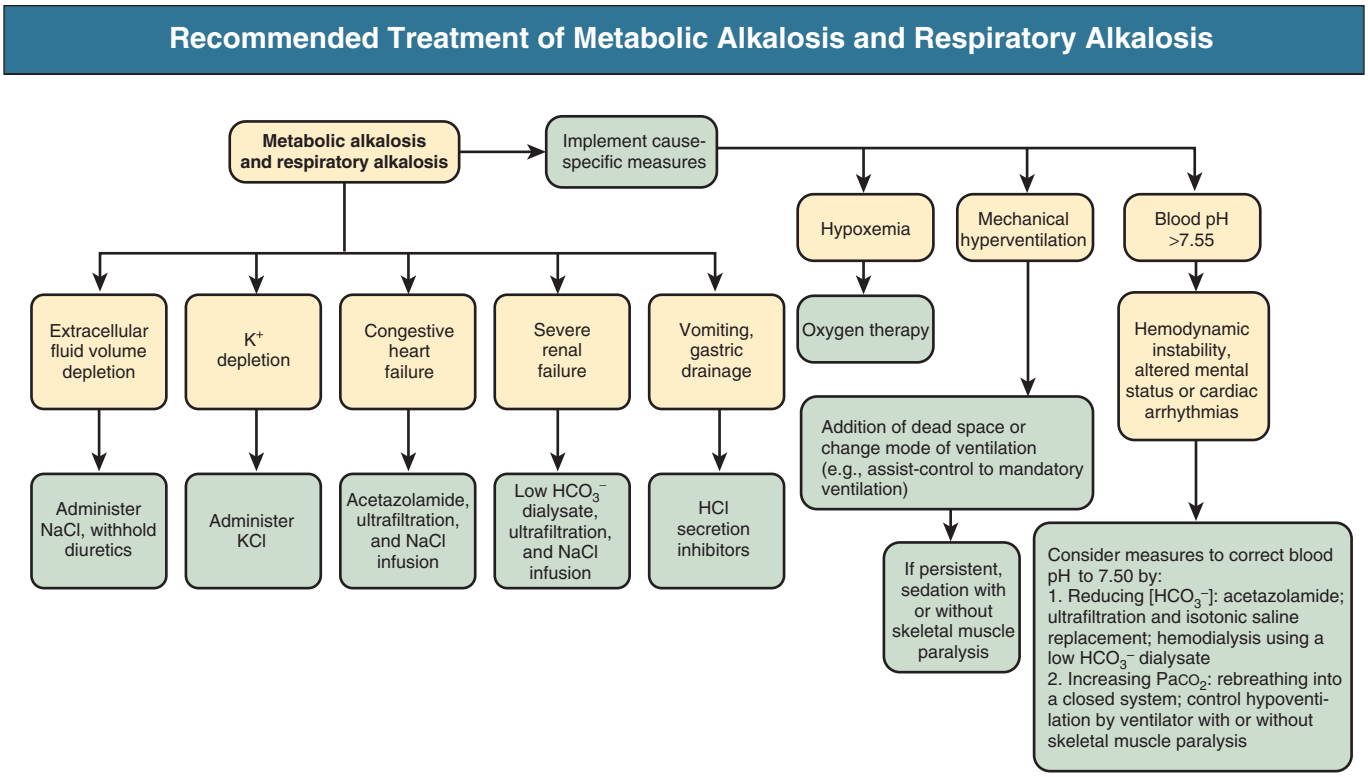

Figure 14-8 **Recommended management of the patient with metabolic alkalosis and respiratory alkalosis.**

by normal or near-normal blood pH; its two components exert offsetting effects on systemic acidity (Fig. 14-10). This disorder is common in intensive care unit patients and is generally associated with high mortality. Causes of the primary hypocapnia include fever, hypotension, gram-negative septicemia, pulmonary edema, hypoxemia, and mechanical hyperventilation. The component of metabolic acidosis in turn might be lactic acidosis (e.g., complicating shock, hepatic failure) or renal acidosis. A considerable fraction of adults and children develop respiratory alkalosis and lactic acidosis in the course of acute severe asthma. In some patients, the lactic acidosis appears to be caused by excessive use of β_2-adrenergic agonists and corticosteroids. The resulting increased ventilatory demands might worsen abnormal lung mechanics and precipitate ventilatory failure.[23,24] Salicylate intoxication is another cause of mixed metabolic acidosis and respiratory alkalosis. Stimulation of the ventilatory center in the brainstem accounts for the respiratory alkalosis, whereas the accelerated production of organic acids, including pyruvic, lactic, and keto acids, and to a lesser extent the accumulation of salicylic acid itself are responsible for the metabolic acidosis.

Metabolic Acidosis and Metabolic Alkalosis

Metabolic acidosis and metabolic alkalosis are typically observed in patients with alcoholic liver disease who develop fasting ketoacidosis or lactic acidosis in conjunction with metabolic alkalosis caused by vomiting, diuretics, or other causes (Table 14-5, examples 2 and 3). Protracted vomiting or nasogastric suction superimposed on uremic acidosis, diabetic ketoacidosis, or metabolic acidosis caused by diarrhea might also generate this offsetting metabolic combination. A similar picture might develop after administration of alkali during CPR or as therapy for diabetic ketoacidosis.

Mixed Metabolic Acidosis

Mixed high anion gap metabolic acidosis in patients with diabetic or alcoholic ketoacidosis may be combined with lactic acidosis resulting from circulatory failure. Uremic patients with associated lactic acidosis or ketoacidosis provide another example of mixed high anion gap acidosis. Mixed hyperchloremic metabolic acidosis is seen in patients with RTA or those receiving carbonic anhydrase inhibitors who also have substantial fecal losses of HCO_3^- caused by severe diarrhea. Mixed hyperchloremic and high anion gap metabolic acidosis occurs in patients with profuse diarrhea whose circulation becomes sufficiently compromised to generate in turn a high anion gap metabolic acidosis, as a result of renal failure or lactic acidosis. Patients with diabetic ketoacidosis whose renal function is maintained at reasonable levels by adequate salt and water intake might develop an element of hyperchloremic metabolic acidosis because of preferential excretion of ketone anions and conservation of Cl^- (Table 14-5, example 1).[25]

Mixed Metabolic Alkalosis

The coexistence of several processes with each contributing to a primary increase in plasma [HCO_3^-], including diuretic therapy, vomiting, mineralocorticoid excess, and severe potassium depletion, will give rise to mixed metabolic alkalosis.

Triple Disorders

The most frequent triple disorders comprise two cardinal metabolic disturbances in conjunction with either respiratory acidosis or respiratory alkalosis, such as severely ill patients with COPD and CO_2 retention who simultaneously develop metabolic alkalosis (usually caused by diuretics and a Cl^--restricted diet) and metabolic acidosis (usually lactic acidosis caused by hypoxemia, hypotension, or sepsis). This type of triple disorder also might be encountered during CPR when an element of metabolic alkalosis caused by alkali administration is superimposed on preexisting respiratory acidosis and metabolic (lactic) acidosis. Patients with respiratory alkalosis caused by advanced congestive heart failure also might have diuretic-induced metabolic alkalosis and lactic acidosis from tissue hypoperfusion.

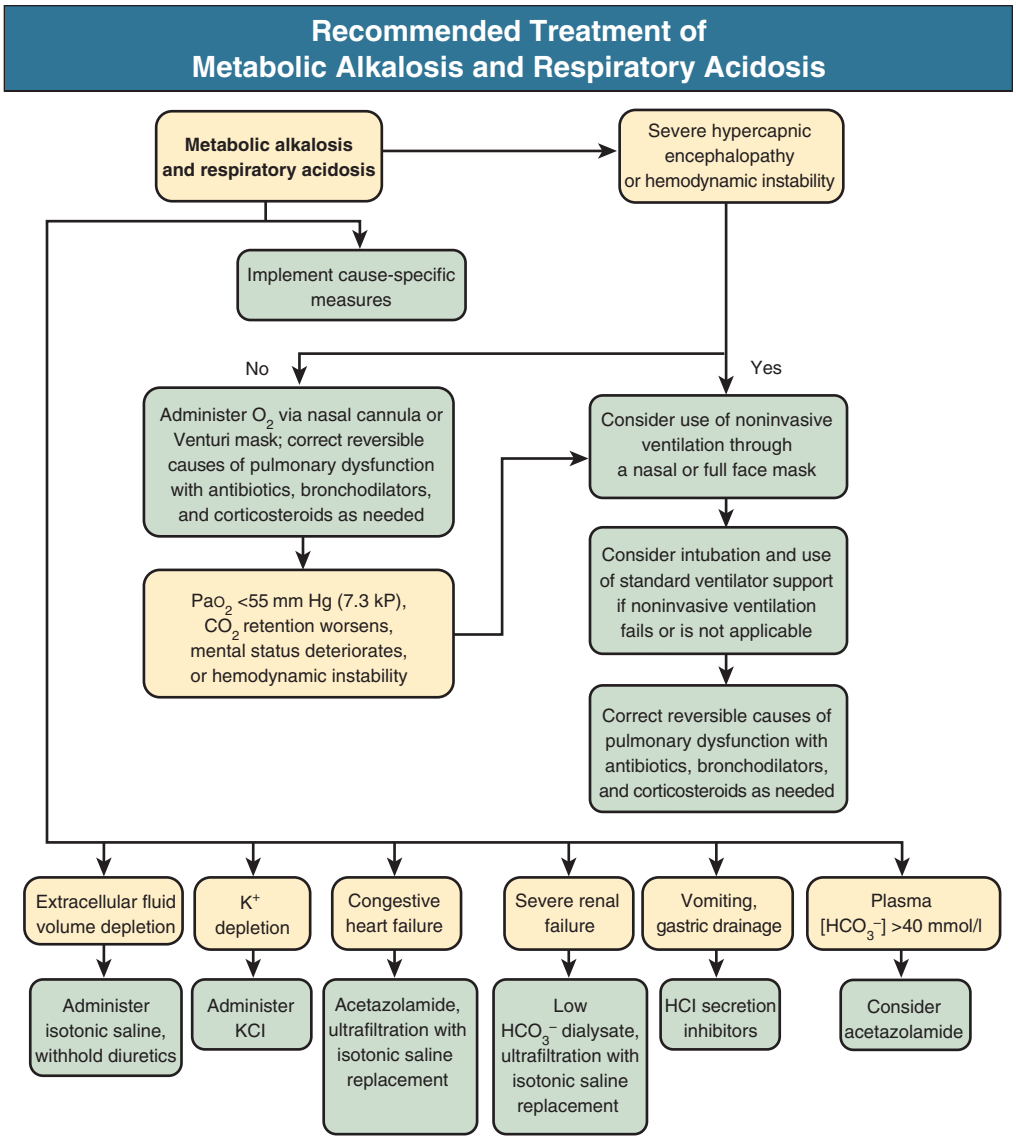

Figure 14-9 Recommended management of the patient with metabolic alkalosis and respiratory acidosis.

Such triple acid-base disorders can also be seen in patients with chronic alcoholism who develop metabolic alkalosis from vomiting, lactic acidosis from volume depletion or ethanol intoxication, and respiratory alkalosis from hepatic encephalopathy or sepsis.

Less common triple disorders encompass two cardinal respiratory disturbances in combination with either metabolic acidosis or metabolic alkalosis. The typical presentation involves critically ill patients with chronic respiratory acidosis who experience an abrupt reduction in $Paco_2$ because of mechanical ventilation and superimposed metabolic acidosis (usually lactic acidosis, reflecting circulatory failure) or metabolic alkalosis (e.g., from gastric fluid loss or diuretics). With superimposed metabolic alkalosis, extreme alkalemia might ensue because of the concomitant presence of hypocapnia and hyperbicarbonatemia. Even more infrequently, this same clinical setting might lead to a quadruple acid-base disorder in which all four cardinal acid-base disturbances coexist.

Clinical Manifestations

The symptoms and signs of the underlying disease that give rise to the observed mixed acid-base disorder dominate the clinical picture, but the development of severe abnormalities in either $Paco_2$ (severe hypocapnia or hypercapnia) or systemic acidity (profound acidemia or alkalemia) might be responsible for the superimposition of additional clinical manifestations. On the one hand, profound hypocapnia might induce obtundation, generalized seizures, and occasionally even coma or death as a result of a critical reduction in cerebral blood flow and other mechanisms. Rarely, angina pectoris also might occur. On the other hand, severe hypercapnia might generate a profound encephalopathy with the classic features of pseudotumor cerebri, including headaches, obtundation, vomiting, and bilateral papilledema, caused by increased ICP. Extreme acidemia results in depression of the central nervous system as well as the cardiovascular system.[7] Reduction in myocardial contractility and peripheral vascular resistance triggered by acidemia might result in severe hypotension. Profound alkalemia might elicit paresthesias, tetany, cardiac dysrhythmias, or generalized seizures.

Diagnosis

The basic principles underlying the diagnosis of mixed acid-base disorders are identical to those required for the identification of simple acid-base disturbances. These include assessment of the accuracy of the acid-base data by ensuring that the available values

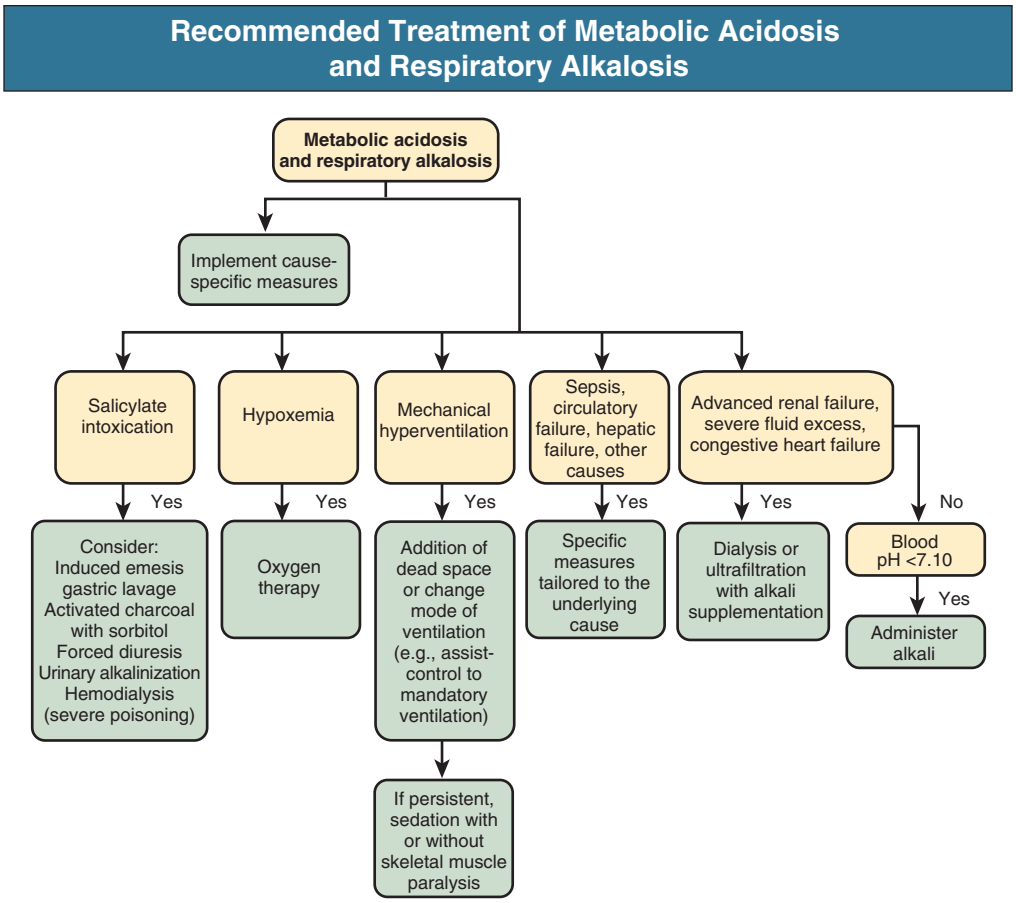

Figure 14-10 Recommended management of the patient with metabolic acidosis and respiratory alkalosis.

Blood Parameters in Diagnosis of Mixed Metabolic Acid-Base Disorders

Blood Composition	Normal	High Anion Gap Acidosis	High Anion Gap and Normal Anion Gap Acidosis	Metabolic Alkalosis	High Anion Gap Acidosis and Metabolic Alkalosis
pH	7.40	7.29	7.10	7.50	7.38
$Paco_2$ (mm Hg)	40	30	20	45	35
Bicarbonate (mmol/l)	24	14	6	34	20
Anion gap (mmol/l)	10	20	20	12	26
ΔBicarbonate	0	−10	−18	+10	−4
ΔAnion gap	0	+10	+10	+2	+16

Table 14-6 Blood parameters in diagnosis of patients with mixed metabolic acid-base disorders.

for pH, $Paco_2$, and plasma [HCO_3^-] satisfy the mathematical constraints of the Henderson-Hasselbalch equation; a careful history and performance of a complete physical examination; analysis of the plasma anion gap and other ancillary laboratory data; and knowledge of the quantitative aspects of the adaptive response to each of the four simple acid-base disturbances. Adherence to these principles cannot be overemphasized. Even experienced clinicians risk misdiagnosis of the prevailing acid-base status by bypassing this systematic approach.[3]

Normality of the acid-base parameters is not in itself sufficient for diagnosis of normal acid-base status; indeed, normal acid-base values might be the fortuitous result of mixed acid-base disorders (e.g., high anion gap acidosis treated with alkali infusion, diarrhea-induced metabolic acidosis in conjunction with vomiting-induced metabolic alkalosis). A given set of acid-base parameters is never diagnostic of a particular acid-base disorder, whether it is simple or mixed in nature; rather, it is consistent with a range of acid-base abnormalities. What on the surface appears to be a clear-cut simple acid-base disorder might actually reflect the interplay of a number of coexisting acid-base disturbances. The patient history and physical examination frequently provide important insights into the prevailing acid-base status as well as useful clues to the differential diagnosis.

A critical component of the diagnostic process is the examination of the plasma anion gap (Table 14-6). This derived parameter provides important insights into the nature of the prevailing changes in plasma [HCO_3^-]. An elevated plasma anion gap might offer the first clue to the presence of disordered acid-base status despite

normal acid-base parameters. With a plasma HCO_3^- concentration deficit ($\Delta[HCO_3^-]_p$), a normal or subnormal value for the plasma anion gap denotes that the entire decrease in HCO_3^- can be attributed to acidifying processes resulting in the loss of alkali (e.g., diarrhea, RTA) or to respiratory alkalosis. By comparison, with a high anion gap metabolic acidosis, there is usually a close reciprocal stoichiometry between the decrease in serum HCO_3^- and the increase in the anion gap, termed the Δ(anion gap). A reduction in serum HCO_3^- of 10 mmol/l is therefore associated with a Δ(anion gap) of 10 mmol/l. Addition of the value for the Δ(anion gap) to the prevailing level of serum HCO_3^- allows the derivation of the basal value of HCO_3^- existing before the development of the high anion gap metabolic acidosis. Appreciation of this reciprocal relationship between the $\Delta[HCO_3^-]_p$ and the Δ(anion gap) is important in distinguishing between a pure high anion gap metabolic acidosis and a mixed high and normal anion gap metabolic acidosis and in detecting a mixed high anion gap metabolic acidosis and metabolic alkalosis. Additional diagnostic insights are often obtained by examination of other laboratory data, including the serum potassium, glucose, urea nitrogen, and creatinine concentrations; semiquantitative measures for ketonemia or ketonuria; screening of blood or urine for toxins; and estimation of the serum osmolar gap.

Mild acid-base disorders pose particular diagnostic difficulty because of the overlap of values for the simple disturbances near the normal range. In such patients, any of several simple disorders or a variety of mixed disturbances might fully account for the acid-base data under evaluation. Again, careful correlation of all available clinical information should guide the diagnostic process.

Treatment

The management of mixed acid-base disturbances is aimed at restoration of the altered acid-base status by treatment of each simple acid-base disorder involved.[1,2,20,26] Figures 14-7 to 14-10 provide recommendations for treatment of patients with some common mixed acid-base disturbances.

Given the variable response time to therapy of the individual components, it is crucial to be aware of the effect that graded correction might have on systemic acidity. The asynchronous reversal of the individual components might be used at times to therapeutic advantage; on other occasions, such a practice might prove catastrophic. For example, extreme acidemia caused by metabolic acidosis and respiratory acidosis, or extreme alkalemia caused by metabolic alkalosis and respiratory alkalosis, might be safely corrected by a rapid return of $Paco_2$ toward normal. By comparison, an asynchronous return of $Paco_2$ to normal in a patient with profound metabolic acidosis and superimposed respiratory alkalosis might prove disastrous. Similarly, extreme caution should be exercised in treating patients with respiratory acidosis and metabolic alkalosis, one of the most common mixed acid-base disorders. Although therapeutic measures intended to improve alveolar ventilation should be instituted, an abrupt decrease in $Paco_2$ risks development of severe alkalemia. Therefore, aggressive measures should be taken to treat metabolic alkalosis, making certain that reversal of the metabolic component does not lag behind treatment of the respiratory element. In fact, because the ventilatory drive in patients with chronic respiratory acidosis depends in part on the prevailing acidemia, reversal of a complicating element of metabolic alkalosis regularly results in improved alveolar ventilation, thus achieving a decrease in $Paco_2$ and an increase in Pao_2.

SECTION IV

Glomerular Disease

CHAPTER 15

Introduction to Glomerular Disease: Clinical Presentations

Jürgen Floege and John Feehally

DEFINITION

Glomerular disease has clinical presentations that vary from the asymptomatic individual who is found to have hypertension, edema, hematuria, or proteinuria at a routine medical assessment to a patient who has fulminant illness with acute kidney injury possibly associated with life-threatening extrarenal disease (Fig. 15-1). The most dramatic symptomatic presentations are uncommon. Asymptomatic urine abnormalities are much more common, but less specific, and may also indicate a wide range of nonglomerular urinary tract disease.

CLINICAL EVALUATION OF GLOMERULAR DISEASE

The history, physical examination, and investigations are aimed at excluding nonglomerular disease, finding evidence of associated multisystem disease, and establishing renal function.

History

The majority of glomerular diseases do not lead to symptoms that patients will report. However, specific questioning may reveal edema, hypertension, foamy urine, or urinary abnormalities during prior routine testing (e.g., during scheduled medical examinations). Multisystem diseases associated with glomerular disease include diabetes, hypertension, amyloid, lupus, and vasculitis. Apart from the individual history suggestive of these diseases, a positive family history may also be obtained in some cases. Other causes of familial renal disease may include Alport syndrome, especially if associated with hearing loss (see Chapter 48); uncommon familial forms of IgA nephropathy (see Chapter 23); focal segmental glomerulosclerosis (FSGS; see Chapters 18 and 19); complement-mediated glomerulonephritis (see Chapter 22); hemolytic uremic syndrome (HUS; see Chapter 29); and other rare conditions (see Chapter 28). Morbid obesity can be associated with FSGS. Certain drugs and toxins may cause glomerular disease, including nonsteroidal anti-inflammatory agents (NSAIDs) and interferon in minimal change disease (MCD); penicillamine, NSAIDs, and mercury (e.g., in skin-lightening creams) in membranous nephropathy; pamidronate and heroin in FSGS; and cyclosporine, tacrolimus, mitomycin C, and oral contraceptives in HUS. Recent or persistent infection, especially streptococcal infection, infective endocarditis, and certain viral infections (see Chapters 21, 57, and 58), may also be associated with a variety of glomerular diseases.

Malignant neoplasms associated with glomerular disease include lung, breast, and gastrointestinal (GI) carcinoma in membranous nephropathy; Hodgkin disease in MCD; non-Hodgkin lymphoma in membranoproliferative glomerulonephritis; and renal carcinoma in amyloid disease (see Chapter 27). Patients will occasionally present with the renal disease as the first manifestation of a tumor.

Physical Examination

The presence of dependent pitting edema suggests the nephrotic syndrome, heart failure, or cirrhosis. In the nephrotic patient, edema is often periorbital in the morning (Fig. 15-2), whereas the face is not affected overnight in edema associated with heart failure (edema distributes by gravity, and patient with heart failure cannot lie flat because of orthopnea resulting from pulmonary congestion) or cirrhosis (patient cannot lie flat because of pressure on the diaphragm from ascites). As it progresses, edema of genitals and abdominal wall becomes apparent, and accumulation of fluid in body spaces leads to ascites and pleural effusions. Edema is unpleasant, leading to feelings of tightness in the limbs and a bloated abdomen, with practical problems of clothes and shoes no longer fitting. Surprisingly, however, edema may become massive in nephrotic syndrome before patients seek medical help; fluid gains of 20 kg (44 lb) or more are not unusual (Fig. 15-3). The edema becomes firm and stops pitting only when it is longstanding. In children, fluid retention may also be striking with nephritic syndrome. Chronic hypoalbuminemia is also associated with loss of normal pink color under the nails, resulting in white nails or white bands if the nephrotic syndrome is transient (Muehrcke lines, Fig. 15-4). Xanthelasmas may also be present as a result of the hyperlipidemia associated with longstanding nephrotic syndrome (Fig. 15-5).

The presence of pulmonary signs should suggest one of the pulmonary-renal syndromes (see Boxes 24-3 and 24-4). Palpable purpura may be seen in vasculitis, systemic lupus, cryoglobulinemia, or endocarditis.

Laboratory Studies

Assessment of renal function and careful examination of the urine are critical (see Chapters 3 and 4). The quantity of urine protein and the presence or absence of dysmorphic red cells and casts will help classify the clinical presentation (see Fig. 15-1).

Certain serologic tests are also helpful. These include antinuclear and anti-DNA antibodies for lupus, cryoglobulins and rheumatoid factor suggesting cryoglobulinemia, anti–glomerular basement membrane (anti-GBM) antibodies for Goodpasture disease, antineutrophil cytoplasmic autoantibody (ANCA) for vasculitis, and antistreptolysin O titer or streptozyme test for poststreptococcal glomerulonephritis. Serum and urine electrophoresis will detect monoclonal light chains or heavy chains and assays for free light chains in serum or urine may aid in their quantification, as in myeloma-associated amyloid or light-chain deposition disease.

Testing for the presence of ongoing bacterial or viral infections is also useful. This includes blood cultures and testing for hepatitis

B, hepatitis C, and human immunodeficiency virus (HIV) infection.

Measurement of systemic complement pathway activation by testing for serum C3, C4, and CH50 (50% hemolyzing dose of complement) is often helpful in limiting the differential diagnosis (Table 15-1).

The emerging role for genetic evaluation in patients with glomerulonephritis (GN) is discussed in Chapters 19 and 22.

Imaging

Ultrasound scanning is recommended in the workup to ensure the presence of two kidneys, to rule out obstruction or anatomic abnormalities, and to assess kidney size. Renal size is often normal in GN,

Hypocomplementemia in Glomerular Disease			
Pathways Affected	**Complement Changes**	**Glomerular Disease**	**Nonglomerular Disease**

	Hereditary C2 or C4 deficiency Factor H deficiency	Lupus nephritis Familial HUS Dense deposit disease	

Table 15-1 Hypocomplementemia in glomerular disease. *Glomerulonephritis *(GN)* with visceral abscesses is generally associated with normal or increased complement (elevations occur because complement components are acute-phase reactants). *CH50,* 50% Hemolyzing dose of complement; *HUS,* hemolytic uremic syndrome.

although large kidneys (>14 cm) are sometimes seen in nephrotic syndrome associated with diabetes, amyloid disease, or HIV infection. Large kidneys can also occasionally be seen with any acute severe GN. The occurrence of small kidneys (<9 cm) suggests advanced chronic kidney disease (CKD) and should limit enthusiasm for renal biopsy or aggressive immunosuppressive therapies.

Renal Biopsy

Renal biopsy is generally required to establish the type of glomerular disease and to guide treatment decisions (see Chapter 6). In some patients, however, renal biopsy is not performed. If nephrotic children have no unusual clinical features, the probability of MCD is so high that corticosteroids can be initiated without biopsy (see Chapter 17). In patients with acute nephritic syndrome, if all features point to poststreptococcal GN, especially in an epidemic, biopsy can be reserved for the minority who do not show early spontaneous improvement (see Chapter 57). In Goodpasture disease (see Chapter 24), the presence of lung hemorrhage and rapidly progressive renal failure with urinary red cell casts and high levels of circulating anti-GBM antibody establishes the diagnosis without the need for a biopsy, although a biopsy may still provide valuable prognostic information. In patients with systemic features of vasculitis, a positive ANCA titer, negative blood cultures, and a tissue biopsy specimen from another site showing vasculitis are sufficient to secure a diagnosis of renal vasculitis. Again, however, renal biopsy may provide important clues to disease activity and chronicity. Biopsy is also not generally performed in patients with longstanding diabetes with characteristic findings suggestive of diabetic nephropathy and other evidence of microvascular complications of diabetes (see Chapter 30). Biopsy may also not be indicated in many patients with glomerular disease presenting with minor, asymptomatic urine abnormalities and well-preserved renal function because the prognosis is excellent, and histologic findings will not alter management.

ASYMPTOMATIC URINE ABNORMALITIES

Urine testing that detects proteinuria or microhematuria is often the first evidence of glomerular disease. The random nature of urine testing in most communities inevitably means that much mild glomerular disease remains undetected. In some countries, symptomless individuals may have a urine test only if they require medical approval for some key life event, such as obtaining life insurance, joining the armed forces, or sometimes for employment purposes. In other countries, for example, Japan, urinalysis is performed routinely in school or for employment. These different practices may partly account for the apparently variable incidence of certain diseases, such as IgA nephropathy. Asymptomatic low-grade proteinuria and microhematuria and the combination of the two, increase in prevalence with age[1] (Fig. 15-6). Nevertheless, there is no evidence to justify routine population-wide screening for asymptomatic urine abnormalities as renal biopsy and therapeutic intervention are rarely required when renal function is preserved. Screening, in particular for microalbuminuria, may be indicated for high-risk populations, for example, patients with diabetes, hypertension, or cardiovascular disease, and those with a family history of renal disease.

Asymptomatic Microhematuria

Microhematuria is defined as the presence of more than two red blood cells (RBCs) per high-power field in a spun urine sediment (3000 rpm for 5 minutes) or more than 10×10^6 RBCs/l. Microhematuria is common in many glomerular diseases, especially IgA nephropathy and thin basement membrane nephropathy, although there are many other causes of hematuria (see Chapter 48). A glomerular origin should especially be considered if more than 5% of RBCs are acanthocytes (see Chapter 4) or if the hematuria is accompanied by RBC casts or proteinuria (Fig. 15-7).

Pathogenesis

Glomerular hematuria is thought to result from small breaks in the glomerular basement membrane that allow extravasation of RBCs into the urinary space. This may occur in the peripheral capillary wall but more often occurs in the paramesangial basement membrane, particularly in diseases involving injury to the mesangium (mesangiolysis). As long as the renal tubules are intact, low amounts of serum proteins lost together with RBCs in damaged glomeruli can be fully reabsorbed, resulting in "isolated" microhematuria.

Evaluation

The evaluation of microhematuria, discussed further in Chapters 48 and 61, begins with a thorough history. Urine culture should exclude urinary or prostatic infection. Phase contrast microscopy should follow in cases of persistent microhematuria to search for dysmorphic RBCs and RBC casts. In the absence of urine infection or a

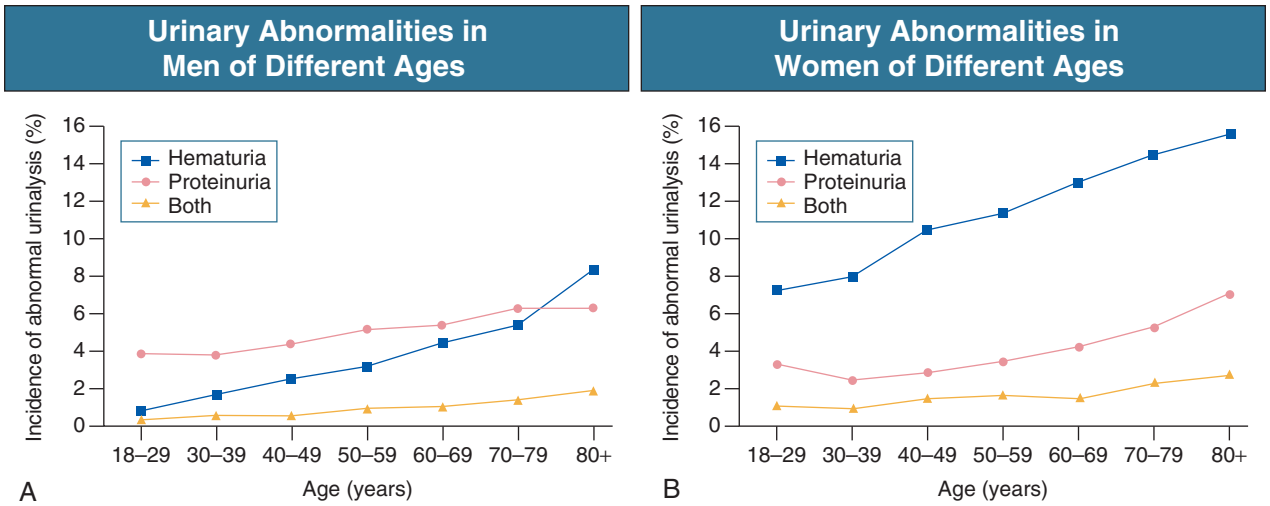

Figure 15-6 Prevalence of asymptomatic proteinuria and hematuria with age. Mass screening of a population of 107,192 adult men (**A**) and women (**B**) in Okinawa, Japan. Hematuria is more common in women. *(Modified from reference 1.)*

Figure 15-7 Red blood cell cast. An RBC cast typical of glomerular hematuria.

bladder catheter, any detectable proteinuria in the patient with asymptomatic microhematuria virtually excludes "urologic" bleeding and strongly suggests a glomerular origin. If this evaluation is nondiagnostic, renal imaging is performed to exclude anatomic lesions such as stones, tumors, polycystic kidneys, or arteriovenous malformations.

In those older than 40 years who have persistent isolated microhematuria without evidence of a glomerular origin (see previous discussion), cystoscopy is mandatory to exclude uroepithelial malignant disease. In people younger than 40 years, such malignant disease is so rare that cystoscopy is not recommended. If all the prior study results are normal, a glomerular etiology is likely.[2] The glomerular etiology can be determined only by renal biopsy, but this is rarely done because the prognosis is excellent in patients with normal renal function, normal blood pressure, and low-grade proteinuria (<0.5 g/day). However, repeated evaluation and prolonged follow-up are mandatory.

Asymptomatic Non-nephrotic Proteinuria

The hallmark of glomerular disease is the excretion of protein in the urine. Normal urine protein excretion is less than 150 mg/24 h, consisting of 20 to 30 mg of albumin, 10 to 20 mg of low-molecular-weight proteins that undergo glomerular filtration, and 40 to 60 mg of secreted proteins (e.g., Tamm-Horsfall, IgA). Proteinuria is identified and quantified by dipstick testing or by assay in timed urine collections; Chapter 4 discusses test interpretation.

Microalbuminuria is defined as the excretion of 30 to 300 mg of albumin per day, equivalent to a urine albumin to creatinine (g/g) ratio of 0.03 to 0.3, and is detected by quantitative immunoassay or by special urine dipsticks because this is below the sensitivity of the normal dipstick (see Chapter 30). This measurement is primarily used to identify diabetic subjects at risk for development of nephropathy and to assess cardiovascular risk, for example, in patients with hypertension.

Non-nephrotic proteinuria is usually defined as a urine protein excretion of less than 3.5 g/24 h or a urine protein-creatinine ratio of less than 3 g/g. Whereas nephrotic-range proteinuria is absolutely characteristic of glomerular disease, asymptomatic proteinuria (<3.5 g/24 h) is much less specific and may occur with a wide range of nonglomerular parenchymal diseases as well as with nonparenchymal renal and urinary tract conditions that must be excluded by clinical evaluation and investigation.

Increased urine protein excretion may result from alterations in glomerular permeability or tubulointerstitial disease, although only in glomerular disease will it be in the nephrotic range. Protein excretion can also increase from increased filtration through normal glomeruli (overflow proteinuria).

Overflow Proteinuria

Overflow proteinuria is typical of urinary light-chain excretion. It is seen in myeloma but can occur in other settings (e.g., release of lysozyme by leukemic cells) and should be suspected when the urine dipstick is negative for albumin despite detection of large amounts of proteinuria by other tests.

Tubular Proteinuria

Tubulointerstitial disease can be associated with low-grade proteinuria (usually <2 g/day). In addition to the loss of tubular proteins such as α_1- or β_2-microglobulin, there will also be some albuminuria due to impaired tubular reabsorption of filtered albumin. Tubular proteinuria accompanying glomerular proteinuria is an adverse prognostic sign in various glomerular diseases because it usually indicates advanced tubulointerstitial damage.

Glomerular Proteinuria

Glomerular proteinuria is further classified into transient or hemodynamic (functional), that present only during the day (orthostatic), and persistent or fixed.

Functional Proteinuria Functional proteinuria refers to the transient non-nephrotic proteinuria that can occur with fever, exercise, heart failure, and hyperadrenergic or hyperreninemic states. Functional proteinuria is benign, usually assumed to be hemodynamic in origin and the result of increases in single-nephron flow or pressure.

Orthostatic Proteinuria In children and young adults, low-grade glomerular proteinuria may be orthostatic, meaning that proteinuria is absent when urine is generated in the recumbent position. If there is no proteinuria in early-morning urine, the diagnosis of orthostatic proteinuria can be made. In patients with fixed orthostatic proteinuria, renal plasma flow and glomerular filtration rate (GFR) decrease in the upright position because of a lower systemic blood pressure. As recently proposed, the decreased GFR translates into a lower *streaming potential* across the filtration barrier, and albumin can no longer be excluded as efficiently from the filter by electrophoresis.[3]

Total urine protein in the patient with orthostatic proteinuria is usually less than 1 g/24 h; hematuria and hypertension are absent. Renal biopsy usually shows normal morphology or occasionally mild glomerular change. The prognosis is uniformly good, and renal biopsy is not indicated.[4]

Fixed Non-nephrotic Proteinuria Fixed non-nephrotic proteinuria is usually caused by glomerular disease. If GFR is preserved and proteinuria is less than 0.5 to 1 g/day, biopsy is not indicated but prolonged follow-up is necessary if significant proteinuria persists, to rule out the possibility of disease progression. Previous studies indicate that the biopsy findings in these patients can be similar to those seen in nephrotic syndrome (e.g., FSGS or membranous GN), although milder lesions are more common, particularly mesangial proliferative GN or IgA nephropathy. In general, other than regular monitoring and blood pressure control as needed, no treatment is necessary.

Although it is controversial, many nephrologists will perform a renal biopsy in patients with normal GFR if non-nephrotic proteinuria exceeds 1 g/day, in particular if it persists after initiation of angiotensin-converting enzyme (ACE) inhibitor or angiotensin receptor blocker (ARB) therapy.

Figure 15-8 summarizes the evaluation of isolated asymptomatic proteinuria.

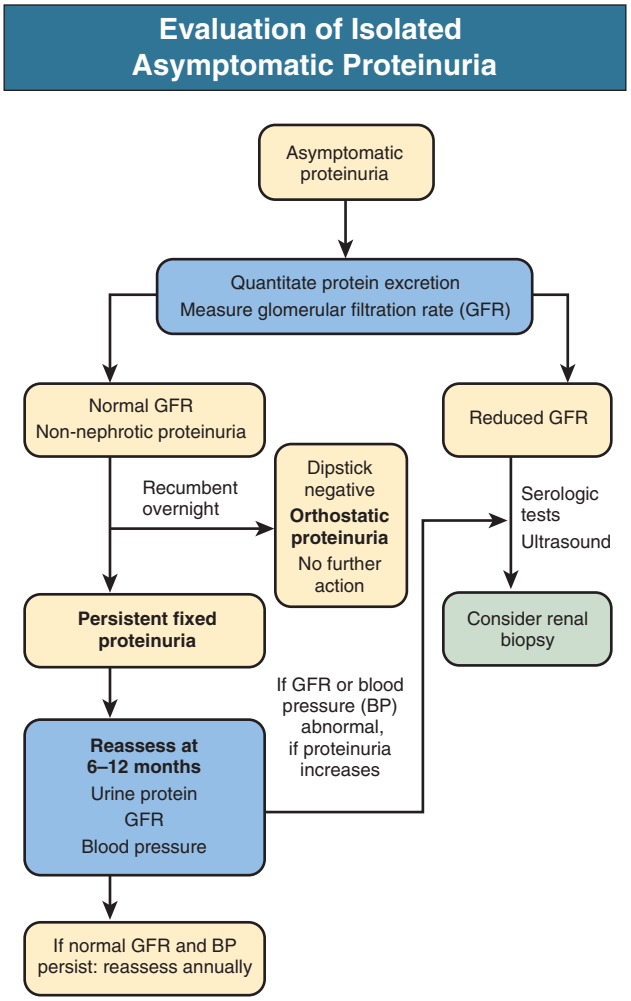

Figure 15-8 Evaluation of patients with isolated asymptomatic proteinuria.

Asymptomatic Proteinuria with Hematuria

Patients with coincident asymptomatic hematuria and proteinuria have a much greater risk of significant glomerular injury, hypertension, and progressive renal dysfunction. Minor histologic changes are less common. Renal biopsy is indicated even if urine protein is only 0.5 to 1 g/24 h if there is also persistent microhematuria with casts.

MACROHEMATURIA

Episodic painless macrohematuria associated with glomerular disease is often brown or "smoky" rather than red, and clots are unusual. Macrohematuria must be distinguished from other causes of red or brown urine, including hemoglobinuria, myoglobinuria, porphyrias, consumption of food dyes (particularly beetroot), and intake of drugs (especially rifampin).

Macrohematuria caused by glomerular disease is observed primarily in children and young adults and rarely is seen after age 40. Most cases are caused by IgA nephropathy, but hematuria may occur with other glomerular and nonglomerular renal diseases, including acute interstitial nephritis. Although macrohematuria is typically painless, the patient may have an accompanying dull loin ache that suggests other diagnoses, such as stone disease or loin-pain hematuria syndrome. In IgA nephropathy, the frank hematuria is usually episodic, occurring within a day of an upper respiratory infection. The clear distinction between this history and the 2- to 3-week latency between an upper respiratory tract infection and hematuria is highly suggestive of postinfectious (usually poststreptococcal) GN; furthermore, patients with poststreptococcal disease usually will have other features of nephritic syndrome.

Macrohematuria requires urologic evaluation, including cystoscopy, at any age unless the history (as shown previously) is characteristic of glomerular hematuria.

NEPHROTIC SYNDROME

Definition

Nephrotic syndrome is pathognomonic of glomerular disease. It is a clinical syndrome with a characteristic pentad[5] (see Fig. 15-1). Patients may be nephrotic with preserved renal function, but in

many, progressive renal failure will become superimposed when nephrotic syndrome is prolonged.

Independent of the risk of progressive renal failure, the nephrotic syndrome has far-reaching metabolic effects that can influence the general health of the patient. Fortunately, some episodes of nephrotic syndrome are self-limited, and a few patients respond completely to specific treatment (e.g., corticosteroids in MCD). For most patients, however, it is a relapsing or chronic condition. Not all patients with proteinuria above 3.5 g/24 h will have a full nephrotic syndrome; some have a normal serum albumin concentration and no edema. This difference presumably reflects the varied response of protein metabolism; some patients sustain an increase in albumin synthesis in response to heavy proteinuria that may even normalize serum albumin.

Etiology

Table 15-2 shows the major causes of nephrotic syndrome. Proteinuria in the nephrotic range in the absence of edema and hypoalbuminemia has similar etiologies. The relative frequency of the different glomerular diseases varies with age (Table 15-3). Although it is predominant in childhood, MCD remains common at all ages.[6] Prevalence of FSGS in African Americans has increased, which may explain why FSGS is becoming more common in U.S. adults but not in European adults.[7,8]

Hypoalbuminemia

Hypoalbuminemia is mostly a consequence of urinary losses. The liver responds by increasing albumin synthesis, but this compensatory mechanism appears to be blunted in nephrotic syndrome.[9] The end result is that serum albumin falls further. White bands in the nails (Muehrcke lines) are a characteristic clinical sign of hypoalbuminemia (see Fig. 15-4). The increase in protein synthesis in response to proteinuria is not discriminating; as a result, proteins not being lost in the urine may actually increase in concentration in plasma. This is chiefly determined by molecular weight; large molecules will not spill into the urine and will increase in the plasma, whereas smaller proteins, although synthesized to excess, will enter the urine and will decrease in the plasma. These variations in plasma proteins

Common Glomerular Diseases Presenting as Nephrotic Syndrome in Adults

Disease	Associations	Serologic Tests
Minimal change disease (MCD)	Allergy, atopy, NSAIDs, Hodgkin disease	None
Focal segmental glomerulosclerosis (FSGS)	African Americans HIV infection Heroin, pamidronate	— HIV antibody —
Membranous nephropathy (MN)	Idiopathic drugs: gold, penicillamine, NSAIDs Infections: hepatitis B and C; malaria Lupus nephritis Malignancy: breast, lung, gastrointestinal tract	Anti-PLA_2R antibody Hepatitis B surface antigen, anti–hepatitis C virus antibody Anti-DNA antibody —
Membranoproliferative glomerulonephritis (MPGN) type I	C4 nephritic factor	C3 ↓, C4 ↓
Dense deposit disease (MPGN type II)	C3 nephritic factor	C3 ↓, C4 normal
Cryoglobulinemic MPGN	Hepatitis C	Anti–hepatitis C virus antibody, rheumatoid factor, C3 ↓, C4 ↓, CH50 ↓
Amyloid disease	Myeloma Rheumatoid arthritis, bronchiectasis, Crohn disease (and other chronic inflammatory conditions), familial Mediterranean fever	Plasma free light chains Serum protein electrophoresis, urine immunoelectrophoresis C-reactive protein
Diabetic nephropathy	Other diabetic microangiopathy	None

Table 15-3 Age-related variations in nephrotic syndrome. *(Data modified from references 6 and 7.)*

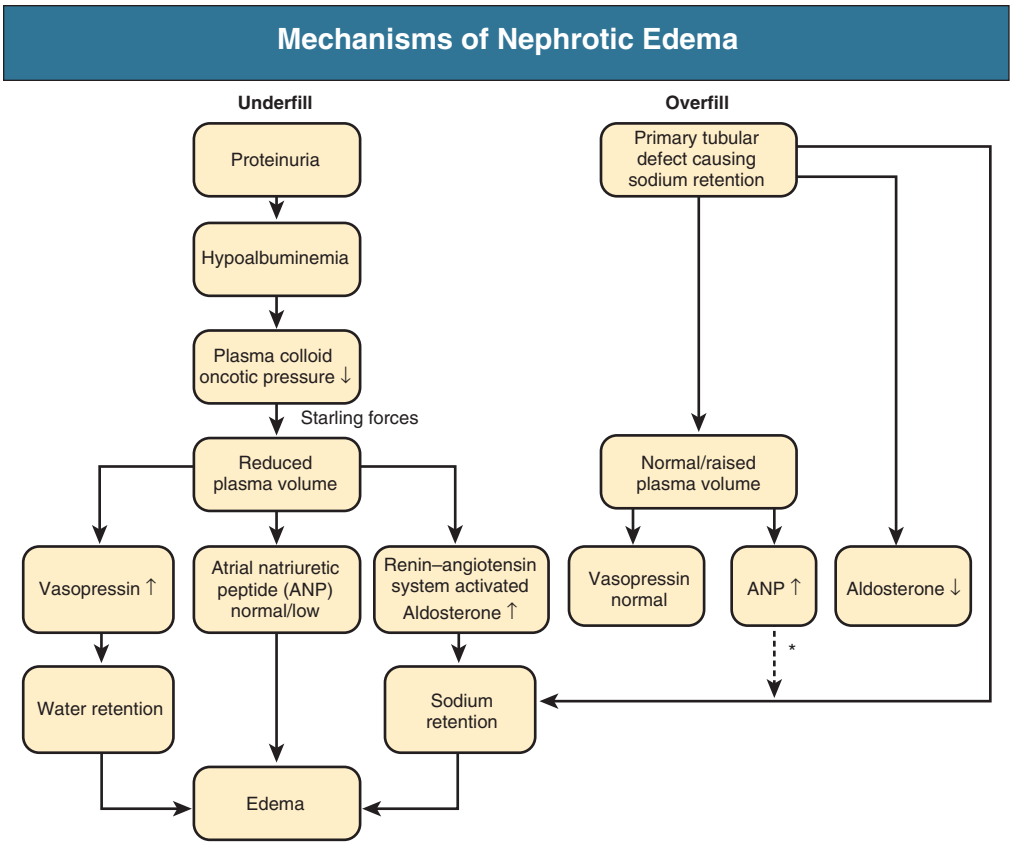

Figure 15-9 Mechanisms of nephrotic edema.* The kidney is relatively resistant to ANP in this setting, so ANP has little effect in countering sodium retention.

are clinically important in two areas, hypercoagulability and hyperlipidemia (see later discussion).

Edema

At least two major mechanisms are involved in the formation of nephrotic edema, underfill and overfill[10] (Fig. 15-9; see Chapter 7). In the first mechanism, which is more common in children with MCD, the edema appears to result from the low serum albumin, producing a decrease in plasma oncotic pressure, which allows increased transudation of fluid from capillary beds into the extracellular space according to the laws of Starling. The consequent decrease in circulating blood volume *(underfill)* produces a secondary stimulation of the renin-angiotensin system (RAS), resulting in aldosterone-induced sodium retention in the distal tubule. This attempt to compensate for hypovolemia merely aggravates edema because the low oncotic pressure alters the balance of forces across the capillary wall in favor of hydrostatic pressure, forcing more fluid into the interstitial space rather than retaining it within the vascular compartment.

Many nephrotic patients, however, appear to have a primary defect in the ability of the distal nephron to excrete sodium, possibly related to activation of the epithelial sodium channel (ENaC) by proteolytic enzymes that enter the tubular lumen in heavy proteinuria.[11] As a result, there is an increased blood volume; suppression of renin, angiotensin, and vasopressin; and a tendency to hypertension rather than to hypotension. The kidney is also relatively resistant to the actions of atrial natriuretic peptide. An elevated blood volume results *(overfill),* which, in association with the low plasma oncotic pressure, provokes transudation of fluid into the extracellular space and edema. The mechanism for the defect in sodium excretion remains unknown, although it has been hypothesized that inflammatory leukocytes in the interstitium, which are found in many glomerular diseases, may impair sodium excretion by producing angiotensin II and oxidants (oxidants inactivate local nitric oxide, which is natriuretic).[12]

Metabolic Consequences of Nephrotic Syndrome

Negative Nitrogen Balance

The heavy proteinuria leads to marked negative nitrogen balance, usually measured in clinical practice by serum albumin. Nephrotic syndrome is a wasting illness, but the degree of muscle loss is masked by edema and is not fully apparent until the patient is rendered edema free. Loss of 10% to 20% of lean body mass can occur. Albumin turnover is increased in response to the tubular catabolism of filtered protein rather than merely to urinary protein loss. Increasing protein intake does not improve albumin metabolism because the hemodynamic response to an increased intake is a rise in glomerular pressure, increasing urine protein losses. A low-protein diet in turn will reduce proteinuria, but also reduces the albumin synthesis rate and in the longer term may increase the risk of a worsening negative nitrogen balance.

Hypercoagulability

Multiple proteins of the coagulation cascade have altered levels in nephrotic syndrome; in addition, platelet aggregation is enhanced.[13] The net effect is a hypercoagulable state that is enhanced further by immobility, coincidental infection, and hemoconcentration if the patient has a contracted plasma volume (Fig. 15-10). Not only is venous thromboembolism common at any site, but spontaneous arterial thrombosis may occur. Arterial thrombosis may occur in adults in the context of atheroma, promoting coronary and

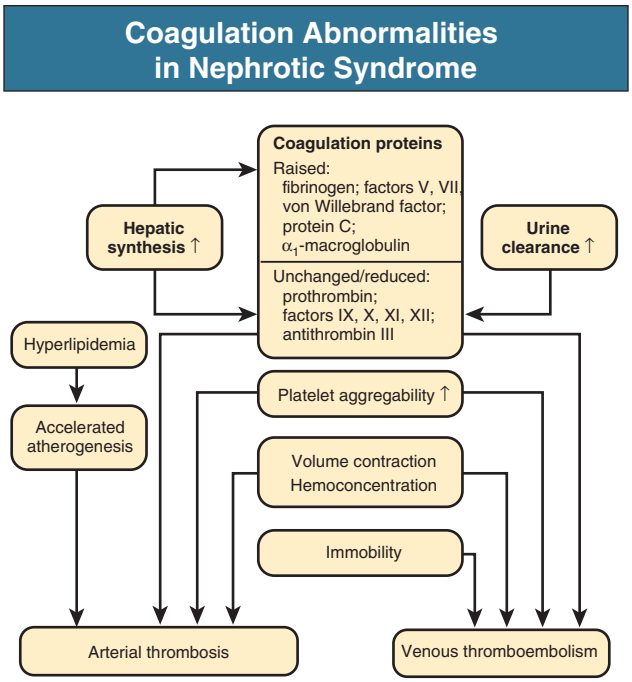

Figure 15-10 **Coagulation abnormalities in nephrotic syndrome.**

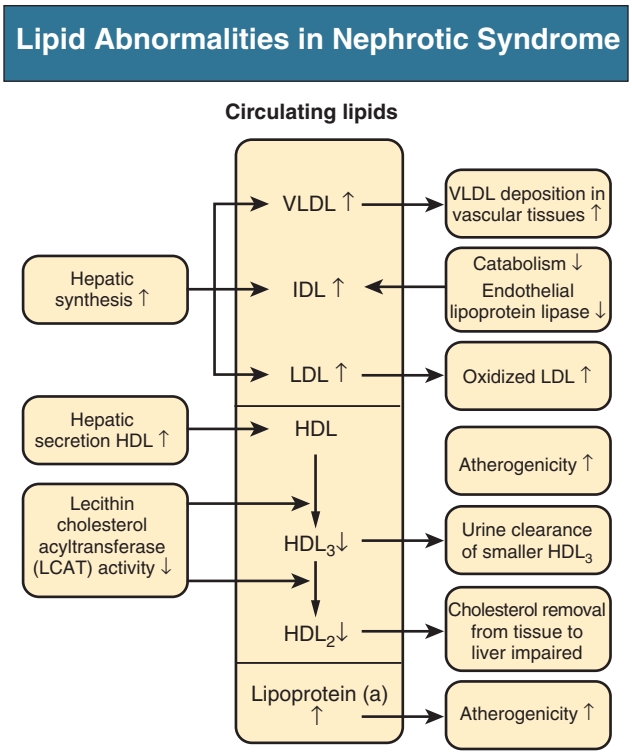

Figure 15-11 **Lipid abnormalities in nephrotic syndrome.** Changes in high-density lipoprotein *(HDL)* are more controversial than those in very-low-density lipoprotein *(VLDL)*. *IDL,* Intermediate-density lipoprotein; *LDL,* low-density lipoprotein.

cerebrovascular events in particular, but it also occurs in nephrotic children, in whom spontaneous thrombosis of major limb arteries is an uncommon but feared complication. Up to 10% of nephrotic adults and 2% of children will have a clinical episode of thromboembolism. For unexplained reasons, the risk appears particularly high in those with membranous nephropathy.[14] Individual levels of coagulation proteins are not helpful in assessing the risk of thromboembolism, and serum albumin is mostly used as a surrogate marker. Thromboembolic events increase greatly if the serum albumin concentration decreases to less than 2 g/dl.

The hypoproteinemia and dysproteinemia produce a marked increase in erythrocyte sedimentation rate, and ESR no longer serves as a marker of an acute-phase response in nephrotic patients.

Renal vein thrombosis is an important complication of nephrotic syndrome (see Chapter 66). Although once considered possible, renal vein thrombosis is no longer thought to cause nephrotic syndrome. Renal vein thrombosis is reported clinically in up to 8% of nephrotic patients; but when sought systematically by ultrasound or contrast venography, the frequency increases to 10% to 50%. Symptoms when the thrombosis is acute may include flank pain and hematuria; rarely, acute kidney injury (AKI) can occur if the thrombosis is bilateral. However, the thrombosis often develops insidiously with minimal symptoms or signs because of the development of collateral blood supply. Pulmonary embolism is an important complication.

Hyperlipidemia and Lipiduria

Hyperlipidemia is such a frequent finding in patients with heavy proteinuria that it is regarded as an integral feature of nephrotic syndrome.[15] Clinical stigmata of hyperlipidemia, such as xanthelasmas, may have a rapid onset (see Fig. 15-5). Serum cholesterol concentration can be above 500 mg/dl (13 mmol/l), although serum triglyceride levels are highly variable. The lipid profile in nephrotic syndrome is known to be highly atherogenic in other populations (Fig. 15-11). The presumption that coronary heart disease is increased in nephrotic syndrome because of the combination of hypercoagulation and hyperlipidemia has been difficult to prove. Many patients who are nephrotic for more than 5 to 10 years will develop additional cardiovascular risk factors, including hypertension and uremia, so it is difficult to separate these influences. However, it is now generally accepted that nephrotic patients do have about a fivefold increased risk of coronary death, except for those with MCD, presumably because the nephrotic state is transient before remission with corticosteroid treatment and does not subject the patient with MCD to prolonged hyperlipidemia.

Experimental evidence shows that hyperlipidemia contributes to progressive renal disease by various mechanisms, with protection afforded by lipid-lowering agents. However, clinical evidence to support a role of statins in slowing CKD progression is inconclusive.[16] Adequate prospective clinical studies on this issue remain to be done, and lipid-lowering drugs are indicated in nephrotic syndrome primarily for cardiovascular reasons.

Several mechanisms account for the lipid abnormalities in nephrotic syndrome. These include increased hepatic synthesis of low-density lipoprotein (LDL), very-low-density lipoprotein (VLDL), and lipoprotein(a) secondary to the hypoalbuminemia; defective peripheral lipoprotein lipase activity resulting in increased VLDL; and urinary losses of high-density lipoprotein (HDL; Fig. 15-11).

Lipiduria, the fifth component of the nephrotic syndrome pentad, is manifested by the presence of refractile accumulations of lipid in cellular debris and casts (oval fat bodies and fatty casts; Fig. 15-12). However, the lipiduria appears to be a result of the proteinuria and not of the plasma lipid abnormalities.

Other Metabolic Effects of Nephrotic Syndrome

Vitamin D–binding protein is lost in the urine, resulting in low plasma 25-hydroxyvitamin D levels, but plasma-free vitamin D is usually normal, and overt osteomalacia or uncontrolled hyperparathyroidism is very unusual in nephrotic syndrome in the absence of

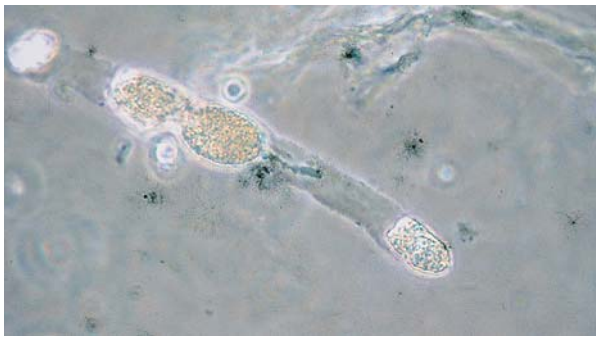

Figure 15-12 Fat in the urine. This hyaline cast contains oval fat bodies, which are tubular epithelial cells full of fat. Oval fat bodies often appear brown.

renal impairment. Thyroid-binding globulin is lost in the urine and total circulating thyroxine reduced, but again free thyroxine and thyroid-stimulating hormone are normal, and there are no clinical alterations in thyroid status. Occasional patients have been described with copper, iron, or zinc deficiency caused by the loss of binding proteins in the urine.

Drug binding may be altered by the decrease in serum albumin. Although most drugs do not require dose modifications, one important exception is clofibrate, which at normal doses produces a severe myopathy in nephrotic patients. Reduced protein binding may also reduce the dose of warfarin (Coumadin) required to achieve adequate anticoagulation or the dose of furosemide required to achieve adequate fluid loss (see later discussion).

Infection

Nephrotic patients are prone to bacterial infection. Before corticosteroids were shown to be effective in childhood nephrotic syndrome, sepsis was the most common cause of death and remains a major problem in the developing world. Primary *peritonitis,* especially that caused by pneumococci, is particularly characteristic of nephrotic children. It is less common with increasing age; by 20 years most adults have antibodies against pneumococcal capsular antigens. Peritonitis caused by both β-hemolytic streptococci and gram-negative organisms occurs, but staphylococcal peritonitis is not reported. Cellulitis, especially in areas of severe edema, is also common, most frequently caused by β-hemolytic streptococci.

The increased risk of infection has several explanations. Large fluid collections are sites for bacteria to grow easily; nephrotic skin is fragile, creating sites of entry; and edema may dilute local humoral immune factors. Loss of IgG and complement factor B (of the alternative pathway) in the urine impairs host ability to eliminate encapsulated organisms such as pneumococci. Zinc and transferrin are lost in the urine, and both are required for normal lymphocyte function. Neutrophil phagocytic function is impaired in patients with nephrotic syndrome, and several forms of *in vitro* T cell dysfunction are described, although their clinical significance is uncertain.

Acute and Chronic Changes in Renal Function

Acute Kidney Injury

Patients with nephrotic syndrome are at risk for the development of AKI,[17] through a variety of mechanisms (Box 15-1). These include volume depletion or sepsis, resulting in either pre-renal AKI or acute tubular necrosis[18]; transformation of the underlying disease, such as development of crescentic nephritis in a patient with membranous

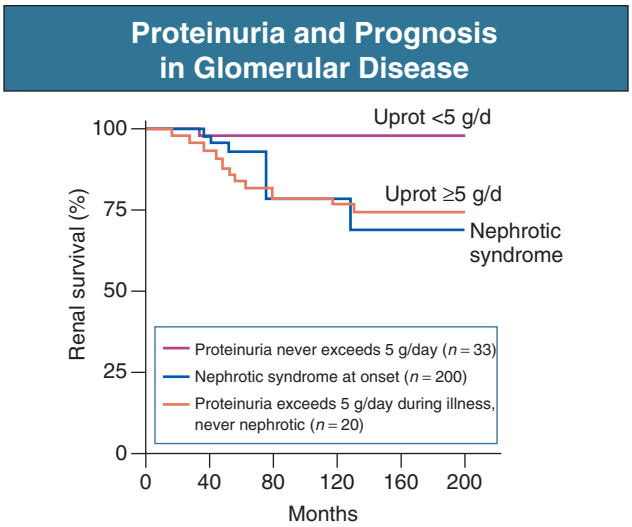

Figure 15-13 Proteinuria and prognosis in glomerular disease. The influence of heavy proteinuria on long-term renal function in 253 patients with primary glomerular disease at Manchester Royal Infirmary, United Kingdom. Heavy proteinuria at any time during long-term follow-up substantially worsens the prognosis even without frank nephrotic syndrome. *(Courtesy Dr. C. D. Short.)*

Acute Kidney Injury in Nephrotic Syndrome

- Pre-renal failure caused by volume depletion
- Acute tubular necrosis caused by volume depletion and/or sepsis
- Intrarenal edema
- Renal vein thrombosis
- Transformation of underlying glomerular disease (e.g., crescentic nephritis superimposed on membranous nephropathy)
- Adverse effects of drug therapy
- Acute allergic interstitial nephritis secondary to various drugs, including diuretics
- Hemodynamic response to nonsteroidal anti-inflammatory drugs (NSAIDs) and angiotensin-converting enzyme (ACE) inhibitors or angiotensin receptor blockers (ARBs)

Box 15-1 Acute kidney injury in nephrotic syndrome. Problems to consider in the evaluation of acute deterioration in renal function in the patient with nephrotic syndrome.

nephropathy; development of bilateral renal vein thrombosis; increased disposition to pre-renal AKI from NSAIDs and ACE inhibitors or ARBs; and increased risk of allergic interstitial nephritis secondary to drugs, including diuretics. Also, some patients may develop AKI from intrarenal edema with compression of tubules and, as with nephrotic patients with pre-renal azotemia, may respond with diuresis to albumin infusions combined with a loop diuretic.

Chronic Kidney Disease

With the exception of MCD, most causes of nephrotic syndrome are associated with some risk for the development of progressive renal failure. In this regard, one of the greatest risk factors for progression is the degree of proteinuria (see Chapter 80). Progression is uncommon if there is sustained proteinuria of less than 2 g/day. The risk increases in proportion to the severity of the proteinuria, with marked risk of progression when protein excretion is more than 5 g/day (Fig. 15-13). This risk may result because proteinuria identifies patients with severe glomerular injury, although experimental and clinical evidence also suggests that proteinuria itself may be toxic, especially to the tubulointerstitium.[19] In experimental models,

Differentiation Between Nephrotic Syndrome and Nephritic Syndrome		
Typical Features	**Nephrotic**	**Nephritic**
Onset	Insidious	Abrupt
Edema	++++	++
Blood pressure	Normal	Raised
Jugular venous pressure	Normal/low	Raised
Proteinuria	++++	++
Hematuria	May/may not occur	+++
Red blood cell casts	Absent	Present
Serum albumin	Low	Normal/slightly reduced

Table 15-4 Differentiation between nephrotic syndrome and nephritic syndrome.

measures that reduce proteinuria (e.g., ACE inhibitors) also prevent tubulointerstitial disease and progressive renal failure.

Common Glomerular Diseases Presenting as Nephritic Syndrome		
Disease	**Associations**	**Serologic Tests**
Poststreptococcal glomerulonephritis	Pharyngitis, impetigo	ASO titer, streptozyme antibody
Other postinfectious disease		
Endocarditis	Cardiac murmur	Blood cultures, C3 ↓
Abscess	—	Blood cultures, C3, C4 normal or increased
Shunt	Treated hydrocephalus	Blood cultures, C3 ↓
IgA nephropathy	Upper respiratory or gastrointestinal infection	Serum IgA ↑
Lupus nephritis	Other multisystem features of lupus	Antinuclear antibody, anti-double-stranded DNA antibody, C3 ↓, C4 ↓

Table 15-5 Common glomerular diseases presenting as nephritic syndrome.

NEPHRITIC SYNDROME

In *nephrotic* syndrome, the glomerular injury is manifested primarily as an increase in permeability of the capillary wall to protein. By contrast, in the *nephritic* syndrome, there is evidence of glomerular inflammation resulting in a reduction in GFR, non-nephrotic proteinuria, edema and hypertension (secondary to sodium retention), and hematuria with RBC casts.

The classic nephritic syndrome presentation is that seen with acute poststreptococcal GN in children. These children usually present with rapid onset of oliguria, weight gain, and generalized edema during a few days. The hematuria results in brown rather than red urine, and clots are not seen. The urine contains protein, RBCs, and RBC casts. Because proteinuria is rarely in the nephrotic range, serum albumin concentration is usually normal. Circulating volume increases with hypertension, and pulmonary edema follows without evidence of primary cardiac disease.

The distinction between typical nephrotic syndrome and nephritic syndrome is usually straightforward on clinical and laboratory grounds (Table 15-4). The use of these clinical descriptions in the approach to patients with suspected GN at first presentation helps to narrow the differential diagnosis. However, the classification systems are imperfect, and patients with certain glomerular disease patterns, such as membranoproliferative GN, may present with either a nephrotic or a nephritic picture.

Etiology

Table 15-5 lists the primary glomerular diseases associated with the nephritic syndrome and the serologic tests helpful in diagnosis. The classification is even more challenging than for nephrotic syndrome, because some diseases are identified by histology (IgA nephropathy), others by serology and histology (ANCA-associated vasculitis and lupus nephritis), and others by etiology (postinfectious GN).

RAPIDLY PROGRESSIVE GLOMERULONEPHRITIS

Rapidly progressive glomerulonephritis (RPGN) describes the clinical situation in which glomerular injury is so acute and severe that renal function deteriorates during days or weeks. The patient may present as a uremic emergency, with nephritic syndrome that is not self-limited but moves on rapidly to renal failure, or with rapidly deteriorating renal function when being investigated for extrarenal disease (many of the patterns of GN associated with RPGN occur as part of a systemic immune illness).

The histologic counterpart of RPGN is crescentic GN. The proliferative cellular response seen outside the glomerular tuft but within Bowman space is known as a "crescent" because of its shape on histologic cross section (see Fig. 16-8). Typically, the glomerular tuft also shows segmental necrosis, or focal segmental necrotizing GN; this is particularly characteristic of the vasculitis syndromes.

The term *rapidly progressive* GN is therefore often used to describe acute deterioration in renal function in association with a crescentic nephritis. Unfortunately, not all patients with a nephritic urine sediment and AKI will fit this syndrome. For example, AKI may also occur in milder forms of glomerular disease if it is complicated by accelerated hypertension, renal vein thrombosis, or acute tubular necrosis. This emphasizes the need to obtain histologic confirmation of the clinical diagnosis.

Etiology

Table 15-6 show the primary glomerular diseases associated with RPGN and helpful serologic tests. As with nephritic syndrome, different assessment methods are useful for different diseases causing RPGN.

PROGRESSIVE CHRONIC KIDNEY DISEASE

In most types of chronic GN, a proportion of patients (often between 25% and 50%) will have slowly progressive renal impairment. If no clinical event early in the course of the disease brings them to medical attention, patients may present late with established hypertension, proteinuria, and renal impairment. In longstanding GN, the kidneys shrink, but remain smooth and symmetric. Renal biopsy at this stage is more hazardous and less likely to provide diagnostic material. Light microscopy often shows nonspecific features of

Common Glomerular Diseases Presenting as Rapidly Progressive Glomerulonephritis

Disease	Associations	Serologic Tests
Goodpasture Syndrome		
	Lung hemorrhage	Anti–glomerular basement membrane antibody (occasionally antineutrophil cytoplasmic antibody [ANCA] present)
Vasculitis		
Wegener granulomatosis	Upper and lower respiratory involvement	Cytoplasmic ANCA
Microscopic polyangiitis	Multisystem involvement	Perinuclear ANCA
Pauci-immune crescentic glomerulonephritis	Renal involvement only	Perinuclear ANCA
Immune Complex Disease		
Systemic lupus erythematosus	Other multisystem features of lupus	Antinuclear antibody, anti-double-stranded DNA antibody, C3 ↓, C4 ↓
Poststreptococcal glomerulonephritis	Pharyngitis, impetigo	ASO titer, streptozyme antibody C3 ↓, C4 normal
IgA nephropathy; Henoch-Schönlein purpura	Characteristic rash ± abdominal pain in HSP	Serum IgA ↑ (30%) C3 and C4 normal
Endocarditis		
	Cardiac murmur; other systemic features of bacteremia	Blood cultures ANCA (occasionally) C3 ↓, C4 normal

Table 15-6 Glomerular diseases presenting as rapidly progressive glomerulonephritis (RPGN). Note the overlap between these diseases and those in Table 15-5. A number of glomerular diseases may present with either nephritic syndrome or RPGN.

end-stage renal disease (ESRD), consisting of focal or global glomerulosclerosis and dense tubulointerstitial fibrosis, and it may not be possible to define with confidence that a glomerular disease was the initiating renal injury, let alone define the pattern further. Immunofluorescence may be more helpful; in particular, mesangial IgA may be present in adequate amounts to allow a diagnosis of IgA nephropathy to be made. However, when renal imaging shows small kidneys, only rarely will biopsy be appropriate. For this reason, chronic GN has often been a presumptive diagnosis in patients presenting late with shrunken kidneys, proteinuria, and renal impairment. This is imprecise and in the past has led to an overestimate of the frequency of GN as a cause of ESRD in registry data. GN should be diagnosed only if there is confirmatory histologic evidence.

TREATMENT OF GLOMERULAR DISEASE

General Principles

Before any therapeutic decisions, it should always be ascertained that glomerular disease is *primary* and that no specific therapy is available. For example, treatment of an underlying infection or tumor may result in remission of GN. In the remaining cases, both general supportive treatment (see Chapter 80) and disease-specific therapy should be considered. Supportive treatment includes measures to treat blood pressure, reduce proteinuria, control edema, and address other metabolic consequences of nephrotic syndrome. If successful, these relatively nontoxic therapies can prevent the need for immunosuppressive drugs, which have multiple potential side effects. Supportive therapy is usually not necessary in corticosteroid-sensitive MCD with rapid remission or in patients with IgA nephropathy, Alport syndrome, or thin basement membrane nephropathy, provided the patient exhibits no proteinuria, loss of GFR, or hypertension.

Hypertension

Hypertension is very common in GN; it is virtually universal as chronic GN progresses toward ESRD and is the key modifiable factor in preserving renal function. Sodium and water overload is an important part of the pathogenetic process, and high-dose diuretics with moderate dietary sodium restriction are usually an essential part of the treatment. As in other chronic renal diseases, the aim of blood pressure control is not only to protect against the cardiovascular risks of hypertension, but also to delay progression of the renal disease. In the Modification of Diet in Renal Disease (MDRD) study, patients with proteinuria (>1 g/day) had a better outcome if their blood pressure was reduced to 125/75 mm Hg rather than to the previous standard of 140/90 mm Hg.[20,21] The recent Kidney Disease: Improving Global Outcomes (KDIGO) CKD guideline recommends a blood pressure target below 130/80 mm Hg in proteinuric patients.[22] There are strong theoretical and experimental reasons for ACE inhibitors and ARBs to be first-choice therapy, and this is now well documented in clinical studies.[23-25] Nondihydropyridine calcium channel blockers may also have a beneficial effect on proteinuria as well as on blood pressure. In contrast, dihydropyridine calcium channel blockers may exacerbate proteinuria because of their ability to dilate the afferent arteriole, but these agents are considered relatively safe to use if the patient is receiving either an ACE inhibitor or an ARB. As in primary hypertension, lifestyle modification (salt restriction, weight normalization, regular exercise, and smoking cessation) should be an integral part of the therapy.[22] If target blood pressure cannot be achieved with these measures, antihypertensive therapy should be stepped up according to current guidelines (see Chapter 36).

Treatment of Proteinuria

Besides hypertension, proteinuria represents the second key modifiable factor to preserve GFR in patients with glomerular disease (see also Chapters 80 and 81). Most studies suggest that the progressive loss of renal function observed in many glomerular diseases can largely be prevented if proteinuria can be reduced to levels below 0.5 mg/day. This may be because many of the measures to reduce protein excretion (e.g., ACE inhibitors, ARBs) also reduce glomerular hypertension, which contributes to progressive renal failure. However, there is also increasing evidence that proteinuria or factors present in proteinuric urine may be toxic to the tubulointerstitium.[19] In nephrotic patients, a reduction of proteinuria to a non-nephrotic range can induce serum proteins to rise, with alleviation of many of the metabolic complications of nephrotic syndrome.

Most of the agents used to reduce urinary protein excretion do so hemodynamically, either by blocking efferent arteriolar constriction (ACE inhibitors or ARBs) or by reducing preglomerular pressure (most other classes of antihypertensive drugs). As mentioned,

dihydropyridine calcium antagonists are the exception because they can increase intraglomerular pressure and thus exacerbate proteinuria. Some of the agents, such as ACE inhibitors and ARBs, may also directly reduce the increased glomerular capillary wall permeability. A consequence of this type of therapy is a reduction in GFR; in general, however, the decrease in GFR is of a lower magnitude than the decrease in protein excretion. The antiproteinuric agents of choice are ACE inhibitors and ARBs, which reduce proteinuria by an average of 40% to 50%, particularly if the patient is on dietary salt restriction. There is little clinical evidence to suggest that ACE inhibitors differ from ARBs in this respect. The combination of the two may result in additive antiproteinuric activity but increases the risk of AKI.[26] Similar concerns relate to the combination of ACE inhibitor or ARB with a direct renin inhibitor.[27] In addition, whereas other classes of antihypertensive agents will reduce proteinuria coincident with a decrease in systemic blood pressure, particularly the nondihydropyridine calcium channel blockers such as diltiazem, both ACE inhibitors and ARBs usually reduce proteinuria independent of blood pressure. If doses are increased slowly to minimize symptomatic hypotension, treatment with ACE inhibitors and ARBs is usually possible in the normotensive proteinuric patient. Increasing the inhibitor or ARB dose may further reduce proteinuria without lowering blood pressure, which may indicate the inefficacy of other antihypertensive drugs in blocking the stimulated intrarenal RAS. Common side effects include hyperkalemia in patients with advanced CKD, which may necessitate a loop diuretic but rarely should lead to cessation of ACE inhibitors and ARBs, and cough ACE inhibitors, in which case ARBs should be used instead. Because both agents lower GFR, a 10% to 30% increase in serum creatinine concentration may be observed. Unless creatinine continues to increase, this moderate increase reflects the therapeutic effect of ACE inhibitors and ARBs and should not prompt their withdrawal.

The NSAIDs lessen proteinuria by reducing intrarenal prostaglandin production and dipyridamole through adenosine-mediated afferent arteriolar vasoconstriction. Given the safety of the therapies discussed previously, as well as the risk of profound decreases in GFR, salt retention, and diuretic resistance with NSAIDs, these are generally contraindicated despite their potential benefit on proteinuria.

A low-protein diet will lessen proteinuria but must be advised with great care because of the risk of malnutrition.[22] Adequate compensation must be made for urine protein losses,[28] and the patient must be carefully monitored for evidence of malnutrition (see Chapter 87). Whether a low-protein diet is still antiproteinuric in patients treated with a full-dose ACE inhibitor or ARB is not established.

Treatment of Hyperlipidemia

Treatment of hyperlipidemia (or hypercholesterolemia) in patients with glomerular disease should usually follow the guidelines that apply to the general population to prevent cardiovascular disease. A statin or statin/ezetimibe combination is recommended in adults older than 50 with CKD stage 3 to 5. Statins alone are also recommended in adults over 50 with earlier-stage CKD. In younger adults, statins should be considered if the patient has significant comorbidity (coronary disease, diabetes mellitus, stroke). Statin therapy may also protect from a decrease in GFR, although this is not firmly established. Dietary restriction alone has only modest effects on hyperlipidemia in glomerular disease, particularly nephrotic syndrome. Side effects of some medications, such as rhabdomyolysis provoked by fibrates, occur more frequently in patients with renal failure. The addition of bile acid sequestrants such as cholestyramine may lower LDL further and increase HDL, but it is usually not tolerated because of GI effects.

Avoidance of Nephrotoxic Substances

Apart from NSAIDs, which may induce AKI, particularly in patients with preexisting renal impairment and dehydration, other nephrotoxic substances, such as radiocontrast agents, some cytotoxic drugs, and antibiotics (e.g., aminoglycoside antibiotics), should also be used with caution in patients with glomerular disease and renal impairment or nephrotic syndrome.

Special Therapeutic Issues in Patients with Nephrotic Syndrome

Treatment of Nephrotic Edema

In contrast to the lack of therapies in the past (Fig. 15-14), the mainstay of current treatment of nephritic edema is diuretic therapy accompanied by moderate dietary sodium restriction (60 to 80 mmol/24 h). Nephrotic patients are diuretic resistant even if GFR is normal. Loop diuretics must reach the renal tubule to be effective, and transport from the peritubular capillary requires protein binding, which is reduced in hypoalbuminemia. When the drug reaches the renal tubule, it will become 70% bound to protein present in the urine and therefore be less effective. Oral diuretics with twice-daily administration are usually preferred, given the longer therapeutic effect compared with intravenous (IV) diuretics. However, in severe nephrosis, GI absorption of the diuretic may be uncertain because of intestinal wall edema, and IV diuretic, by bolus injection or infusion, may be necessary to provoke an effective diuresis. Alternatively, combining a loop diuretic with a thiazide diuretic or with metolazone may overcome diuretic resistance (see Chapter 7). Significant hypovolemia is not often a clinical problem, provided fluid removal is controlled and gradual. Daily weight is the best measurement of progress; ideally it should decrease by no more than 1 to 2 kg/day. Nephrotic children are much more prone to hypovolemic shock than adults. A stepwise approach to diuretic use is required, aiming at

Figure 15-14 Treatment of nephrotic edema before the availability of diuretics. Edema in nephrotic syndrome was very difficult to treat. In 1953, this child with anasarca stands in a bowl while edema fluid drips out through small tubes placed through needles in the skin of the feet. Nevertheless, this was effective treatment. The two pictures of the same child were taken 4 days apart, during which time the child lost 4.5 kg (10 lb), or 18% of body weight. *(Courtesy Dr. Robert Vernier.)*

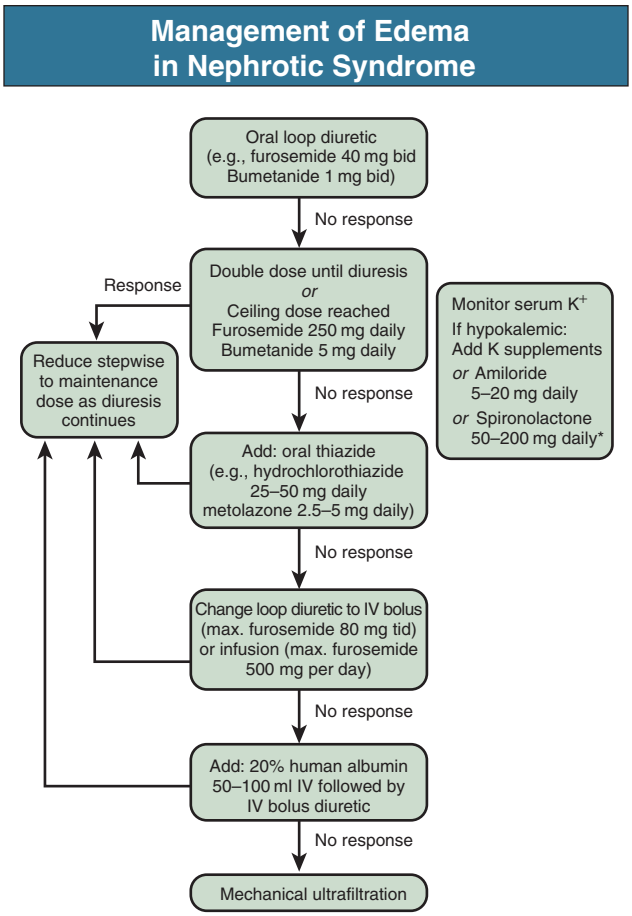

Figure 15-15 Management of edema in the patient with nephrotic syndrome. Edema is often diuretic resistant, but the response is not predictable. Therefore, stepwise escalation of therapy is appropriate until diuresis occurs. Even when there is anasarca, diuresis should not proceed faster than 2 kg/day in adults to minimize the risk of clinically significant hypovolemia; *bid,* twice daily. Mechanical ultrafiltration is rarely required for nephrotic edema unless there is associated renal impairment. *Spironolactone is less effective in nephrotic syndrome than in cirrhosis and is often poorly tolerated because of gastrointestinal side effects. Spironolactone should be used with great caution if the GFR is very low.

fluid removal in adults of no more than 2 kg daily, moving on to the next drug level if this is not achieved (Fig. 15-15).

Correction of Hypoproteinemia

In view of the problems associated with either increased protein administration or dietary protein restriction in nephrotic patients, adequate dietary protein should be ensured (0.8 to 1 g/kg/day) with a high carbohydrate intake to maximize use of that protein. In patients with heavy proteinuria, the amount of urinary protein loss should be added to dietary protein intake.

In the rare setting of proteinuria so severe that the patient is dying of the complications of nephrotic syndrome, the physician may need to resort to nephrectomy to prevent continued protein losses. This may be done as a *medical* nephrectomy: the deliberate use of NSAIDs combined with ACE inhibitors and diuretic to lessen proteinuria by provoking AKI. If medical nephrectomy alone does not adequately reduce proteinuria, bilateral renal artery embolization can be considered. It is a painful procedure and is not always as successful as might be expected (perhaps because of collateral arterial supply to kidneys, which is not blocked by embolization). A final alternative is bilateral nephrectomy, which carries significant mortality in these severely ill hypoproteinemic patients and is rarely used in adults, although it is a conventional part of management of infants with congenital nephrotic syndrome.

Treatment of Hypercoagulability

The risk of thrombotic events becomes progressively more important as serum albumin values decrease to less than 2.5 g/dl. Immobility as a consequence of edema or intercurrent illness further aggravates the risk. Prophylactic low-dose anticoagulation (e.g., heparin 5000 units subcutaneously twice daily) is indicated at times of high risk, such as relative immobilization in the hospital and albumin levels between 2 and 2.5 g/dl. Full-dose anticoagulation with low-molecular-weight heparin or warfarin should be considered if serum albumin decreases to less than 2 g/dl,[13,29] and this is mandatory if a thrombosis or pulmonary embolism is documented. Heparin is used for initial anticoagulation, but an increased dose may be needed because part of the action of heparin depends on antithrombin III, which is often reduced in the plasma in nephrotic patients. Warfarin (target international normalized ratio [INR] 2 to 3) is the long-term treatment of choice but should be adjusted with special care because of altered protein binding, which may require dose reductions.

Management of Infection

A high order of clinical suspicion for infection is vital in nephrotic patients. Especially in nephrotic children, ascitic fluid should be examined microscopically and cultured if there is any suspicion of systemic infection. Bacteremia is common even if clinical signs are localized. ESR is unhelpful, but an elevated C-reactive protein level may be informative. Parenteral antibiotics should be started once culture specimens are taken, and the regimen should include benzylpenicillin (to cover pneumococci). If repeated infections occur, serum immunoglobulins should be measured. If serum IgG is less than 600 mg/dl, evidence in an uncontrolled study showed that infection risk is reduced by monthly administration of intravenous immune globulin (10 to 15 g) to keep the IgG levels above 600 mg/dl.[30]

Disease-Specific Therapies

Specific treatments for glomerular diseases are discussed in the subsequent chapters; the general principles are discussed here. Because most glomerular disease is thought to have an immune pathogenesis, treatment has generally consisted of immunosuppressive therapy aimed at blocking both the systemic and the local effects. In the patient with glomerular disease resulting from ineffectual elimination of a foreign antigen, treatment involves measures to eliminate this antigen whenever possible, such as antibiotics in endocarditis-associated GN or antiviral therapy for cryoglobulinemia resulting from hepatitis C infection.

In general, the more severe and acute the presentation of GN, the more successful is immunosuppressive treatment. Immunosuppression in several patterns of chronic GN has had minimal success. When renal function is declining rapidly, as in RPGN, the toxicity of intensive regimens becomes acceptable for a short period, although it would be unacceptable if prolonged. Furthermore, the nonspecific nature of most immunosuppressive treatments results in widespread interruption of immune and inflammatory events at multiple levels. In the acute situation, this broad-based attack is a virtue; in more indolent disease, more specific treatment is needed but is largely unavailable. Despite great increases in the understanding of immune mechanisms in glomerular disease since the 1970s, most immunosuppressive therapies are not yet much more specific or precise. The mainstays of treatment remain agents that were available in the 1960s: corticosteroids, azathioprine, and cyclophosphamide. Other,

newer immunosuppressive agents developed for use in transplantation, including cyclosporine, tacrolimus, mycophenolate mofetil, sirolimus, and everolimus, or those developed in oncology, including rituximab, have emerging indications in glomerular disease.

The use of immunosuppressive therapies to treat GN patients has certain drawbacks. In many diseases, treatment is based on small series, and good prospective controlled trials are often lacking. Because of both the rarity and the variable natural history of GN, proof of efficacy for a particular therapy often requires a multicenter approach with prolonged follow-up, which is logistically difficult. If sufficient glomerular damage is present, proteinuria and progressive deterioration of renal function may occur by nonimmune pathways that may not be responsive to immunosuppressive therapies. This is particularly relevant in patients in whom the GN has already resulted in advanced CKD. Unfortunately, good noninvasive markers to assess disease activity are missing in most clinical circumstances. Given the frequent uncertainty of the response to immunosuppressive therapy, it becomes mandatory to weigh the potential benefits against the risks of therapy.

Immunosuppression may be associated with reactivation of tuberculosis and hepatitis B infection and can also lead to a hyperinfection syndrome in patients with *Strongyloides* infection. Therefore, high-risk patients should be screened for these diseases before embarking on therapy.

Alkylating agents such as cyclophosphamide and chlorambucil have considerable toxicity. In the short term, leukopenia is common, as is alopecia, although hair will regrow within a few months with discontinuation of therapy. These agents can cause infertility (observed in adults with cumulative doses of cyclophosphamide >200 mg/kg and chlorambucil 10 mg/kg). There is also an increased incidence of leukemias (observed with total doses of cyclophosphamide >80 g and chlorambucil 7 g). Cyclophosphamide is also a bladder irritant, and treatment can result in hemorrhagic cystitis and bladder carcinoma, particularly after therapy lasting more than 6 months.[31] Irritation of the bladder is caused by a metabolite, acrolein. The effect can be minimized in patients receiving IV cyclophosphamide by enforcing a good diuresis and administering mesna. The dose of mesna (mg) should equal the dose of cyclophosphamide (mg); 20% is given intravenously with the IV cyclophosphamide, and the remaining 80% should be given in two equal oral doses at 2 and 6 hours by IV infusion at the same dosage as the cyclophosphamide. Chlorambucil and cyclophosphamide also require dose reduction in the setting of renal impairment. Given all these concerns, oral treatment with these agents should ideally be limited to 12 weeks.

The modes of action and potential adverse effects of corticosteroids, azathioprine, and other immunosuppressive agents occasionally used in glomerular disease are discussed further in Chapter 101.

CHAPTER 16

Introduction to Glomerular Disease: Histologic Classification and Pathogenesis

Richard J. Johnson, Jürgen Floege, and John Feehally

HISTOLOGIC CLASSIFICATION

Glomerular disease may have a wide variety of etiologies and clinical presentations (see Chapter 15). Some glomerular diseases are given the generic title of glomerulonephritis (GN), which implies an immune or inflammatory pathogenesis. Although a specific diagnosis can be made in some patients based on clinical presentation and laboratory tests, in most patients a renal biopsy is useful for both classification and prognosis. Ideally, the renal biopsy should be examined by light microscopy, immunofluorescence, and electron microscopy. Using this approach, a histologic pattern can be diagnosed. Some histologic patterns can be coupled with other laboratory tests to identify a specific etiology, but in many cases the condition is idiopathic. However, because treatments are often developed for specific histologic patterns, this approach is currently favored in the management of patients with glomerular disorders.

HISTOPATHOLOGY

The full assessment of a renal biopsy requires light microscopy, electron microscopy, and examination for deposits of complement and immunoglobulin by immunofluorescence (IF) or immunoperoxidase (IP) techniques.

Light Microscopy

In GN the dominant, but not the only, histologic lesions are in glomeruli (Fig. 16-1). GN is described as *focal* (only some glomeruli are involved) or *diffuse*. In any individual glomerulus, injury may be *segmental* (affecting only part of any glomerulus) or *global*. Sampling error is possible in a renal biopsy; the extent of a focal lesion may be misjudged in a small biopsy specimen, and sections through glomeruli may miss segmental lesions. Lesions may also be hypercellular because of an increase in endogenous endothelial or mesangial cells (termed *proliferative*) and an infiltration of inflammatory leukocytes (termed *exudative*). Severe acute inflammation may produce glomerular necrosis, which is often segmental. The walls of the glomerular capillaries can also be thickened by a number of processes, which include an increase in glomerular basement membrane (GBM) material and immune deposits. Segmental sclerosis and scarring may also occur and are characterized by segmental capillary collapse with the accumulation of hyaline material and mesangial matrix and often with attachment of the capillary wall with Bowman capsule (synechiae or adhesion formation).

The classic stains used in light microscopy include hematoxylin-eosin (HE) and the periodic acid–Schiff (PAS) reaction, which is particularly effective for evaluating cellularity and matrix expansion. More specific stains include methenamine silver, which stains GBM and other matrix black and may reveal a double contour to the GBM because of the interposition of cellular material or may show increased mesangial matrix not easily seen with other techniques. Trichrome staining is also useful to show areas of scarring (blue) and immune deposits (red).

Crescents are inflammatory collections of cells in Bowman space. Crescents develop when severe glomerular injury results in local rupture of the capillary wall or Bowman capsule, allowing plasma proteins and inflammatory material to enter into the Bowman space. Crescents consist of proliferating parietal and visceral epithelial cells, infiltrating fibroblasts, and lymphocytes and monocytes/macrophages, often with local fibrin deposition. They are called "crescents" because of their appearance when the glomerulus is cut in one plane for histology. These cell collections are destructive and rapidly increasing in size and may lead to glomerular tuft occlusion (Fig. 16-1). If the acute injury is stopped, the crescents may either resolve with restitution of normal morphology or heal by fibrosis, causing irreversible loss of renal function. Crescents are most frequently observed with vasculitis, in Goodpasture disease, and in severe acute GN of any etiology.

Tubulointerstitial injury and fibrosis can also accompany GN and may play an important role in the prognosis (see Chapter 79).

Immunofluorescence and Immunoperoxidase Microscopy

Indirect IF and IP staining are both used to identify immune reactants (Fig. 16-2). Examination consists of staining for immunoglobulins (IgG, IgA, and IgM), for components of the complement system (usually C3, C4, and C1q), and for the presence of fibrin, which is typically observed in crescents and in capillaries in thrombotic disorders such as hemolytic uremic syndrome and the antiphospholipid syndrome. Immune deposits may occur along the capillary loops or in the mesangium. They may be continuous (linear) or discontinuous (granular) along the capillary wall or in the mesangium.

Electron Microscopy

Electron microscopy (EM) is valuable for defining the morphology of the basement membranes, which is abnormal in some forms of hereditary nephropathy (e.g., Alport syndrome and thin basement membrane nephropathy; see Chapter 48), and for identifying fibrils (e.g., in amyloidosis) or tubuloreticular intracellular structures (e.g., in lupus nephritis). EM is also useful for localizing the site of immune deposits, which are usually homogeneous and electron dense (Fig. 16-3). Electron-dense deposits are seen in the mesangium or along the capillary wall on the subepithelial or subendothelial side of the

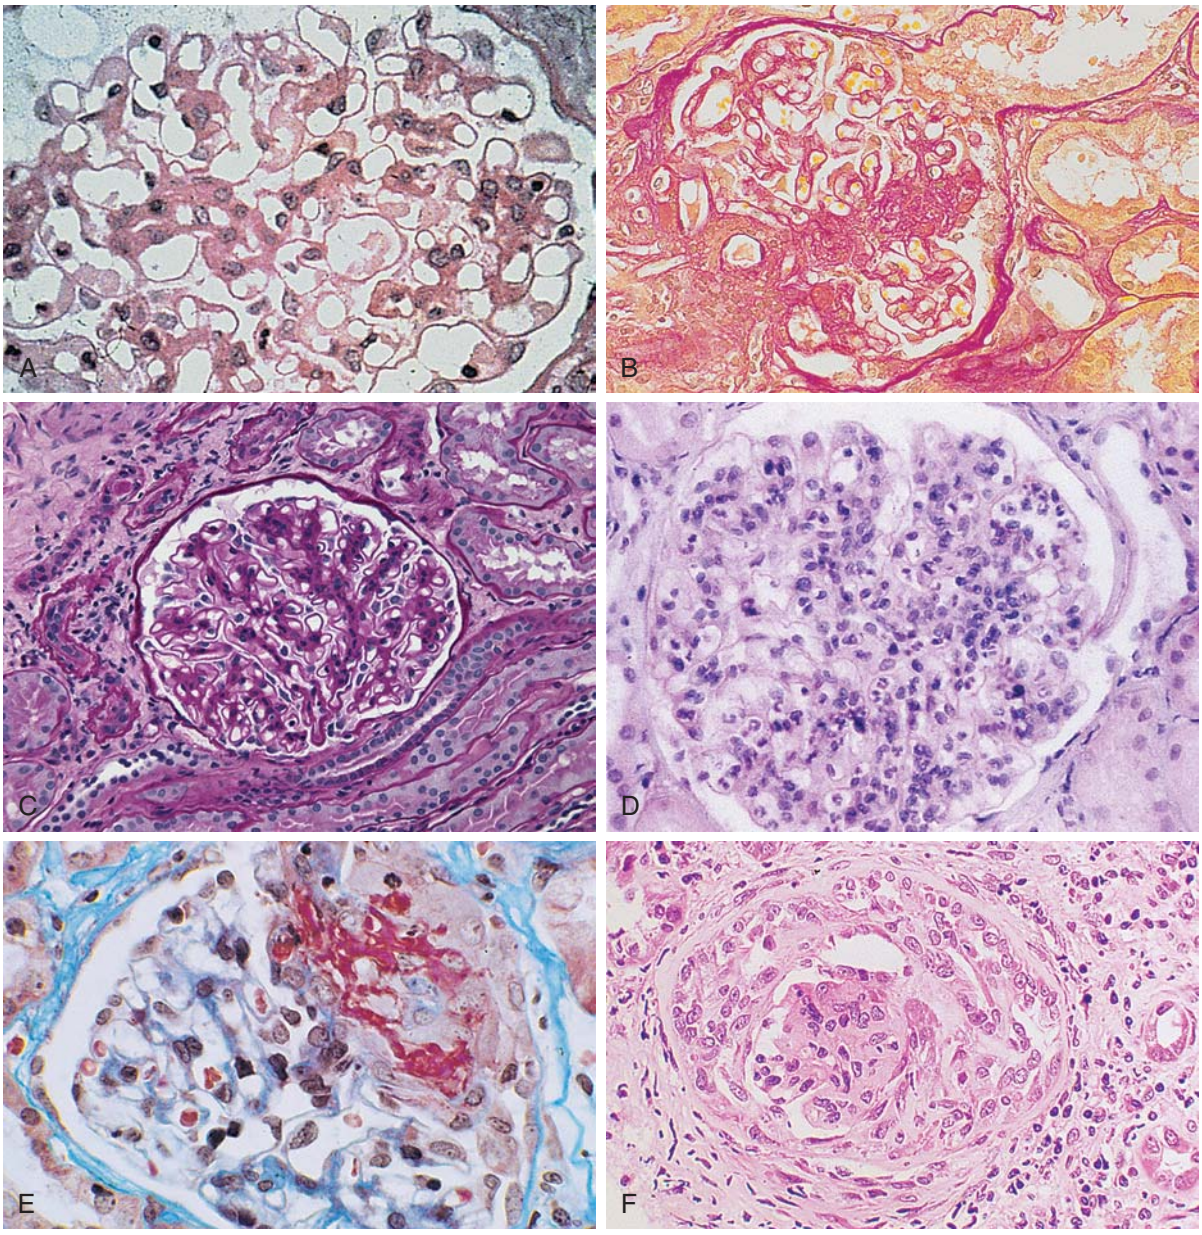

Figure 16-1 Pathology of glomerular disease: light microscopy. GBM. Infrequently, the electron-dense material lies linearly within the GBM. The sites of immune deposits are helpful in the classification of the types of GN.

GENERAL MECHANISMS OF GLOMERULAR INJURY

Proteinuria

Proteinuria is the hallmark of glomerular disease. The endothelial glycocalyx and the GBM may repel proteins in part through their highly negative charge (proteins are mostly negatively charged as well) and prevent them from entering Bowman space. A central barrier for protein is the slit diaphragm between the podocyte foot processes[1] (Fig. 16-4). The slit diaphragm consists of several transmembrane proteins that extend from adjacent interdigitating foot processes to form a zipper-like scaffold on the outer side of the GBM (Fig. 16-5).

The importance of the slit diaphragm in proteinuric states has been documented in numerous hereditary types of nephrotic syndrome in which the mutations involve various slit diaphragm proteins (see Chapter 19). These diseases usually present as a type of steroid-resistant minimal change disease or focal segmental glomerulosclerosis (FSGS). Whereas most recessive mutations of slit diaphragm or podocyte proteins manifest in childhood or even prenatally, dominant mutations tend to manifest in early adult life.[2]

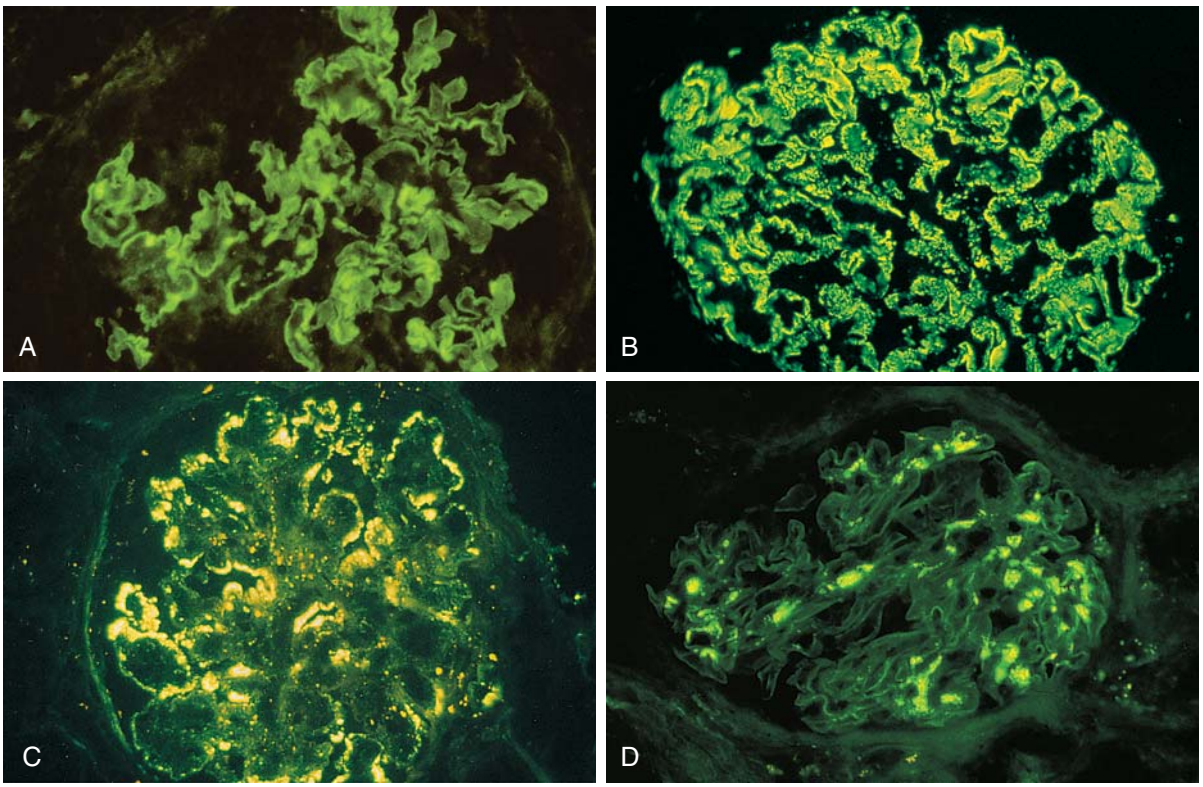

Figure 16-2 Pathology of glomerular disease: immunofluorescence microscopy. Common patterns of glomerular staining found by immunofluorescence. **A,** Linear capillary wall IgG: anti–glomerular basement membrane disease. **B,** Fine granular capillary wall IgG: membranous nephropathy. **C,** Coarse granular capillary wall IgG: membranoproliferative glomerulonephritis type I. **D,** Granular mesangial IgA: IgA nephropathy.

An exception is steroid-resistant autosomal recessive nephrotic syndrome, in which the homozygous mutation in podocin *(NPHS2)* presents in childhood, but the heterozygous mutation, when it coexists with the p.R229Q variant polymorphism, may present clinically in young adulthood (age 20 to 40 years old).[3]

Although it may result from injury or mutation of slit diaphragm proteins, proteinuria may be caused by nonspecific injury to the podocyte in many cases. When the podocyte is injured, it may undergo shape changes with swelling and loss or fusion of the foot processes. Filtration is reduced at sites where the foot processes fuse (possibly accounting for reduction of filtration coefficient K_f seen in nephrotic syndrome), but there are gaps where the podocytes are detached from the GBM. Massive protein filtration may occur at these sites; structurally, the capillary wall defects are likely to correspond to the large pores noted in functional studies[4] (Fig. 16-6). Podocyte immaturity can also result in nephrotic syndrome, perhaps from incomplete differentiation and slit diaphragm development. Congenital nephrotic syndrome with mesangial sclerosis has recently been linked with mutations in phospholipase C epsilon gene *(PLCE1),* which is important in podocyte development.[5]

In addition to podocyte damage, and in particular slit diaphragm defects, evidence also shows that proteinuria can result from changes in the glomerular endothelium, especially its glycocalyx, as well as from changes in the GBM and altered electrical forces across the GBM.

Severe albuminuria reflects a glomerular defect, but some albumin is normally filtered but then endocytosed and metabolized in the proximal tubule or is transcytosed intact through the tubular cell. Proximal tubular dysfunction can therefore result in albuminuria if endocytosis is impaired, although this is generally in the nonnephrotic range.

Antibody and Antigen

Many glomerular diseases are associated with deposition or glomerular trapping of immunoglobulins, often with components of the complement system, and with the presence of electron-dense deposits by EM. These findings likely represent immune complexes. Experimentally, immune complexes can localize in glomeruli by two major mechanisms. In some conditions, such as mesangial proliferative GN, membranoproliferative GN (MPGN), or lupus nephritis, the immune complexes are thought to originate in the circulation and to be passively trapped in the mesangium or subendothelial areas. However, circulating immune complexes cannot readily pass across the GBM. Therefore, the presence of IgG on the subepithelial aspect of the basement membrane, such as occurs in membranous nephropathy, either results from the direct binding of podocyte antigens by antibody or represents binding of an antibody to an antigen that was temporarily "trapped" or bound at this site (*in situ* complex formation).[6] GN may also occur only with complement activation in the glomeruli in the absence of IgG, as occurs in dense deposit disease (DDD), in which ribbon-like deposits replace the basement membrane (see Chapter 22). Some antigens may also deposit in glomeruli and directly activate the alternative pathway of complement in the absence of IgG, as may occur in poststreptococcal GN (PSGN). Antibody with aberrant characteristics may also aggregate in glomeruli and activate complement in the absence of antigen, as occurs in IgA nephropathy with aberrantly glycosylated IgA.[7]

Normally, immune complexes are removed from the circulation by binding of the complex to the C3b receptors on erythrocytes. The immune complexes are then removed and degraded during transit of the erythrocytes in the liver and spleen. If antigenemia persists or clearance of complexes is impaired (e.g., chronic liver disease), immune complexes may deposit in the glomerulus by binding to Fc

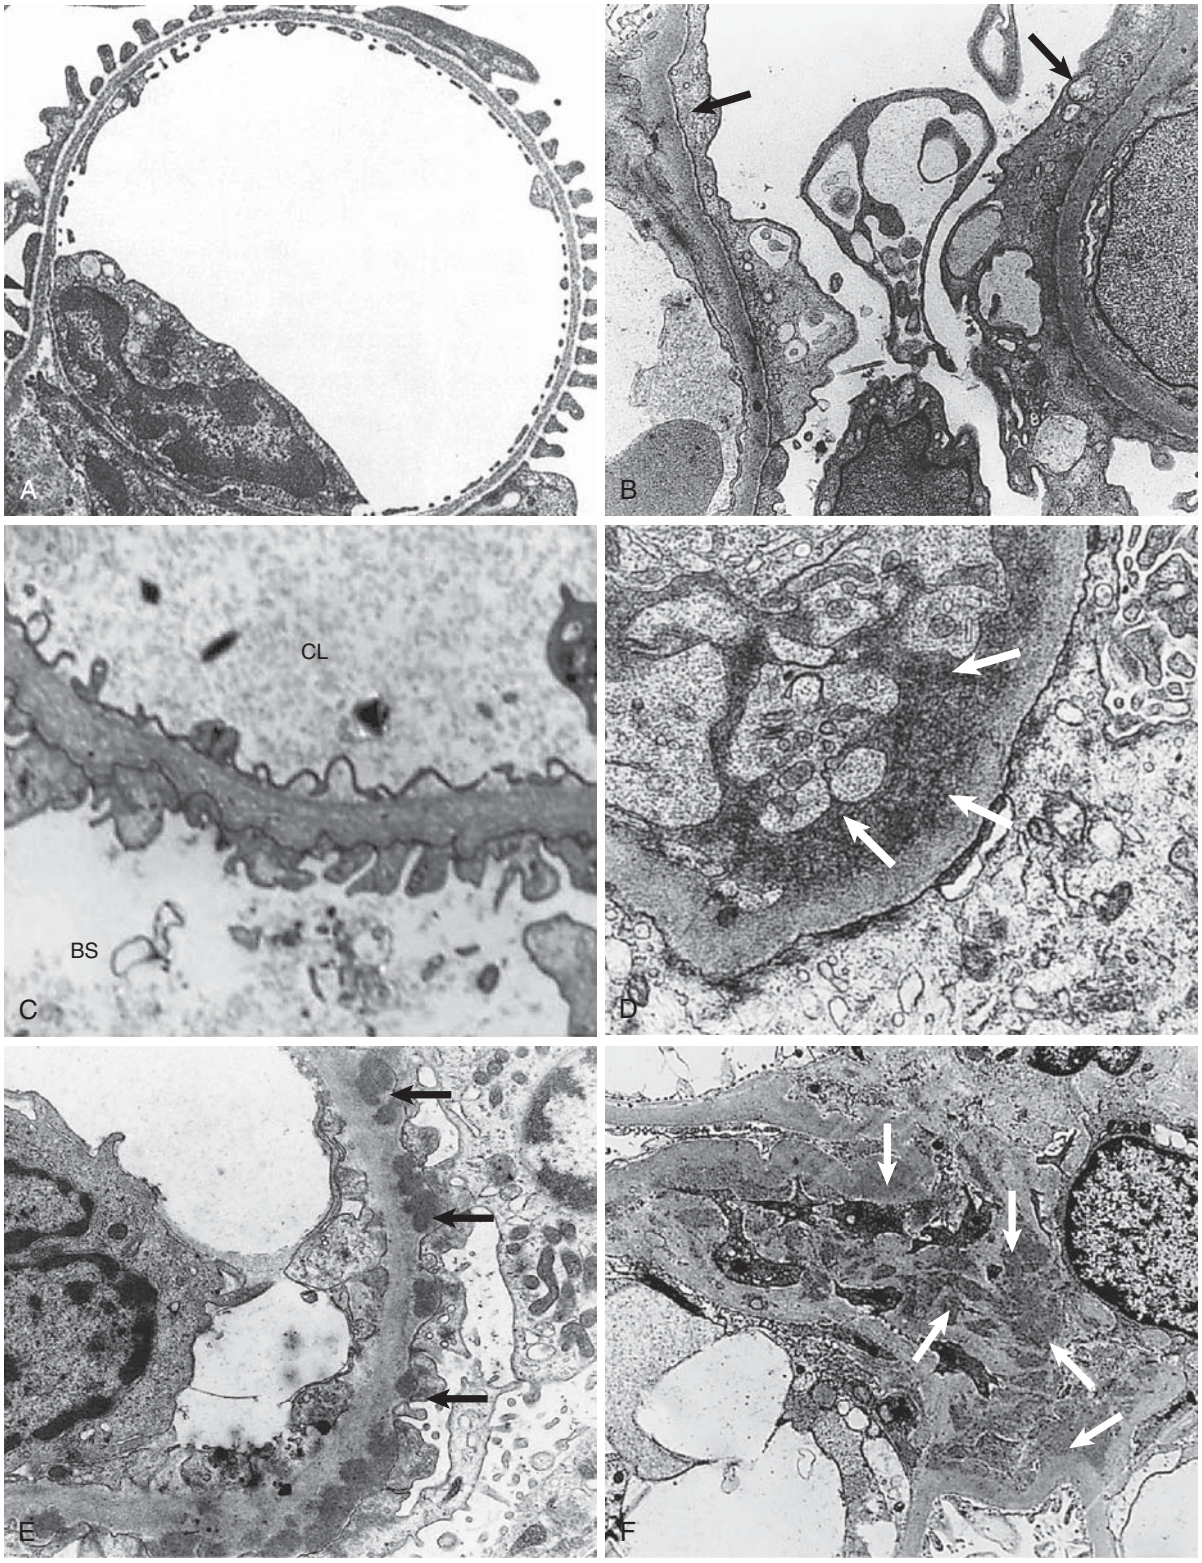

Figure 16-3 Ultrastructural pathology of glomerular disease. Some characteristic patterns of electron-dense deposits and GBM abnormalities seen in glomerular disease. **A,** Normal. **B,** Foot process effacement: minimal change disease *(arrows)*. **C,** GBM thickening and splitting: Alport syndrome. *CL,* Capillary lumen; *BS,* Bowman space. **D,** Subendothelial electron-dense deposits *(arrows):* membranoproliferative glomerulonephritis type I. **E,** Subepithelial electron-dense deposits *(arrows):* membranous nephropathy. **F,** Mesangial electron-dense deposits *(arrows):* IgA nephropathy.

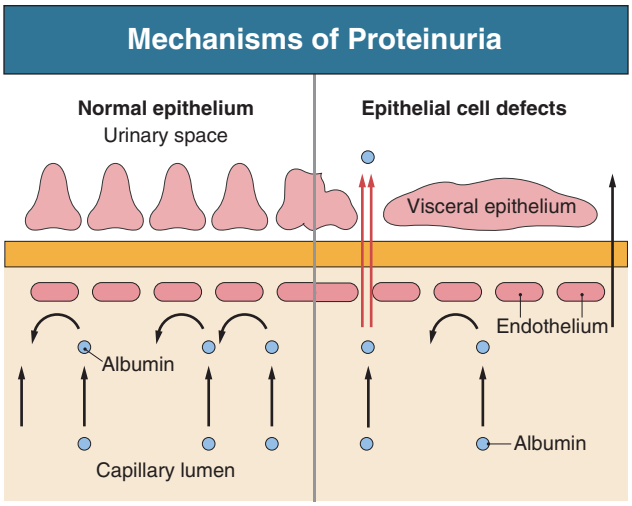

Figure 16-4 Mechanisms of proteinuria. Normally, negatively charged proteins such as albumin *(blue circles)* are repelled by the negatively charged proteins in the endothelium (sialoglycoproteins) and basement membrane (heparan sulfate proteoglycans) as well as by a size barrier in the GBM and at the slit diaphragm so that only small amounts of albumin pass into the urinary space. In most proteinuric states, the podocytes are injured, leading to foot process swelling and injury to the slit diaphragm; in these situations, large amounts of protein (albumin) can pass through the GBM and the gaps between the fused foot processes *(red arrows)*.

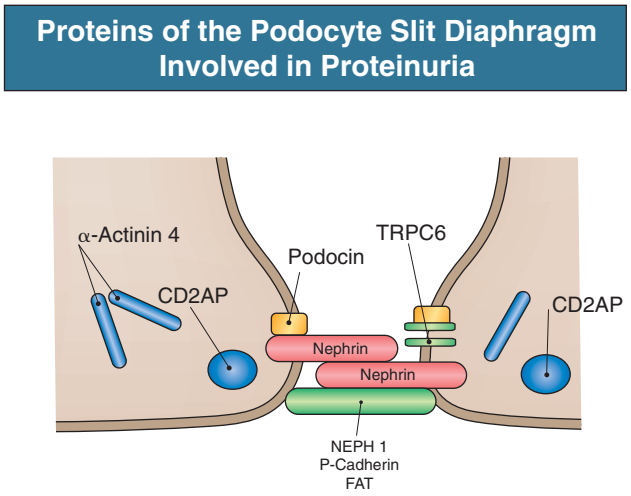

Figure 16-5 Proteins of the podocyte slit diaphragm involved in proteinuria. Several inherited glomerular diseases involve mutations of antigens associated with the slit diaphragm. These include nephrin in congenital nephrotic syndrome of the Finnish type; podocin in autosomal recessive FSGS; and α-actinin and TRPC6 (transient receptor potential cation channel), both associated with autosomal dominant FSGS. In addition, mutation of CD2-associated protein results in nephrotic syndrome in mice. *(Modified from reference 1.)*

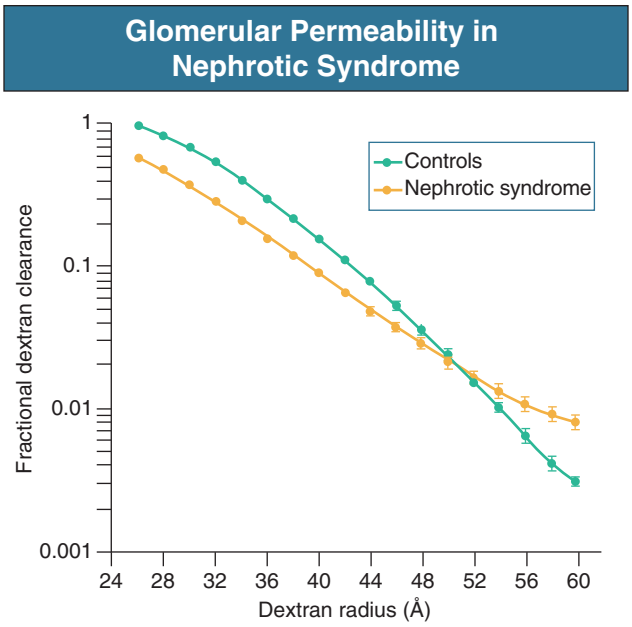

Figure 16-6 Glomerular permeability in nephrotic syndrome. Dextran sieving curve shows the relative glomerular permeability of different-sized dextrans in normal individuals and nephrotic patients with membranous nephropathy and minimal change disease. Nephrotic patients actually have a lower fractional dextran clearance for small dextrans (26 to 48 Å [2.6 to 4.8 nm]) but have an increased clearance for dextrans of larger molecular weight (52 to 60 Å [5.2 to 6.0 nm]). This is consistent with large pores appearing in the GBM. *(Modified from reference 4.)*

Antigens Identified in Glomerulonephritis

Disease	Antigens
Poststreptococcal GN	Streptococcal pyrogenic exotoxin B (SPEB), plasmin receptor
Anti-GBM disease	α3 Type IV collagen (likely induced by molecular mimicry)
IgA nephropathy	Possibly no antigen but rather polymerized polyclonal IgA (?superantigen driven)
Membranous nephropathy	Phospholipase A_2 receptor (idiopathic) Neutral endopeptidase (NEP) in podocyte (congenital) HBeAg (hepatitis associated)
Staphylococcus aureus–associated GN	*Staphylococcus* superantigens induce polyclonal response; not necessarily antigen in glomeruli
Membranoproliferative GN	HCV and HBsAg in hepatitis-associated MPGN
ANCA-associated vasculitis	Endopeptidase (proteinase) 3 (c-ANCA) and myeloperoxidase (p-ANCA) in neutrophils Antibodies to lysosome-associated membrane protein 2 (LAMP-2) on endothelial cells, likely induced by molecular mimicry to fimbriated bacterial antigens

Table 16-1 Antigens identified in glomerulonephritis *(GN).* *ANCA,* Antineutrophil cytoplasmic autoantibody (antibody); *GBM,* glomerular basement membrane; *HCV,* hepatitis C virus; *HBsAg,* hepatitis B surface antigen.

receptors on mesangial cells or by passive deposition in the mesangium or subendothelial space. Physical characteristics of the complexes may also favor deposition, including avidity, charge, and size. However, measurement of circulating immune complexes in patients with GN does not correlate reliably with glomerular events and thus is not typically measured.

In some glomerular diseases, the target antigen has been identified (Table 16-1). In other patients, glomerular disease develops as a result of infection with organisms that release superantigens that cause a polyclonal activation of B cells. The classic organism responsible for superantigen-associated GN is *Staphylococcus aureus*, and the pattern of immune deposits often includes the presence of both IgG and IgA. Some infections initiate an immune response that cross-reacts with endogenous antigens. This type of molecular mimicry may be responsible for Goodpasture disease and certain types of vasculitis[8,9] (Table 16-1). Once an immune response is

initiated, local injury may lead to the release of additional antigens that extend the immune response (epitope spreading). In Goodpasture disease, in which the antigen is α3 chain of type IV collagen, the antigen is present in the lung alveolar basement membrane but is normally sequestered. In tobacco smokers, however, the inhalation results in oxidative injury with exposure of the α3 chain, allowing the binding of antibody.[10] This may explain why lung involvement rarely occurs in nonsmokers with Goodpasture disease.

Complement

The complement system is often activated in glomerular disease (Fig. 16-7). Complement can be activated through three pathways. *Classical pathway* activation involves the binding of C1q to the Fc region of antibody in IgG- and IgM-containing immune complexes and can result in reduced serum C4 and C3. This is common in lupus nephritis, type I MPGN, and cryoglobulinemic MPGN. Complement may also be activated by the *alternative pathway,* which is activated independently of immune complexes and can be triggered by polysaccharide antigens, polymeric IgA, injured cells, bacterial products (e.g., streptococcal antigens), and antibodies to complement pathway components (C3 convertase). The alternative pathway appears to be activated in IgA nephropathy, DDD, and PSGN. Serum complement levels are generally normal in IgA nephropathy; in DDD and PSGN, however, the C3 is typically low but C4 is normal. In DDD the activation of the alternative pathway may not involve an antigen but rather results from continuous activation of the pathway through altered factor H or an IgG autoantibody (nephritic factor) that stabilizes the C3 convertase (see Chapter 22). Complement can also be activated through the *mannose-binding lectin* (MBL) *pathway* initiated by MBL, which has a similar structure to C1q. The role of the MBL pathway in GN is emerging in IgA nephropathy and idiopathic membranous nephropathy. However, despite evidence for intraglomerular complement activation in these conditions, major serum complement components such as C3 and C4 generally remain in the normal range.

Activation of the complement pathway has several consequences. Leukocyte recruitment is facilitated by the chemotactic factor C5a, and C3b binding is important in the binding and opsonization of the immune complexes by the infiltrating leukocytes. The terminal membrane attack complex of the cascade, C5b-9, inserts into cell membranes, where it can kill cells or activate them to secrete cytokines, oxidants, and extracellular matrix. C5b-9 likely has a role in mediating injury to the glomerular epithelial cell in membranous nephropathy, in which immune deposits and complement activation occur in the subepithelial space. Complement can also be activated

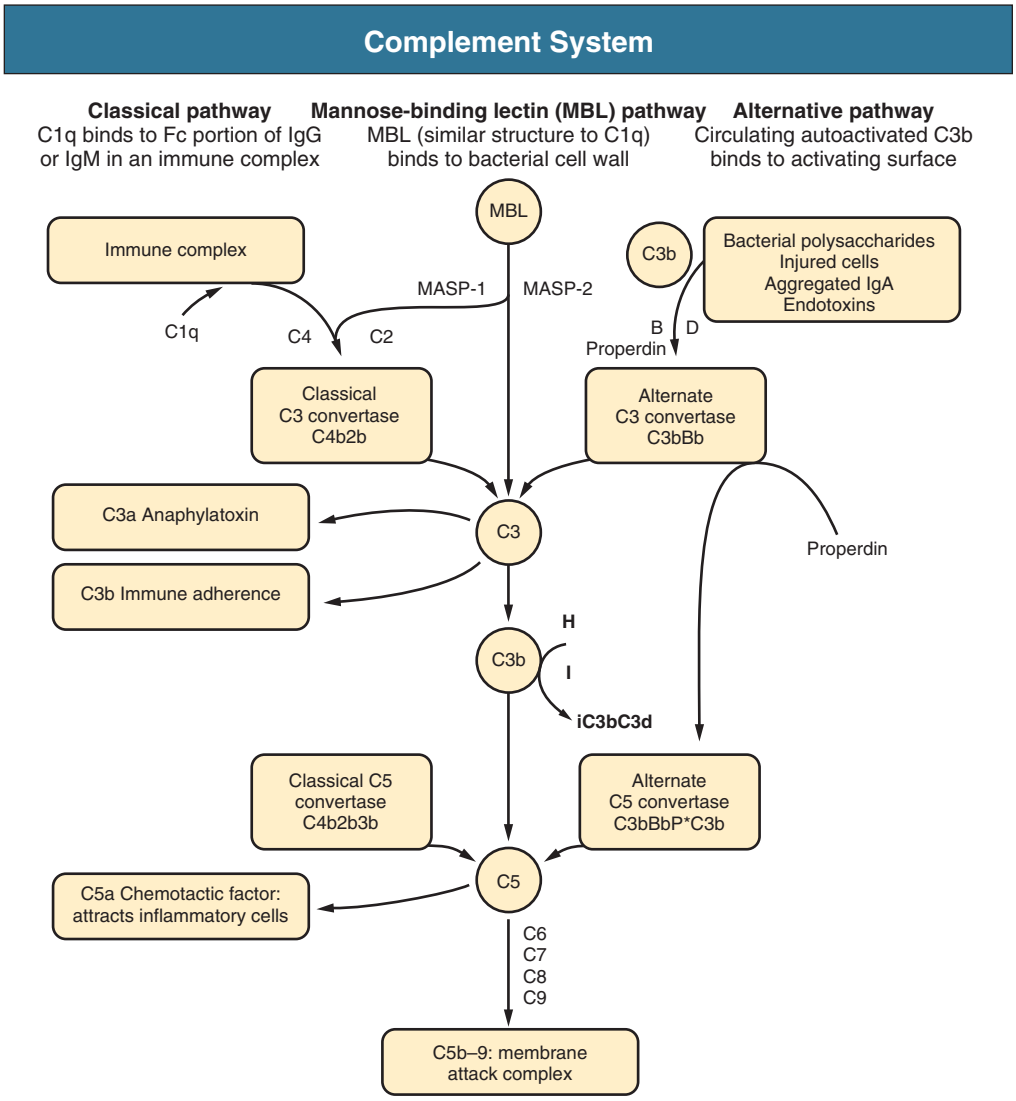

Figure 16-7 Complement system. The complement system is a self-amplifying cascade of proteins that generates a membrane attack complex, which is cytolytic; the cascade promotes inflammation by the activity of the fragments it produces. The amplifying cascades result from activated fragments of the components combining to make convertase enzymes that degrade C3 and C5. The complement cascade is controlled in part by the short active life of many of its components. There are also inhibitory regulatory proteins, most notably factors H and I inhibiting C3b. Activated fragments of any component are designated *b* (e.g., C3b); anaphylatoxic fragments are designated *a* (e.g., C5a). Inflammatory functions of complement components are shown in *green*. *MASP,* MBL-associated serine protease.

in proteinuric urine because of amidation of C3 by ammonia, which may have a role in mediating tubulointerstitial injury even in conditions not associated with immune complex formation. Experimental studies have emphasized the importance of local synthesis of complement components by the tubular cells as a mechanism that may augment this process.[11]

Activation of complement is controlled by complement regulatory proteins (Fig. 16-7). A genetic absence or malfunction of factor H or other regulatory proteins can result in increased susceptibility to glomerular endothelial injury, resulting in hemolytic uremic syndrome (HUS; Chapter 29) or less often in hereditary forms of GN (see Chapter 22).

Mechanisms of Immune Glomerular Injury

Two major mechanisms account for the presence of immune complexes in glomerular diseases. There may be ineffectual clearance of an antigen from an impaired immune response, as in chronic viral infections caused by hepatitis B or hepatitis C virus (HBV or HCV). Despite a strong humoral response, viral infection persists because the cell-mediated response required for elimination of these viruses is impaired. The consequence is a state of persistent antigenemia with circulating antigen-antibody complexes, which predisposes to glomerular injury. Eradication of the virus with antiviral therapy can be associated with remission of the glomerular disease.

More often, glomerular disease results from *autoimmunity*. In health, a tension exists between the normal immune response to foreign antigen and tolerance, which is the cellular process that prevents an immune response to self antigen. Tolerance develops because self-reactive T and B cells are clonally deleted during fetal and neonatal life, although small numbers survive outside the thymus or bone marrow, respectively. Under certain conditions, these peripheral self-reactive cells can be stimulated to generate a cellular and humoral response to a self antigen. Infection or toxins may play a role in initiating the response by releasing antigens from sequestered sites so they have access to dendritic cells (DCs), which carry the antigen to lymph nodes for presentation to T cells, by altering host proteins to make them more immunogenic, or by molecular mimicry, in which antibodies to an exogenous antigen (e.g., those present in infecting organism) cross-react with a native protein. Activation of T cells may be further enhanced by the release of cytokines or endogenous danger-associated molecular patterns, such as Toll-like receptor ligands or inflammasome activators, and the conversion of normally innocuous endogenous renal cells into antigen-presenting cells through the upregulated or *de novo* expression of human leukocyte antigen (HLA) class II molecules and cytokines.

Regulatory T cells ($CD4^+CD25^+$) have a key role in controlling T cell responses and preventing the development of autoimmunity. These cells are decreased in patients with Goodpasture disease at presentation and may play a role in the loss of tolerance. Indeed, in experimental anti-GBM nephritis, the administration of regulatory T cells reduces glomerular damage by blocking T cell–dependent renal injury.[12]

Variations in HLA molecules and the T cell receptor are under strong genetic influence. Close immunogenetic associations, particularly between HLA expression and various patterns of GN, have been described in IgA nephropathy, membranous nephropathy, and other glomerular diseases. For example, whereas HLA-DR2 identifies a powerful relative risk of the development of Goodpasture disease, some individuals can develop the disease without HLA-DR2, and the vast majority with HLA-DR2 never develop this rare disease. HLA associations also differ among various ethnic groups. To date, HLA associations have no practical diagnostic or therapeutic implications, and HLA typing is not needed in the clinical management of GN patients.

Inflammation

The presence of glomerular inflammation is largely determined by the site of immune deposits. Immune deposits with direct access to the circulation (subendothelial and basement membrane locations) are usually associated with leukocyte accumulation. Mesangial deposits elicit an intermediate response, whereas immune deposits in the subepithelial space generally are not associated with inflammatory cells.

In GN associated with subendothelial deposits, such as class IV lupus nephritis or MPGN, leukocyte infiltration is common. With acute injury, the predominant infiltrating cells are neutrophils, platelets, and monocytes, and in chronic injury, the predominant cells are monocyte/macrophages and T cells. The primary mechanism for attracting these cells is the secretion of chemokines and the expression of leukocyte adhesion molecules by local endothelial and resident cells; local release of complement activation fragments (C5a) is also important.

Although neutrophils are common with immune complex disease, cell-mediated immunity is important in some glomerular diseases. For example, T cells likely have a role in crescentic nephritis, becoming sensitized to endogenous or exogenous antigen and then recruiting macrophages that mediate crescent formation.

Proliferation, Apoptosis, and Fibrosis

Intrinsic glomerular cells (epithelial, mesangial, and endothelial) are also activated in various glomerular diseases. Mesangial cells can become myofibroblast-like cells that proliferate and produce excessive extracellular matrix. Endothelial cells produce nitric oxide and other anti-inflammatory proteins, and injury to this cell population can result in the expression of leukocyte adhesion molecules and activation of the coagulation system. Podocytes are terminally differentiated cells; injury may not only result in proteinuria (see earlier) but when associated with apoptosis, may also result in glomerulosclerosis. Important growth factors associated with glomerular injury include transforming growth factor β (TGF-β), which mediates matrix deposition; platelet-derived growth factor (PDGF), which mediates mesangial cell proliferation; and vascular endothelial growth factor (VEGF), required for endothelial health.

Crescent formation represents a severe cellular response and is initiated by cytokine-driven proliferation, particularly of the parietal epithelial cells. Local breaks in the GBM or Bowman capsule, mediated by activated leukocytes, are followed by macrophage infiltration, myofibroblast accumulation, and local fibrin deposition (Fig. 16-8).

Glomerular scarring is characterized by proliferation of mesangial cells with loss (apoptosis) of endothelial cells and podocytes. Tubulointerstitial fibrosis also accompanies progressive glomerular disease and correlates with both renal function and prognosis. Proteinuria has been shown to activate tubular cells and induce toxicity, either directly or through the generation of oxidants (from iron proteins excreted in urine) or from complement activation, which can be shown in proteinuric urine. Tubulointerstitial ischemia after loss of glomerular and peritubular capillaries may also drive fibrosis. Finally, loss of renal function may result from leakage of plasma ultrafiltrate into the peritubular space, resulting in a scarring response (misdirected filtration), or stenosis/occlusion of the opening of the proximal tubule from Bowman space, resulting in nonfunctional (atubular) glomeruli. A detailed discussion of current mechanisms involved in glomerulosclerosis is presented in Chapter 79. Specific

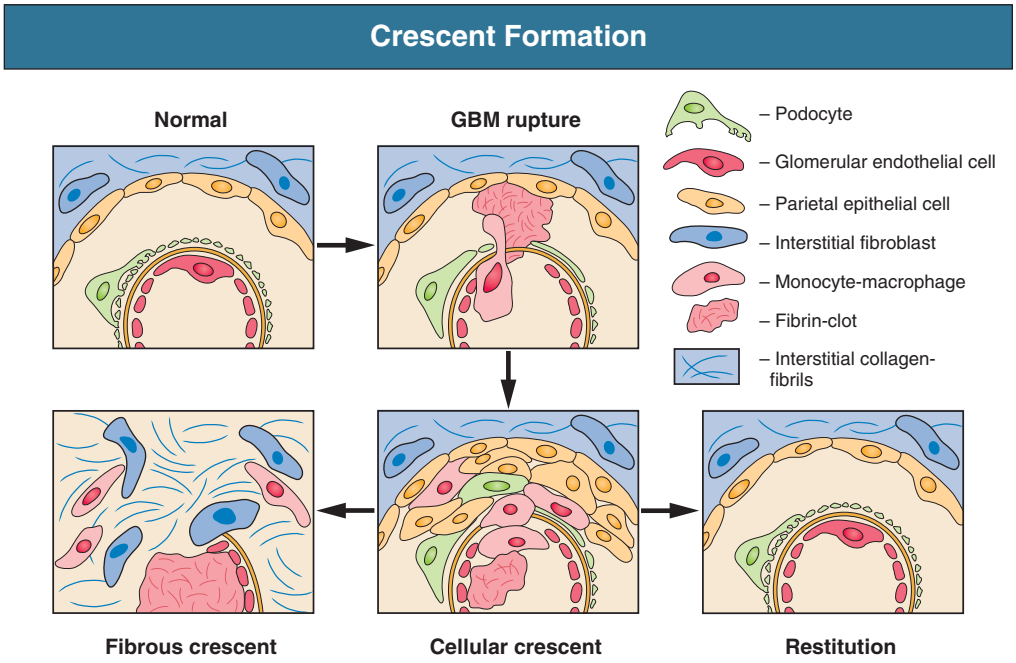

Figure 16-8 Crescent formation. In early crescent formation, cytokines and growth factors cross the glomerular basement membrane *(GBM)* to initiate proliferation of the parietal epithelial cells. Small breaks in the GBM occur secondary to injury from oxidants and proteases from neutrophils and macrophages, thus allowing the macrophage to enter Bowman space, where it can proliferate. Breaks in Bowman capsule secondary to the periglomerular inflammation also occur, allowing the entrance of more inflammatory cells as well as fibroblasts. The proliferation of parietal and visceral epithelial cells and macrophages is associated with fibrin deposition, slowly choking the glomerular tuft until filtration becomes impossible. In the late stages, the crescent becomes fibrotic and the glomerulus end stage. Alternatively, in less severe cases, complete restitution of the glomerular tuft can occur.

pathogenic mechanisms in the different patterns of glomerular disease are discussed in subsequent Section IV chapters.

PATHOGENESIS OF SPECIFIC GLOMERULAR SYNDROMES

Minimal Change Disease

Minimal change disease (MCD) is a steroid-sensitive nephrotic syndrome in which the only structural abnormality is podocyte swelling and fusion of foot processes on EM (see Chapter 17). For many years, the podocyte injury in MCD was thought to be caused by a cytokine released from T cells. T cells are activated in MCD, and T cell hybridomas from these patients secrete a factor that provokes heavy proteinuria in rats.[13] One candidate cytokine is interleukin-13 (IL-13), which is expressed by T cells in MCD patients, and overexpression of IL-13 causes nephrotic syndrome and histologic changes consistent with MCD in rats. However, proteinuria can be induced in immunodeficient mice using CD34-positive hematopoietic bone marrow cells of patients with MCD and recurrent FSGS but not by their T cells.[14] Thus, the role of T cells in this disorder remains to be clarified.

Evidence also suggests that the podocyte injury is associated with overexpression of angiopoietin-like-4, which may be responsible for the proteinuric response.[15] This overexpression can be reduced with corticosteroids and *N*-acetyl-D-mannosamine. In addition, patients with MCD show high levels of CD80 (B7.1) in urine and in podocytes, and the level of urinary CD80 correlates with disease activity. CD80 is an antigen that is normally expressed by DCs and B cells, and hence the observation that the podocyte can express CD80 suggests that the podocyte can acquire some DC-like characteristics.

Focal Segmental Glomerulosclerosis

Focal segmental glomerulosclerosis is a type of nephrotic syndrome that also occurs without immune deposits, but as with MCD, there is a generalized capillary wall defect with foot process fusion (also termed *effacement*) on EM (see Chapter 18). However, unlike MCD, there is segmental scarring (sclerosis) in some glomeruli with FSGS.

Idiopathic FSGS is also thought to be caused by a circulating factor, and recent studies suggest that some cases may be mediated by circulating soluble urokinase receptor (suPAR) that activates the β_3 integrin on podocytes, leading to podocyte activation and proteinuria.[16] The mechanism responsible for stimulating suPAR is unknown, and it is still too early to know if measuring suPAR will reliably discriminate FSGS from other glomerular diseases or even guide therapy. Other proteins, such as cardiotrophin-like cytokine 1, are also being investigated as potential circulating factors that may mediate FSGS.

A variant of FSGS is *collapsing* FSGS, in which there is proliferation of the normally quiescent podocyte, leading to collapse of the glomerular tuft, often in association with massive proteinuria. The pathogenesis may involve production by the podocyte of growth factors such as VEGF or local inhibition of cell cycle proteins that normally maintain the podocyte in a nonproliferative state.[17]

Focal sclerosing lesions in the absence of nephrotic syndrome can also occur in a wide variety of renal lesions, including GN, chronic hypertension, and progressive renal disease of any etiology. These lesions are particularly common in African Americans; recent findings suggest this susceptibility relates to increased frequency of a genetic polymorphism in *APOL1*, a gene coding for a circulating lipoprotein.

Membranous Nephropathy

In membranous nephropathy (MN), immune deposits are localized to the subepithelial space, where they had long been considered to represent autoantibody binding to an intrinsic podocyte antigen (see Chapter 20). This antigen has now been identified as the M-type phospholipase A_2 receptor (PLA_2R) in as many as 70% of cases of idiopathic MN.[18] Antibodies to PLA_2R are specific for MN and are available as a diagnostic test in Europe, although the test is not yet available in the United States or elsewhere. Circulating anti-PLA_2R reflects the immunologic activity of the disease and may be useful to monitor the clinical course, including patient response to treatment. Other autoantibodies have also been found. In neonatal MN, in which the mother genetically lacks neutral endopeptidase (NEP), the maternal transfer of antibody to NEP may occur, resulting in MN in

the child. Another antigen that may cause some forms of childhood MN is bovine serum albumin (BSA); cationic forms of BSA may first localize to the subepithelial space, followed by autoantibody binding.[19] Some cases of MN may also be caused by low-avidity immune complexes, which may dissociate and then re-form at the subepithelial space; this may be a mechanism for some MN caused by viruses such as HBV.

Interestingly, most cases of idiopathic MN caused by anti-PLA_2 antibodies are associated with IgG4 deposition, which is an isoform of IgG that does not activate the classical complement pathway. However, there is new evidence that the IgG4-PLA_2 complex can activate complement through the MBL complement pathway, resulting in local generation of the membrane attack complex (C5b-9), which may insert into the podocyte to cause activation, injury, and proteinuria.

Membranoproliferative Glomerulonephritis

In MPGN type I, the immune deposits localize both to the mesangium and the subendothelial space (see Chapter 21). A similar pattern is observed in cryoglobulinemic GN, in which the immune complexes contain a monoclonal IgM or polyclonal IgM that acts as a rheumatoid factor by binding to the IgG in the immune complex. In both cases, the disease is thought to occur by passive deposition from the circulation, and the antigen is often a component of the HCV virus, especially in adults. When this pattern is seen in lupus nephritis, it may be facilitated by the binding of nucleosomes to the complexes. *Nucleosomes* are cationic nuclear proteins that can interact with the negatively charged proteins within the glomerulus.

Studies in experimental models suggest that the intraglomerular immune complexes cause local complement activation with the generation of chemotactic factors, including C5a, chemokines, and leukotrienes. Leukocyte adhesion molecules on endothelial cells are upregulated (intracellular adhesion molecule 1) or expressed *de novo* (E- and P-selectin). Proinflammatory cytokines (IL-1 and tumor necrosis factor α) are generated locally and augment the inflammatory response. Neutrophils, platelets, and monocytes/macrophages then localize in the glomerulus and release oxidants, particularly hypohalous acids generated by neutrophil myeloperoxidase, and proteases (elastase, cathepsin G, metalloproteinases) that cause local cellular injury and GBM degradation.

Dense Deposit Disease

In contrast to MPGN type I, immune complexes are absent in glomeruli of patients with DDD, also called MPGN type II. Initiation results from spontaneous intraglomerular activation of the alternative complement pathway. The most common cause is nephritic factor, an autoantibody that activates the alternative pathway. Some cases may also be caused by mutations of the complement regulatory factor H, in which case the location of the mutation within the gene determines whether the disease manifests as DDD or atypical HUS.[20]

Mesangial Proliferative Glomerulonephritis

A mesangial proliferative GN, IgA nephropathy is the most common type of glomerulonephritis (see Chapter 23). Production of an abnormally glycosylated IgA, possibly by a bacterial superantigen,[21] or from generalized mucosal hyperreactivity, may lead to IgA polymers that deposit in the mesangium; the glomerular capillary wall is relatively spared. Marked proteinuria is a common feature of the clinical presentation. Mesangial cell injury may be mediated by binding of the IgA-containing immune complexes to Fcα or other IgA receptors on the mesangial cell, resulting in the release of chemokines and growth factors that provokes leukocyte infiltration as well as mesangial cell proliferation and mesangial matrix production.

Poststreptococcal Glomerulonephritis

Poststreptococcal GN has long been considered the human equivalent of acute serum sickness in rabbits (see Chapter 57). It is observed only in patients infected with specific (nephritogenic strains) of group A streptococci. One antigen responsible for some cases of PSGN, streptococcal pyrogenic exotoxin B (SPEB), enters the circulation and localizes to glomeruli, resulting in a brisk inflammatory reaction with local endothelial and mesangial cell proliferation and manifestations of nephritic syndrome. Complement activation occurs through the alternative pathway and may result from direct activation of the pathway by streptococcal antigens. Some deposits ("humps") also form in the subepithelial space and may represent the translocation of immune complexes across the GBM.

Goodpasture Disease

Goodpasture disease (anti-GBM disease) is caused by an autoantibody to the α3 chain of type IV collagen present in the GBM and alveolar basement membrane (see Chapter 24). The autoantibody develops in genetically susceptible individuals because of molecular mimicry between the type IV collagen antigens and certain bacterial antigens.[8] Binding of antibody results in complement activation with the infiltration of inflammatory cells, causing local capillary wall damage and proteinuria. Crescent formation also usually occurs and may be mediated by both T cells and macrophages.

ANCA-Associated Vasculitis

A severe form of segmental necrotizing glomerular injury, often in association with crescents, can be observed with various types of vasculitis (see Chapter 25). The two most common types of vasculitis causing this type of injury are Wegener granulomatosis and microscopic polyangiitis (MPA). Both are associated with circulating antibodies against neutrophil cytoplasmic antigens (ANCAs), with antibodies to endopeptidase (proteinase) 3, which give a cytoplasmic pattern by staining (c-ANCA) in most patients with Wegener granulomatosis, and antibodies to myeloperoxidase, which give a perinuclear staining pattern (p-ANCA) in subjects with MPA. Although experimental evidence suggests that ANCAs are pathogenic by activating neutrophils within the vasculature, pathogenic autoantibodies to lysosome-associated membrane protein 2 (LAMP-2) may have a role in some types of vasculitis.[9] LAMP antibodies appear to develop from molecular mimicry with various bacteria and viruses and when injected into rats results in crescentic nephritis. The clinical value of measuring LAMP autoantibodies is not yet clear.

There is further discussion of specific pathogenic mechanisms in the different patterns of glomerular disease in Chapters 17 to 29.

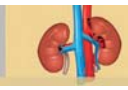
CHAPTER 17



Minimal Change Nephrotic Syndrome

Philip D. Mason and Peter F. Hoyer

DEFINITION

Minimal change disease (MCD) is the cause of nephrotic syndrome in about 90% of children younger than 10 years, about 50% to 70% of older children, and 10% to 15% of adults. MCD is defined by the absence of histologic glomerular abnormalities, other than ultrastructural evidence of fusion of epithelial cell foot process, in a patient presenting with nephrotic syndrome who is typically corticosteroid responsive. *Corticosteroid-sensitive nephrotic syndrome* is the term used to describe the disease occurring in children with nephrotic syndrome who respond to corticosteroids but who have not had a renal biopsy to provide the histologic proof of MCD. The presence of nephrotic syndrome is important because similar histologic findings may be seen in patients with proteinuria in the absence of nephrotic syndrome. Such patients may have different conditions with different prognoses and requirements for management.

Whereas MCD is classically associated with normal-appearing glomeruli and corticosteroid responsiveness, MCD appears to overlap with a variety of histologic variants that have a tendency to be less corticosteroid responsive. These conditions include focal segmental glomerulosclerosis (FSGS; see Chapter 18) and IgM nephropathy (see later discussion). It is possible that both MCD and FSGS have similar initial histologic appearances, but that FSGS is less corticosteroid responsive and thus develops secondary sclerosing lesions over time. Whether this represents a continuum of the same disease, in which some patients are corticosteroid sensitive and others are not, or whether these represent two distinct etiologies remains debatable.

ETIOLOGY AND PATHOGENESIS

In children age 2 to 12 years, MCD is the most common cause of nephrotic syndrome. However, it is also relatively common in adults. Many patients have a history of allergy, including atopy, asthma, or eczema (Box 17-1). Most cases are idiopathic, but MCD has also been associated with certain cancers, especially Hodgkin disease, in which it may be the presenting symptom. MCD is further associated with certain medications, such as interferon alfa and nonsteroidal anti-inflammatory drugs (NSAIDs).

The primary abnormality in MCD is a defect in the glomerular filtration barrier to protein. In normal glomeruli, the barrier to protein filtration is provided by the glomerular basement membrane (GBM) and the slit diaphragm that extends between the podocyte foot processes. Size barriers and charge selectivity of GBM exclude neutral molecules larger than 4 to 4.5 nm from filtration; albumin molecules smaller than this are excluded because they are anionic and are repelled by the negative charge on the epithelial cells and GBM.

In MCD, FSGS, and other causes of nephrotic syndrome, the clearance of proteins becomes greatly enhanced, whereas the filtration of small molecules is actually reduced. Some authorities have attributed the reduction in small molecular clearance to the diffuse foot process fusion, which reduces overall slit diaphragm area and thereby may account for the reduction in the ultrafiltration coefficient (K_f, see Chapter 2) typically observed. In contrast, the albuminuria is thought to result from specific areas ("large pores") where the protein escapes into the urine.

Studies in nephrotic syndrome have implicated injury to the podocyte, and particularly the slit diaphragm, as the key factor leading to proteinuria. The importance of the slit diaphragm for nephrosis was first shown with the congenital nephrotic syndrome of the "Finnish type," in which the primary defect is a mutation in nephrin, a key protein in the slit diaphragm. In particular, this nephrotic syndrome can histologically and clinically appear identical to MCD, except that it typically begins shortly after birth and is corticosteroid resistant (see Chapter 19). Since the discovery of the etiology of this nephrotic syndrome, numerous other genetic causes of nephrotic syndrome have been identified. All have mutations in genes involved in the development, structure, and function of podocytes (*NPHS2, NPHS3, WT1, LAMB2, LMXI2, ACTN4, CD2AP, TRPC6,* and *INF2*) and mitochondrial proteins (e.g., *COQ2, PDSS2, GMS1*).

As evidence for involvement of a primary podocyte abnormality, MCD is associated with expression of CD80 (B7.1) on the podocyte, and shed CD80 can be found in the urine of patients with MCD.[1] CD80 expression by podocytes is associated with shape change and development of proteinuria. Reduced levels of dystroglycans (adhesion molecules believed to anchor podocytes to GBM) have also been reported in MCD but not in FSGS, with normalization after corticosteroid treatment.[2] Podocyte overexpression of angiopoetin-like-4 *(ANGPTL4)* has been shown to bind to the GBM, with loss of charge and associated with nephrotic-range proteinuria. Furthermore, supplementation with *N*-acetyl-D-mannosamine may improve proteinuria, suggesting that hyposialysated *ANGPTL4* may be responsible for inducing proteinuria and may be a therapeutic target.[3]

Others have proposed that the permeability defect is caused by alterations in the GBM, particularly a loss of negative charge. In this case, podocyte changes could be secondary to the proteinuria. This would be consistent with observations of preserved foot processes in the early phase of some highly proteinuric states (e.g., recurrent FSGS after renal transplantation) and of podocyte foot process fusion in children with severe hypoalbuminemia, but not proteinuria, dying of kwashiorkor.[4]

Evidence also suggests that a circulating factor may be responsible for inducing the alteration in the capillary wall. *Hemopexin,* an acute-phase reactant extracted from human plasma, is capable of inducing proteinuria in rats,[5] and in one small study, plasma hemopexin activity was increased in MCD patients in relapse, with evidence of an altered isoform.[6] Evidence of a circulating factor in humans is also supported by the observation that proteinuria resolved within days after transplantation from a cadaveric donor

Minimal Change Disease: Factors Associated with Onset of Nephrotic Syndrome

Drugs
Nonsteroidal anti-inflammatory drugs (NSAIDs)
Interferon alfa
Lithium: rare (usually causes chronic interstitial nephritis)
Gold: rare (usually causes membranous nephropathy)

Allergy
Pollens
House dust
Insect stings
Immunizations

Malignancy
Hodgkin disease
Mycosis fungoides
Chronic lymphocytic leukemia: uncommon (usually associated with membranoproliferative glomerulonephritis)

Box 17-1 Factors associated with onset of nephrotic syndrome in patients with minimal change disease.

Frequency of Types of Nephrotic Syndrome in Children and Adults

Histology	Children	Adults	Zimbabwe	Durban
MCD	76	20	9.2	14
FSGS	8	15	15.1	28
MN	7	40	15.1	41*
MPGN	4	7	33.6	9
Other	5	18	17.0	5

Table 17-1 Frequency of various types of nephrotic syndrome. In annual incidence per 1 million population, in children and adults, from Europe, the United States, and Africa. *MCD,* Minimal change disease; *FSGS,* focal segmental glomerulosclerosis; *MN,* membranous nephropathy; *MPGN,* membranoproliferative glomerulosclerosis. *35 with hepatitis B virus infection. *(Data from references 13, 14, and 15.)*

with MCD.[7] Evidence for a T cell abnormality includes the absence of immune deposits, the remarkable sensitivity of the disease to corticosteroids and cyclosporine, the relationship with Hodgkin disease, and the reports that active measles infection (which depresses cell-mediated immunity) can rapidly induce remission. Studies have shown that T regulatory cells are abnormal in MCD patients, and that generalized activation of T cells occurs during active disease.

Some studies have also implicated interleukin-13 (IL-13) released from T cells in causing the proteinuria, because T cell production of IL-13 is elevated, and overexpression of IL-13 can induce nephrotic syndrome in rats.[8] Interestingly, the mechanism involved the induction of CD80 in the podocyte. IL-13 is also a cytokine associated with allergic states, and MCD can be triggered by vaccination[9] or exposure to an allergen in sensitive individuals. As a result, patients with identified food allergies have been managed with exclusion diets, with reported complete or partial remission and with relapse after reintroduction of the offending food. However, even if a relationship exists, the allergic events may merely trigger relapse, as may infections. B cell involvement was based on some patients' response to rituximab, which binds to CD20 found on B cells. Recently, however, CD20 expression has been demonstrated on podocytes and may be upregulated in abnormal circumstances, and rituximab may also interact with podocyte sphingomyelin phosphodiesterase–like 3 protein.[10] Bisphosphonate therapy may lead to proteinuria, possibly through interference with the podocyte cytoskeleton.

Although steroids are first-line treatment for patients with MCD, the mechanism is unclear, and the optimal dose has never been formally tested. Previous studies describe an association between risk of relapse and suppression of the hypophyseal-adrenal axis.[11] Recent studies report melanocortin-1 receptors on podocytes and, interestingly, a significant reduction of proteinuria with adrenocorticotropic hormone (ACTH) therapy.[12]

EPIDEMIOLOGY

Most frequently presenting between 2 and 7 years of age, MCD affects 2 to 7 per 100,000 children per year, with a prevalence of 15 per 100,000. MCD is also an important cause of nephrotic syndrome in adults of all ages, although the incidence varies geographically. MCD is reported to be as low as 1 per million of the population in the United Kingdom and up to 27 per million in the United States. It is more common in South Asians and Native Americans but is much rarer in African Americans, in whom nephrotic syndrome is much more likely to be caused by FSGS and to be corticosteroid resistant. MCD is also relatively rare in developing countries, such as most countries in Africa and South America[13-15] (Table 17-1). Boys are twice as likely to be affected as girls, but the gender incidence is comparable in adolescents and adults. Data also suggest that MCD has become less common in adults.[16]

CLINICAL MANIFESTATIONS

Patients with MCD typically present with edema that develops during days to weeks, with fluid retention that often exceeds more than 3% of the body weight. Up to two thirds of initial presentations and relapses follow an infection, most often of the upper respiratory tract, but whether these are of causative significance is uncertain.

The clinical signs and symptoms of MCD are the same as for nephrotic syndrome of any cause (see Chapter 15), although nephrotic syndrome is often of rapid onset, increasing the risk of hypovolemia, particularly in children. Ascites is common, particularly in children with MCD, who may present with abdominal pain, a symptom that may suggest peritonitis or herald hypovolemia. Pleural effusions may also occur but are less common. In rare patients, pericardial effusions may occur, but even more rarely cause significant complications. Pulmonary edema is uncommon, except after excessive treatment with albumin or with coexisting cardiac disease. Hepatomegaly is common in children but may be overlooked in the presence of ascites. The distribution of edema is gravitational, but facial puffiness is common, and genital swelling may be extremely uncomfortable, especially in men. Gross edema may predispose to ulceration and infection of dependent skin; striae often appear even without corticosteroids, and lacerations or needlestick punctures weep fluid profusely. Edema of the bowel wall may cause diarrhea, rarely with significant albumin loss from the gut. Other clinical features include white nails, sometimes in bands (Muehrcke lines) correlating with periods of clinical relapse (see Fig. 15-4). In adults, xanthomas may occasionally result in association with gross hyperlipidemia.

Microscopic hematuria is rare in MCD. Although not typical in children, hypertension has been observed at presentation in 30% of 89 adults in one UK study.[17] Higher-than-normal blood pressure has also been described in 14% to 21% of children, compared with appropriate age- and gender-matched blood pressure reference ranges. Hypertension usually resolves during remission, especially in children. Hypertension is sometimes associated with expansion of the intravascular volume but may paradoxically be related to hypovolemia and stimulation of the renin-angiotensin system (RAS).

Before the introduction of corticosteroids, the morbidity and mortality of patients with MCD were high because of complications of nephrotic syndrome, particularly infection. Infection continues to be a serious problem, particularly in those presenting late.[18] Six of 389 children with MCD described by the International Study of Kidney Disease in Children (ISKDC) in 1984 died of sepsis.[19] Peritonitis remains a major cause of mortality in the developing world, mainly in children. *Streptococcus pneumoniae, Haemophilus influenzae,* and other encapsulated bacteria are implicated. Children with frequently relapsing nephrotic syndrome should be immunized against *S. pneumoniae* and *H. influenzae* during remission and given prophylactic oral penicillin in relapse.[20] Peritonitis is rare in adults, who usually have protective antibodies against these bacteria, and prophylactic antibiotics are not indicated.

The risk of thromboembolism is increased in MCD, as in all patients with nephrotic syndrome (see Chapter 15). Venous thromboembolism may occur in the lower extremities, renal veins, and other sites. Pulmonary embolism may be overlooked in children because of a lack of suspicion, even with pulmonary symptoms, and children may compensate better than adults. Nephrotic children occasionally have other catastrophic events, such as intracerebral venous or sinus venous thrombosis. Arterial thrombosis is a rare but feared complication, described in children almost exclusively, and may even result in loss of limbs.

Renal function is generally preserved. Serum creatinine concentrations are usually low in children but can be slightly elevated in adults. Acute kidney injury is a complication particularly seen in adults. AKI may follow hypovolemia, which should be avoided especially during intensive diuretic treatment, but it may also rarely occur in volume-replete patients.

Secondary MCD may mimic idiopathic MCD and may result from drugs or with cancer. The classic drugs associated with MCD are NSAIDs and particularly fenoprofen. This is an idiosyncratic reaction and is usually associated with chronic NSAID use that has occurred for several weeks or months. Unlike classic MCD, this syndrome is usually associated with massive nephrotic syndrome with impaired renal function, and renal biopsy shows MCD with features of an acute interstitial nephritis with T cell infiltration. Other causes of secondary MCD, such as the use of interferon alfa or interferon beta, or MCD observed in Hodgkin disease, may appear clinically identical to idiopathic MCD.

PATHOLOGY

Classically, MCD is associated with normal-appearing glomeruli by light microscopy and is negative for immunoglobulins and complement by immunofluorescence or other methodologies. Podocyte (epithelial cell) foot process effacement is observed with electron microscopy (Fig. 17-1) and is the only abnormality, but this is a nonspecific finding. The tubulointerstitium will show an absence of inflammation. Hyaline casts obstructing tubules, rare foam cells, and occasionally appearances consistent with acute tubular necrosis may be seen, especially if acute kidney injury is present at the time of biopsy.

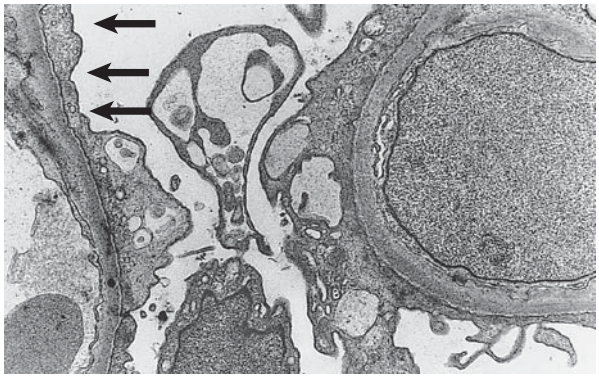


Figure 17-1 Podocyte foot process fusion in minimal change disease. The epithelial cells *(arrows)* are completely effaced along the glomerular basement membranes. (Electron micrograph; magnification ×6000.) The normal appearance of epithelial cell foot processes is shown in Figures 1-6 and 1-7 (see Chapter 1).

Variants

Mild mesangial hypercellularity is an infrequent finding in MCD patients (3% to 5%), and small amounts of mesangial IgG, complement C3, and occasionally IgA may be observed in patients whose clinical course is indistinguishable from classic MCD.

The *glomerular tip lesion* describes structural segmental changes adjacent to the tubular pole of Bowman capsule, with protrusion into the tubular lumen. This lesion is observed more frequently in adults than children, but whether it is a variant of MCD or a type of FSGS remains controversial. Generally considered a benign lesion, it may also be rarely observed in membranoproliferative glomerulonephritis, IgA nephropathy, and renal allografts. The most important reason to recognize the glomerular tip lesion is to prevent a misdiagnosis of a proliferative glomerulonephritis.

The presence of *mesangial hypercellularity* in MCD may correlate with increased resistance to corticosteroid therapy.[21] Some consider mesangial hypercellularity to be an intermediate step in cases of evolution (progression) of MCD to FSGS (see Chapter 18).

IgM Nephropathy

Some patients presenting with nephrotic syndrome have mesangial deposits of IgM, often with a minor degree of mesangial hypercellularity. Patients are more likely to have microscopic (and occasionally macroscopic) hematuria and are also less likely to respond to corticosteroids (50% versus 90% for minimal change nephrotic syndrome).[22] Whether this represents a distinct entity or is part of the spectrum observed with MCD and FSGS remains uncertain (see also Chapter 18).

Focal Segmental Glomerulosclerosis

Some patients who are considered to have MCD by renal biopsy may not respond to corticosteroids and on repeated biopsy are found to have FSGS. Others who initially are responsive to corticosteroids eventually become resistant and are discovered to have FSGS on a subsequent biopsy. This has led some to suggest that MCD and FSGS are part of a spectrum of the same disease process. However, the initial biopsies may have missed the sclerotic lesions of FSGS because they are focal.

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

The clinical diagnosis of nephrotic syndrome is straightforward, with edema in the presence of heavy proteinuria, usually without microscopic hematuria on urine dipstick testing. Urine microscopy reveals hyaline casts and sometimes lipid casts. There is hypoalbuminemia (<2.5 g/dl) and nephrotic-range proteinuria (>3.5 g/24 h in adults or >1 g/m^2/24 h [>40 mg/m^2/h] in children) or a protein/creatinine ratio of more than 0.25 g/mmol (>2 mg protein/mg creatinine) on a spot urine sample. Hyperlipidemia is also a common laboratory finding. Hyponatremia and hemoconcentration may be seen, even before treatment. Elevated urea and creatinine concentrations occur more often in adults. Typically, serum IgG levels are low and IgM is increased. Serum complement levels are normal.

In children, corticosteroid-sensitive MCD is usually associated with selective proteinuria of smaller molecules, including albumin and transferrin, but not of larger molecules, such as immunoglobulins and ferritin. A selectivity index is usually derived from the ratio of IgG clearance to albumin clearance, as follows:

$$\text{Selectivity index} = [(\text{IgG})_u(\text{albumin})_s]/[(\text{IgG})_s(\text{albumin})_u]$$

where subscript *u* is concentration in urine and *s* is that in serum. If the selectivity index is less than 0.1, the proteinuria is highly selective, and if more than 0.2, is nonselective. This is of limited clinical value because highly selective proteinuria is less common in adult MCD and does not influence the decision to treat with corticosteroids. However, highly selective proteinuria, when present, does indicate that MCD is more likely to be the diagnosis, and some argue that such patients should be given a trial of corticosteroids without a renal biopsy, especially if the risk of biopsy complications is high.

In children from the Northern Hemisphere age 2 to 12 years, renal biopsy is unnecessary unless the patient does not respond to a standard prednisone treatment of 60 mg/m^2/day within 4 weeks. In Africa and South America, the prevalence is lower. In this setting, a trial of corticosteroids might depend on the frequency of MCD in this region and should also consider the higher risk of infections.

In adults, in whom there is a wide differential diagnosis for nephrotic syndrome and corticosteroid responsiveness is less likely, a renal biopsy is required to establish the diagnosis.

On occasion, a renal biopsy may histologically appear like MCD, but there is another cause. In patients with nephrotic syndrome, this may be caused by FSGS in which the sclerotic glomeruli are not sampled. In young children, it could result from a hereditary nephrotic syndrome resembling MCD (see Chapter 19). Rarely, early membranous nephropathy will have a light microscopy appearance of normal glomeruli, but immunofluorescence will reveal immune deposits. Early amyloidosis may also mimic MCD histologically in the adult. In non-nephrotic subjects, diseases such as thin basement membrane disease can appear histologically normal but can be diagnosed by demonstration of the thin GBM on electron microscopy.

Natural History

Patients with MCD tend to run a relapsing-remitting course, which is more common in children. Those presenting at a younger age are more likely to have more relapses and a longer disease course (Fig. 17-2).[23] Relapse is common, affecting more than two thirds of children, and about 50% will relapse more than four times, usually after corticosteroid cessation or reduction. If relapse occurs during corticosteroid reduction, the patient is described as "corticosteroid dependent." Long-term remission can be expected in 75% of initial responders who do not relapse within 6 months; those who do relapse become nonrelapsing after an average of 3 years, and 84% are in long-term remission after 10 years.[24] Indeed, it is reassuring that less than 5% of children with MCD enter adulthood still having relapses, although the younger the age at onset of the first attack, the longer the child is likely to continue having relapses.[23,25] In general, increasing time since last relapse reduces the risk of further relapse, but adults occasionally have a relapse after an interval of 10 years or more.

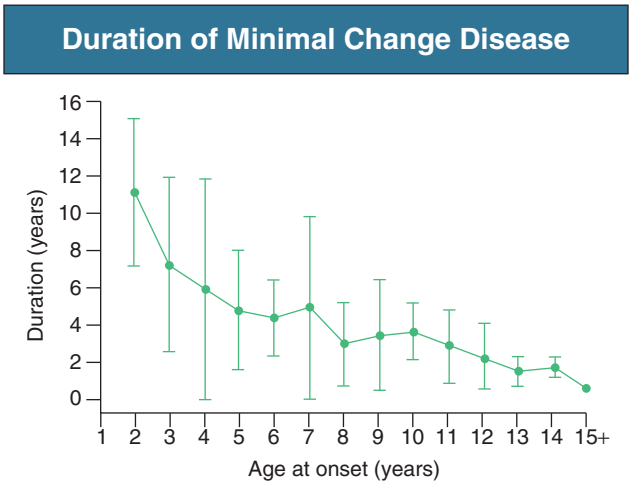

Figure 17-2 Long-term outcome in childhood-onset minimal change disease. The duration of disease is inversely related to the age at presentation. *(Modified from reference 23.)*

Minimal change disease does not progress to renal failure. However, a number of adult patients, but fewer children, with an initial diagnosis of MCD are found to have FSGS on subsequent biopsies and may develop progressive renal failure. It is still unclear whether the focal nature of the disease caused the correct diagnosis to be missed on the initial biopsy, or whether evolution from MCD to FSGS occurs in some individuals.

TREATMENT

Definitions that Guide Treatment

Table 17-2 provides key definitions related to the clinical response of MCD to treatment that are used to guide therapy.[26] For example, patients who relapse more than three times within 1 year are considered *frequently relapsing,* whereas those who respond to corticosteroids but relapse before discontinuation are considered *corticosteroid dependent.* Patients who remain proteinuric despite a course of corticosteroids are considered *corticosteroid resistant.* Stratification of patients into their category can help in management (see later discussion). Our recommendations are consistent with those published by the recent Kidney Disease: Improving Global Outcomes (KDIGO) guidelines,[27] although most of these are based on rather low levels and grades of evidence.

Initial Treatment of Minimal Change Disease

Initial management of MCD includes standard management of nephrotic syndrome as discussed in Chapter 15, including low-sodium diet to control edema. Bed rest should be avoided because of the increased risk for thrombosis. Diuretics are infrequently used in children because of potential further volume depletion, but

Nephrotic Syndrome: Definitions		
	Definitions	
Term	***Adult***	***Pediatric***[17,18]
Relapse	Proteinuria ≥3.5 g/day occurring after complete remission obtained for >1 month	Albu-stix 3+ or proteinuria >40 mg/m²/h occurring on 3 days within 1 week
Frequently relapsing Complete remission	2+ relapses within 6 months Reduction of proteinuria to ≤0.20 g/day and serum albumin >35 g/l	2+ relapses within 6 months <4 mg/m²/h on at least 3 occasions within 7 days; serum albumin >35 g/l
Partial remission	Reduction of proteinuria to between 0.21 g/day and 3.4 g/day ± decrease in proteinuria of ≥50% from baseline	Disappearance of edema; increase in serum albumin >35 g/l and persisting proteinuria >4 mg/m²/h or >100 mg/m²/h
Steroid resistant	Persistence of proteinuria despite prednisone therapy, 1 mg/kg/day × 4 months	Persistence of proteinuria despite prednisone therapy, 60 mg/m² × 4 weeks*
Steroid dependent: nephrotic syndrome recurs when therapy stopped or decreased	Two consecutive relapses occurring during therapy or within 14 days of completing corticosteroid therapy[19]	Two relapses of proteinuria within 14 days after stopping or during alternate-day corticosteroid therapy

Table 17-2 Definition of terms used in idiopathic nephrotic syndrome in adults and children. The definitions were generated by a consensus of the International Society for Kidney Diseases in Children and the German Pediatric Nephrology Society. *(Data from reference 26.)* *Or persistence of proteinuria despite prednisone therapy (60 mg m^{-2} × 4 weeks) and three methylprednisolone pulses.

diuretics are often used to control extracellular fluid volume in adults, in whom hypovolemia before treatment is less common. In patients with prolonged nephrotic syndrome, treatment of hyperlipidemia with statins and thrombosis prophylaxis should be considered.

Childhood Minimal Change Disease

Treatment of First Episode

Corticosteroids are the initial treatment of choice (see algorithm, Fig. 17-3), although never formally tested in a trial setting, with experiences based on the empiric regime introduced by ISKDC consensus. Accordingly, children age 2 to 12 years with a first episode of nephrotic syndrome should be treated with oral prednisone (or prednisolone), 60 mg/m²/day (maximum dose 80 mg/day), in three divided doses (calculated on basis of estimated dry weight). With this regimen, about 75% respond within 2 weeks, and almost all who are corticosteroid sensitive respond within 4 weeks[28] (Fig. 17-4). Patients who do not respond within the period are regarded as *nonresponders.*[22] Whereas the ISKDC recommended continuing the daily dose for 4 weeks, later studies recommend 6 weeks.[29] This daily dose should be followed by an alternate-day dose of 40 mg/m²/48 h for an additional 4 weeks (ISKDC) or 6 weeks.[30] A meta-analysis showed that extending the duration of corticosteroid treatment to at least 3 months reduces the 1- to 2-year risk of relapse (Fig. 17-5).[31] However, a recent randomized controlled trial compared an initial treatment period of 3 months with 6 months with both groups receiving the same cumulative dose of steroid. There was no difference in the relapse rate, so the benefit of an extended duration of steroid therapy previously reported is likely to be explained by an increased cumulative dose.[32]

The German Society for Pediatric Nephrology recommends stopping corticosteroid treatment for the first episode after 12 weeks; others recommend tapering (e.g., reducing every 2 weeks by 15 mg/m² on alternate days). Although these two regimens have never been compared, we do not recommend tapering because of concerns about chronic corticosteroid use affecting growth.

Treatment of Relapses

The urine should be tested daily (usually by a parent) during and after treatment. The rationale is that relapses should be treated on the basis of proteinuria (usually requiring at least three or more positive dipstick measurements for 3 consecutive days) to initiate a further course of corticosteroids. The aim is to treat relapse early to avoid nephrosis-associated complications. The intensity of corticosteroid treatment for relapses has not been shown to influence the probability of further relapses.

Our recommendation is oral prednisone, 60 mg/m²/day (maximum dose 80 mg/day) in three divided doses, until the urine is protein free for 3 days, followed by a course of alternate-day prednisone, 40 mg/m²/48 h for 4 weeks, then stop. An alternative recommendation is to taper the alternate dose during weeks to months to define a relapse threshold. However, the acceptability of this approach depends on the corticosteroid threshold, and there is risk of unnecessarily prolonged treatment with more corticosteroid toxicity.

Frequently Relapsing and Corticosteroid-Dependent Nephrotic Syndrome

For both frequently relapsing and corticosteroid-dependent nephrotic syndrome, second-line therapy is required. The second-line drugs most frequently used to avoid corticosteroid toxicity are alkylating agents (cyclophosphamide and chlorambucil), levamisole, and cyclosporine. The decision to use second-line therapy for chronically relapsing patients will depend on how quickly corticosteroid-induced remission occurs and how corticosteroids are tolerated. However, corticosteroid dependency is a clear indication for second-line treatment, which should be started before severe corticosteroid toxicity is apparent. The patient or parents usually are involved in the decision after the potential side effects of the second-line treatment are considered.

The alkylating agent *cyclophosphamide* is the recommended first choice of second-line therapy. Oral cyclophosphamide, 2 to 2.5 mg/kg/day, is given for 12 weeks, on the basis of a study suggesting a lower 2-year remission rate compared with an 8-week course,[33] although these results have not been supported by all published data.[34] Cyclophosphamide can be associated with serious side effects, initially infection and alopecia, and subsequently sterility,[35] hemorrhagic cystitis, bladder cancer, and hematologic malignant neoplasia. However, if therapy is limited to 12 weeks with 2 mg/kg/day, or a total dose of 200 mg/kg, the risk of these complications is low. Others suggest that cyclophosphamide should not be used in younger children (<5.5 years), in whom it is associated with a reduced duration

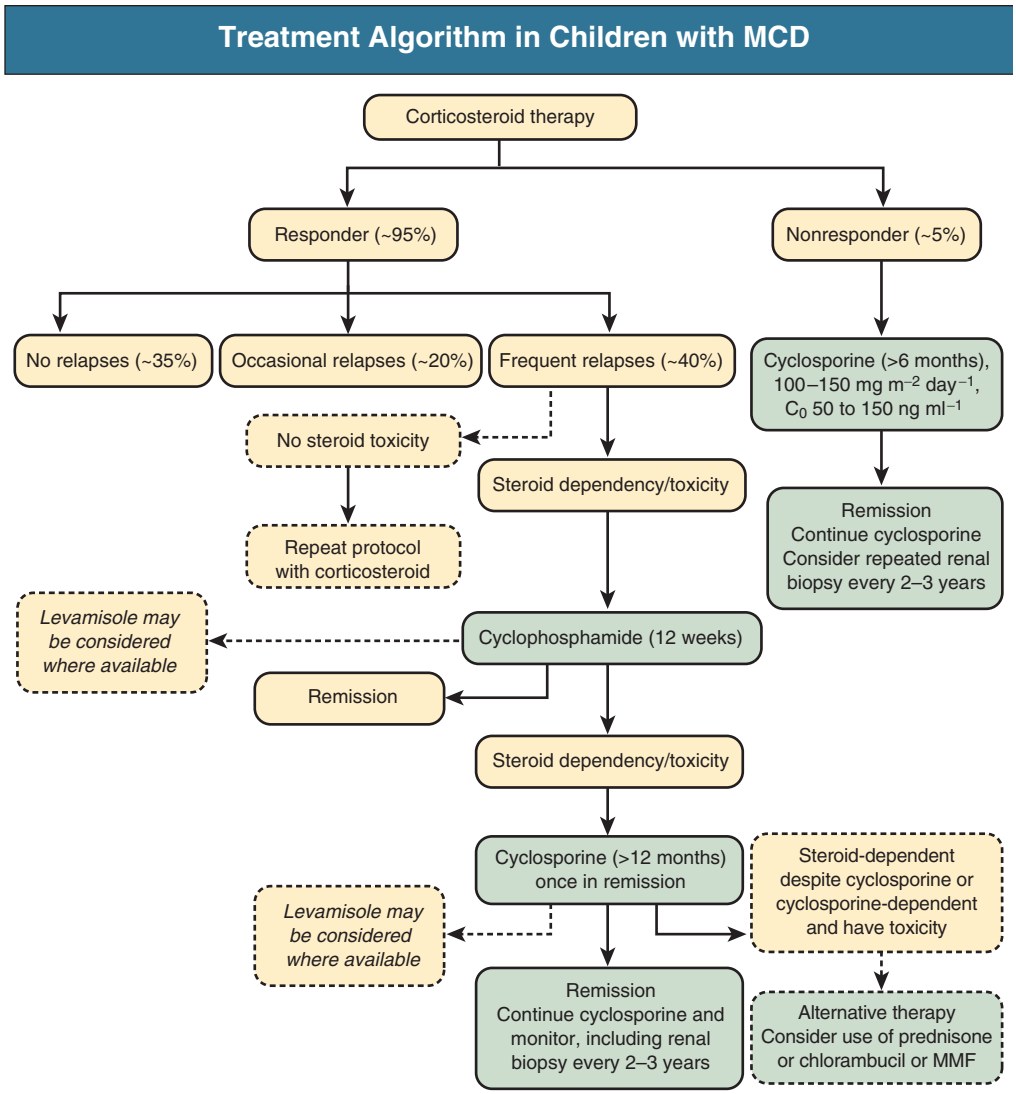

Figure 17-3 Algorithm for treatment of childhood minimal change disease (minimal change nephrotic syndrome). For definitions, see Table 17-2. The patient or parents should be involved in the decision after the potential side effects of the second-line treatment are considered (boxes with interrupted lines show alternative options). In the rare patient who is a nonresponder to standard corticosteroid therapy and by definition "corticosteroid resistant," a trial with cyclosporine may be considered. *MMF,* Mycophenolate mofetil.

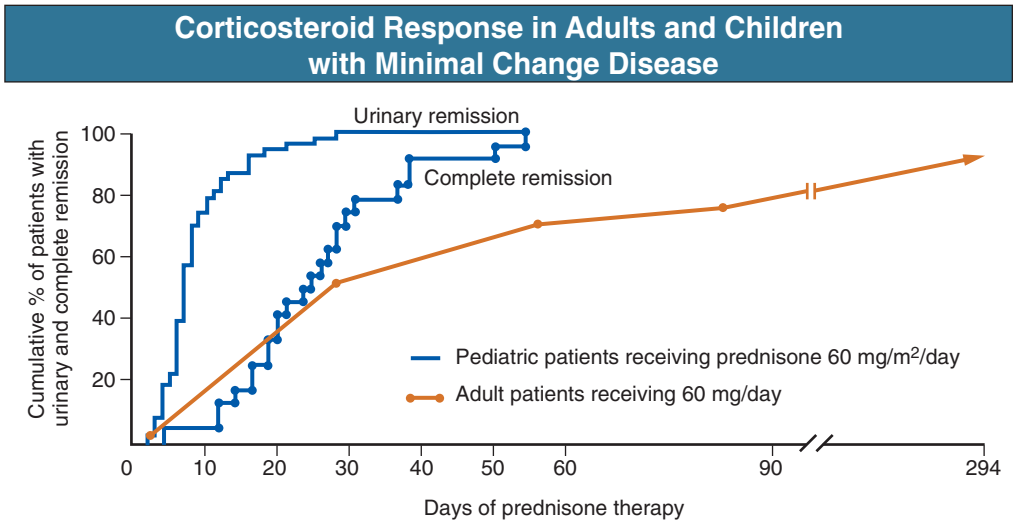

Figure 17-4 Corticosteroid response in adults and children with minimal change disease. Adults with the nephrotic syndrome and MCD take longer to respond than children and are less likely to remit. *Orange line* shows the cumulative percentage of adults with complete remission (i.e., reduction of proteinuria ≤0.2 g/day and serum albumin concentration >35 g/l). *Blue lines* show the cumulative percentage of pediatric patients with urinary remission and with complete remission. Urinary remission is defined by urine on dipstick negative or trace or proteinuria less than 4 mg/m^2/day on at least 3 days; the definition of complete remission requires, in addition to that, a serum albumin concentration above 3.5 g/dl. *(Redrawn from data from references 17 and 28.)*

of remission[36,37] (Fig. 17-6). However, the decision to recommend cyclophosphamide before alternatives may consider the benefits of long-term remission, even if the probability is low.

Chlorambucil, 0.2 mg/kg/day for 2 months, appears to be similar to cyclophosphamide in efficacy but has a greater frequency of adverse effects, including seizures, and therefore is not a preferable substitute.[38]

In general, frequently relapsing children tend to respond better than corticosteroid-dependent children. Second courses of alkylating agents are not recommended because cumulative toxicity occurs.

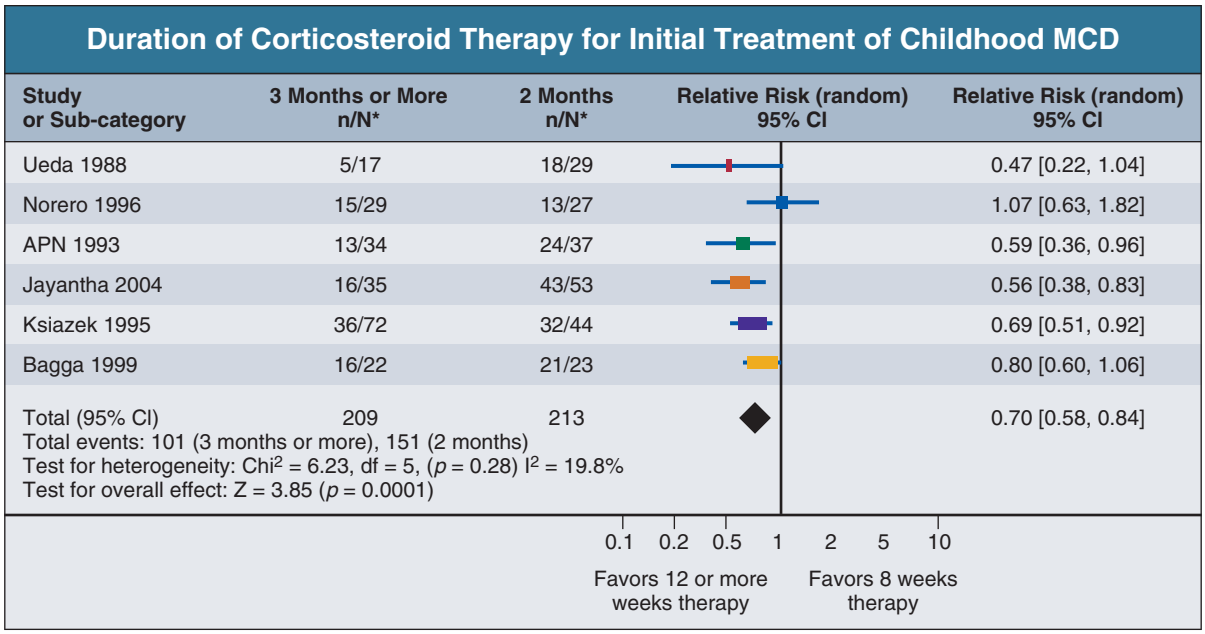

Figure 17-5 Duration of corticosteroid therapy for initial treatment of childhood minimal change disease. Cochrane meta-analysis of studies supports a 12-week or longer course of corticosteroid therapy compared with 8 weeks in the first episode of corticosteroid-sensitive nephrotic syndrome, to induce remission. Summary suggests a 30% better remission rate in patients receiving 12 weeks or more of therapy. **n/N,* Number of children relapsing per total number of children receiving that treatment. *(From reference 31.)*

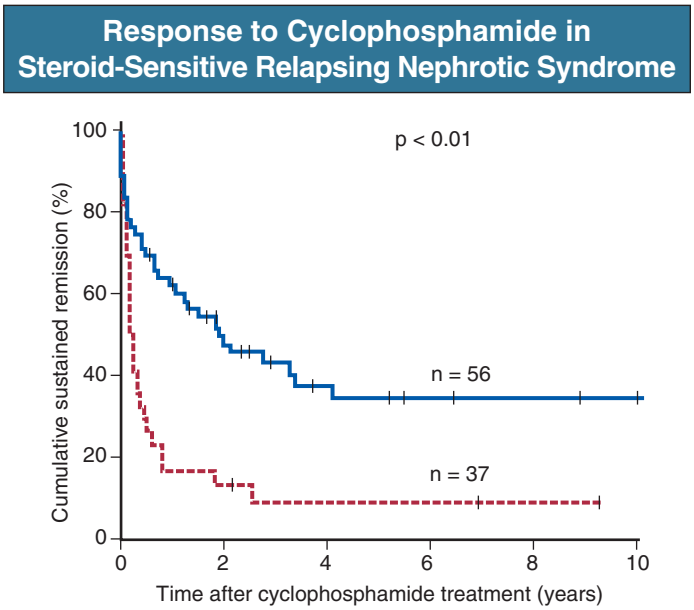

Figure 17-6 Response to cyclophosphamide dependent on age. Sustained remission is higher in children older than 5.5 years *(solid blue line)* than in younger children *(dotted red line)* with steroid-sensitive relapsing nephrotic syndrome. *(From reference 37.)*

During treatment with cyclophosphamide or chlorambucil, blood counts should be checked weekly and dose reductions made if necessary. Primary varicella infection carries a particular risk for nonimmune children receiving immunosuppressive therapy. These children should receive hyperimmune immunoglobulin and probably an antiherpes agent such as valaciclovir if there is an unavoidable contact with active chickenpox or shingles infection.

An alternative medication to alkylating agents is cyclosporine. Cyclosporine, up to 150 mg/m^2 or 3 to 4 mg/kg/day (with whole-blood trough levels of 50 to 150 ng/ml), is usually effective in children with both corticosteroid-dependent and frequently relapsing nephrotic syndrome.[36] However, relapse is almost invariable within 3 months of stopping treatment, and unfortunately, reintroduction of cyclosporine is often less effective once it has been interrupted. Therefore, cyclosporine is often used as long-term therapy. If there is no response, increasing the dose of cyclosporine is sometimes effective, but there is a risk of cyclosporine nephrotoxicity even with low-dose regimens, and careful monitoring of blood levels, glomerular filtration rate (GFR), and blood pressure is required. The aim of therapy is to maintain remission without corticosteroids until the underlying disease remits. The optimal duration of cyclosporine therapy is not established, but early withdrawal is discouraged for children. Besides careful monitoring of renal function, kidney biopsies every 2 to 3 years are recommended to ensure safety of the therapy. Although cyclosporine-associated nephrotoxicity during long-term treatment has been reported, one study with careful follow-up suggested that despite an initial drop in GFR, no further decrease occurred during the subsequent 5 to 10 years. More long-term studies are needed.

Many studies have now reported that tacrolimus is as effective as cyclosporine. Tacrolimus, with its superior cosmetic side effect profile, especially without hypertrichosis and gingival hypertrophy, may be an effective alternative that can improve drug adherence, especially in adolescents. Optimal dosing and drug levels are not fully established, but levels of 4 to 8 ng/l are often targeted. High doses must be avoided because initial experiences in the 1990s reported increased rates of lymphoma with high doses. Drug associated nephrotoxicity with long-term use is not well studied, but the same caution should be exercised with tacrolimus as with cyclosporine.

The antihelmintic levamisole, 2.5 mg/kg on alternate days for 3 months, has also been used successfully as a nontoxic alternative to corticosteroids.[39,40] However, most patients relapse within 3 months of stopping levamisole. It is used in the United States, Japan, and United Kingdom, although it has been withdrawn from the rest of Europe. A clinical trial using levamisole in MCD is ongoing and may provide better insight if there is utility in this disease.

Azathioprine has no proven role in the management of children with MCD and was ineffective in a randomized trial.

Newer Agents

The disadvantages of long-term calcineurin inhibitor (CNI) therapy, particularly the nephrotoxicity, has led to the widespread use of mycophenolic acid (mycophenolate mofetil, MMF), which is not nephrotoxic, in children with corticosteroid-dependent nephrotic syndrome. Many uncontrolled case series have reported MMF as effective in preventing relapses in frequently relapsing or corticosteroid-dependent patients. A small randomized trial with 12 patients in each arm suggested some efficacy with MMF but less than with cyclosporine.[41] A larger randomized crossover trial in 60 frequently relapsing children reported that after 24 months, 84% of cyclosporine-treated patients were relapse free, compared with 64% of the MMF arm. A small subgroup analysis suggested that MMF AUC-adjusted dosing may improve efficacy.[42]

There have been many reports that rituximab is effective in various forms of corticosteroid-dependent nephrotic syndrome refractory to other treatment. Unfortunately, all are uncontrolled case series, and no formal trials have yet been reported. In the largest reported multicenter series, 22 patients age 6 to 22 years with severe corticosteroid- or cyclosporine-dependent nephrotic syndrome had a remission after rituximab treatment, with one or more immunosuppressive drugs withdrawn in 85% of patients.[43] Relapses occurred with reappearance of B cells. However, 45% reported adverse effects, including one death from respiratory infection. The reported experience with rituximab suggests that it may be useful for preventing relapses and, if confirmed, will prevent drug dependency and toxicity. However, the potential role for rituximab in the management of these difficult patients is currently uncertain, and well-designed controlled trials are urgently needed to establish its efficacy, optimal dosing, and long-term safety.

Adult Minimal Change Disease

Studies comparing different corticosteroid regimens in adults with MCD are limited, and the treatment recommendations given here, in line with KDIGO guidelines,[27] are extrapolated from successful approaches in children, although often with slightly lower doses of oral prednisolone (1 mg/kg/day, up to maximum 80 mg/day) (Fig. 17-7). There is no good evidence that alternate-day corticosteroids offer any clinical advantages over daily dosing. Corticosteroids should be combined with gastric protection (H_2 blocker or proton pump inhibitor) and bone protection with a bisphosphonate.

Response is often delayed in comparison with children, and 25% fail to remit after 3 to 4 months[17,27,44] (see Fig. 17-4). Although unclear, the reason may be that many adults are often given a smaller dose of corticosteroids, or that a greater proportion of adults have focal segmental glomerulosclerosis (FSGS), missed on the original biopsy, which is more likely to be corticosteroid resistant.

There are no helpful studies to inform the optimal length of full-dose prednisolone after remission has been induced (absence of protein on urine dipstick). Based on meta-analysis of pediatric patients, however, the recommendation for total length of corticosteroid treatment is at least 3 to 4 months (KDIGO recommends up to 6 months, but based on grade 2D evidence). Full-dose corticosteroids should be continued for at least 2 weeks after full remission is achieved, but for a minimum of 4 weeks if remission occurs early, before tapering the dose. The rate of dose tapering and total length of treatment of the initial episode may need to be foreshortened in individual patients if the steroid toxicity is thought to be a significant factor (e.g., uncontrolled diabetes, psychiatric complications, patient with severe osteoporosis).

If the patient has not responded after 12 to 16 weeks, consideration should be given to concordance (compliance) with corticosteroid treatment or failure of absorption. The latter is unusual unless the patient is vomiting or has diarrhea, in which case some recommend intravenous methylprednisolone, with anecdotal success, although initial treatment with pulse methylprednisolone and lower doses of oral corticosteroid does not seem to be beneficial. A repeat biopsy should be considered in patients failing to respond.

Infrequent relapses should be treated in the same way as the initial presentation, but there is even less evidence that a prolonged course of corticosteroids is beneficial in reducing the frequency of subsequent relapse. Therefore, steroid tapering can start a week after remission, with a taper to finish over 4 to 6 weeks, although this is not evidence based.

Frequently Relapsing and Corticosteroid-Dependent Nephrotic Syndrome

Frequently relapsing nephrotic syndrome usually means two or more relapses within 6 months or four or more within 1 year of initial remission induction. Adults relapse less often than children (30% to 50%). Relapse may also occur in 40% of adults who had MCD in childhood.[45] As in children, some adults have transient non-nephrotic relapses, so it is important to establish that a full relapse has developed with persistent heavy proteinuria, a low albumin level, and fluid retention before recommencing steroids. Frequently relapsing and corticosteroid-dependent patients should receive second-line therapy with cyclophosphamide or cyclosporine, but the timing of this decision will vary between physician and patient. Many factors will influence the decision to abandon repeated corticosteroid courses, including steroid toxicity and tolerance and level of steroid dependence; 5 to 10 mg/day may be acceptable for several months, but more than 20 mg/day would not. The patient should be involved in the decision after explanation of the relative risks with further courses of corticosteroids and the alternative treatments.

Initial second-line management is with a 12-week course of oral cyclophosphamide (2-2.5 mg/kg/day), which induces a permanent remission more often in adults than children (75% and 66% at 2 and 5 years, respectively).[17] Although there are no satisfactory studies comparing 8-week and 12-week courses in adults, the 12-week course is logical on the basis of the pediatric experience. If this treatment is selected, the opportunity for banking sperm or retrieval of eggs should be considered before treatment. Intravenous cyclophosphamide has been recommended to limit the cumulative dose, and two small trials compared outcome with tacrolimus treatment, but the small numbers and trial design limit their value in informing management.

For patients who relapse after cyclophosphamide treatment, cyclosporine, 4 to 6 mg/kg/day, aiming for trough whole-blood levels of 50 to 150 ng/ml for at least 12 months, is also effective, but relapse usually follows dose reduction or withdrawal. Cyclosporine is worth considering as a short-term to medium-term management strategy because evidence suggests that remission eventually occurs in 50% to 75% of patients even without treatment.[16] However, careful monitoring is required because nephrotoxicity is common after more than 1 year of therapy.[46]

Some nephrologists prefer to offer cyclosporine before cyclophosphamide, especially in younger adults and those who want to maximize future fertility, although the risks of the total dose used in MCD are unlikely to cause permanent infertility.

Tacrolimus appears to have similar effectiveness as cyclosporine and may have a more favorable side effect profile. Initial target levels

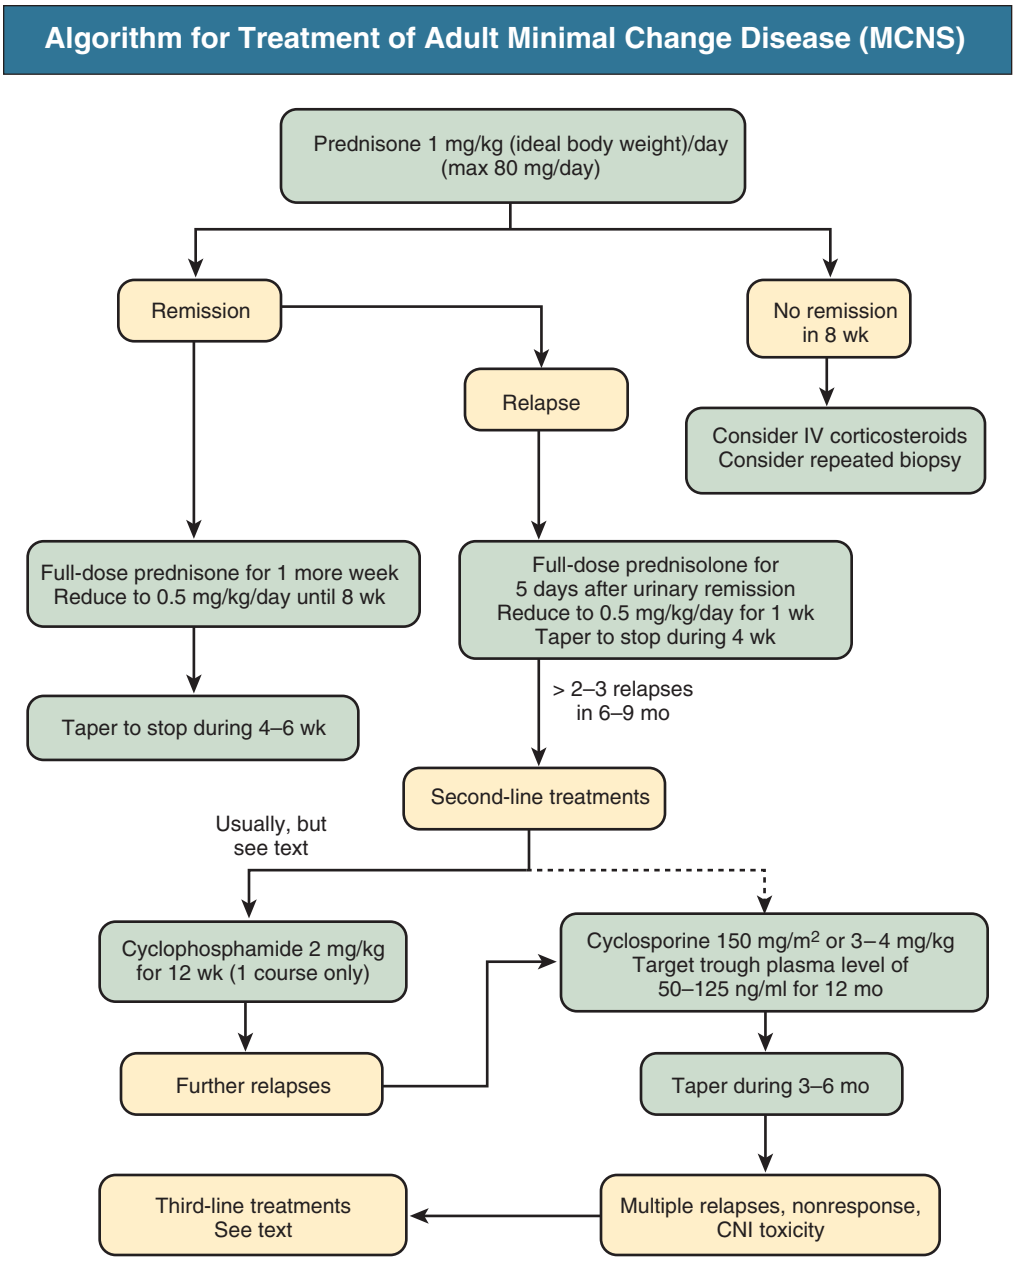

Figure 17-7 Algorithm for treatment of adult minimal change disease (minimal change nephrotic syndrome). *CNI,* Calcineurin inhibitor.

are generally 4 to 8 ng/ml, but higher levels may be required to maintain remission.

Newer Agents

Several uncontrolled reports suggest that MMF may also have a place in management of corticosteroid- and cyclosporine-dependent patients,[47-49] but more data on efficacy, dosage, and duration of treatment are needed before these could be widely recommended. As reported in children, there are many publications suggesting that rituximab results in remission in adults with frequently relapsing disease unresponsive to other treatments. The largest study in adults with corticosteroid-responsive MCD suggests that the safety and efficacy of rituximab are similar to those reported in children, with more than a 10-fold reduction in annual relapse rate.[50] This retrospective study also suggested that response was much better in patients given rituximab during remission. However, as in children, randomized controlled trials are needed to establish efficacy, safety, and optimal dosing schedule.

Minimal Change Disease with Non-nephrotic Proteinuria

In patients with well-documented MCD who have the rare relapse in which the proteinuria is non-nephrotic, treatment does not require corticosteroids but rather can include angiotensin-converting enzyme (ACE) inhibitor or angiotensin receptor blocker (ARB) therapy. If there is any question as to diagnosis, repeated biopsy may be indicated because other conditions can mimic MCD (see Diagnosis and Differential Diagnosis).

Treatment of Secondary Minimal Change Disease

The MCD secondary to NSAIDs requires discontinuation of the offending medication. Many patients are treated with a course of corticosteroids for MCD (higher dose) or for acute interstitial nephritis (see Chapter 62), but evidence of therapeutic benefit is uncertain. Secondary MCD from Hodgkin disease usually responds

to treatment of the lymphoma. Some patients will also receive a drug regimen for MCD as adjunctive therapy in addition to the chemotherapy directed at the tumor.

CHAPTER 18

Primary and Secondary (Non-Genetic) Causes of Focal and Segmental Glomerulosclerosis

Gerald B. Appel and Vivette D. D'Agati

DEFINITION

Focal segmental glomerulosclerosis (FSGS), a histologic pattern of glomerular injury, defines a number of clinicopathologic syndromes that may be primary (idiopathic) or secondary to diverse etiologies[1-5] (see also Chapter 19). Early in the disease process, the pattern of glomerulosclerosis is focal, involving a minority of glomeruli, and segmental, involving a portion of the glomerular tuft.[4,5] Alterations of podocyte cytoarchitecture identified on electron microscopy are relatively diffuse, underscoring the pathogenetic importance of podocyte injury. As the disease progresses, more diffuse and global glomerulosclerosis evolves. Although it accounts for only a small percentage of cases of idiopathic nephrotic syndrome in young children, FSGS represents as many as 35% of cases in adults.[1] It is a major cause of progressive renal disease and end-stage renal disease (ESRD) in certain populations.[6]

Diverse pathogenetic mechanisms have been identified and often manifest as particular histologic subtypes of disease. Through podocyte depletion and dysregulation, structural deterioration of the glomerular tuft leads to FSGS as a final common pathway.[5] Although primary (idiopathic) FSGS is potentially treatable and curable in many patients, the optimal type and duration of immunosuppressive as well as adjunctive therapy remain controversial. For secondary FSGS, effective therapies exist to slow or to modify the disease course (see Chapter 80).

ETIOLOGY AND PATHOGENESIS

Focal segmental glomerulosclerosis represents a common phenotypic expression of diverse clinicopathologic syndromes with distinct etiologies (Box 18-1). Causes include genetic mutations in podocyte components (see Chapter 19), circulating permeability factors, viral infections, drug toxicities, maladaptive responses to reduced number of functioning nephrons, and hemodynamic stress placed on an initially normal nephron population. In all these forms of FSGS, injury directed to or inherent within the podocyte is a central pathogenetic mediator.[2,5,7,8] These injuries promote altered cell signaling, reorganization of the actin cytoskeleton, and resulting foot process effacement. Critical levels of injury cause podocyte depletion through detachment or apoptosis. Stress placed on the remaining podocytes may lead to local propagation of damage (see Chapter 79). Injury to podocytes may spread to adjacent podocytes by reduction in supportive factors such as nephrin signaling or increased toxic factors such as angiotensin II (Ang II) or mechanical strain on remnant podocytes.[9] Cell-to-cell spread of podocyte injury until the entire glomerular lobule is captured could explain the characteristic segmental nature of the sclerosing lesions.[10]

Minimal Change Disease Versus Focal Segmental Glomerulosclerosis

By definition, the etiology of idiopathic or primary FSGS is unknown. Some clinical data support etiologic factors similar to those at work in minimal change disease (MCD; see Chapter 17).[1] Certain corticosteroid-responsive FSGS patients who exhibit MCD on initial biopsy subsequently relapse and display FSGS on repeated biopsy. In some, this may simply represent a sampling error in the initial biopsy. In others with well-documented repeated relapses of nephrotic syndrome and multiple biopsies over years, FSGS truly appears to have evolved from an initial MCD pattern. The relatedness of these two diseases is further supported by the observation that pathologic changes in the nonsclerotic glomeruli of idiopathic FSGS resemble glomeruli of MCD.[5] In addition, sequential biopsies of recurrent FSGS in the allograft show it passes through an early stage that mimics MCD.[11] Thus, MCD and FSGS are often considered together under the rubric of "podocytopathies".

Both MCD and primary FSGS are thought to be mediated by circulating *permeability factors.*[12] Recent studies suggest that the permeability factors in FSGS and MCD differ and that the diseases can be distinguished using biomarkers. Elevated CD80, a costimulatory factor expressed on podocytes and B cells, is found in the urine of corticosteroid-sensitive MCD[13] but not in FSGS. Angiopoietin-like-4, a podocyte-secreted glycoprotein, is upregulated in podocytes and is elevated in the serum of animal models and patients with MCD.[14] In animal models, induction of urokinase plasminogen activator receptor (uPAR) in podocytes produces effacement, proteinuria, and FSGS by promoting a migratory podocyte phenotype through activation of β_3 integrin.[15,16] Patients with primary FSGS have higher levels of circulating soluble uPAR (suPAR) than equally proteinuric patients with MCD or membranous nephropathy.[16] Elevated suPAR levels have been found in 55% of the European PodoNet cohort of FSGS patients and 84% of the American FSGS-CT cohort, and there was an association between treatment-induced reduction in proteinuria and reduction in suPAR levels.[17] Patients with recurrent FSGS in the allograft also have high circulating suPAR levels, which are reduced by plasma exchange in parallel with reduction in proteinuria. However, some studies have found that patients with secondary FSGS and others with reduced GFR also have high circulating levels of suPAR.[18] Thus the pathogenetic role of suPAR and its diagnostic value presently remain uncertain.

Loss of the glomerular filtration barrier allows negatively charged albumin to leak into Bowman space. The alterations in glomerular capillary wall permeability may occur in response to circulating "humoral" substances that act on the podocyte to promote foot process effacement. Circulating permeability factors that enhance *in vitro* permeability of glomeruli to albumin have been found in the

Etiologic Classification of Focal Segmental Glomerulosclerosis

Primary (Idiopathic) FSGS
Probably mediated by circulating/permeability factor(s)

Secondary FSGS

1. Familial/Genetic*
- Mutations in nephrin *(NPHS1)*
- Mutations in podocin *(NPHS2)*
- Mutations in α-actinin 4 *(ACTN4)*
- Mutations in transient receptor potential cation channel *(TRPC6)*
- Mutations in Wilms tumor suppressor *(WT1)*
- Mutations in inverted formin-2 *(INF2)*
- Mutations in phospholipase C epsilon 1 *(PLCE1)*
- Risk alleles for apolipoprotein L1 *(APOL1)*

2. Virus Associated
- HIV-1 ("HIV-associated nephropathy")
- Parvovirus B19
- Simian virus 40 (SV40)
- Cytomegalovirus (CMV)

3. Drug Induced
- Heroin ("heroin-nephropathy")
- Interferon
- Lithium
- Pamidronate
- Sirolimus
- Anabolic steroids

4. Mediated by Adaptive Structural-Functional Responses

Reduced renal mass
- Oligomeganephronia
- Very low birth weight
- Unilateral renal agenesis
- Renal dysplasia
- Reflux nephropathy
- Sequela to cortical necrosis
- Surgical renal ablation
- Chronic allograft nephropathy
- Any advanced renal disease with reduction in functioning nephrons

Initially normal renal mass
- Hypertension
- Atheroemboli or other acute vaso-occlusive processes
- Obesity
- Increased lean body mass
- Cyanotic congenital heart disease
- Sickle cell anemia

Box 18-1 Etiologic classification of focal segmental glomerulosclerosis (FSGS). *For complete list of genetic causes see Chapter 19. *HIV,* Human immunodeficiency virus.

plasma of some FSGS patients. The presence of such permeability factors has been used to predict the recurrence of FSGS in transplanted FSGS patients.[12] Some FSGS patients with recurrence of nephrotic syndrome after transplantation achieve remissions of nephrotic syndrome after plasma exchange or use of a protein A adsorption column, supporting the role of a circulating factor[12,19,20] (see Chapter 108). As described above, one candidate is suPAR.[16] Another candidate factor is cardiotrophin-like cytokine 1 (CLC1), a member of the IL-6 family of interleukins. Receptors for this cytokine are present on podocytes and are upregulated in human recurrent FSGS.[21] The origin of the factor may be $CD34^+$ stem cells.[22] Induction of T regulatory cells attenuates the proteinuria in experimental FSGS, suggesting the capacity to block or to suppress the pathogenic cells.[23]

In contrast to MCD, the proteinuria in FSGS is usually nonselective, including albumin and higher-molecular-weight macromolecules. In human FSGS and toxin-induced animal models of FSGS, such as puromycin or doxorubicin (Adriamycin) nephrosis, nonselective proteinuria develops in conjunction with detachment of podocyte foot processes from the GBM, a finding not seen in MCD.[5] The susceptibility gene to doxorubicin toxicity in Balb/c mice has been identified as *PRKDC,* required for double-stranded DNA break repair.[24] Animals deficient in this DNA repair machinery develop mitochondrial DNA depletion following doxorubicin exposure, leading to podocyte cell death and FSGS. This mechanism illustrates how long-lived cells such as podocytes, which lack the ability to repair themselves by cell division, are especially vulnerable to genotoxic stress. In humans, repeated and diverse stresses to the podocyte could explain the development of FSGS pattern of injury in age-related nephrosclerosis and glomerular senescence.

Glomerular hypertrophy (or glomerulomegaly) may identify children with MCD at risk for development of FSGS. In early idiopathic FSGS and in many secondary forms of FSGS, such as obesity related, there is initially glomerular hypertrophy and a high glomerular filtration rate (GFR), supporting roles for hyperfiltration and increased intracapillary glomerular pressures (glomerular hypertension).[25] Similarly, in secondary forms of FSGS with reduced nephron numbers, maladaptive hemodynamic alterations may be associated with glomerular hyperfiltration and increased intraglomerular capillary pressures. Other factors, such as intraglomerular coagulation and abnormalities of lipid metabolism, may contribute to glomerulosclerosis in these patients (see Chapter 79).

Genetic Variants of Focal Segmental Glomerulosclerosis

Genetic and familial forms of FSGS are covered in detail in Chapter 19. Many cases of apparently primary FSGS may harbor unidentified mutations or polymorphisms in podocyte genes that go unrecognized because of lack of genetic testing and the absence of a heralding presentation with young-onset corticosteroid-resistant disease or familial inheritance. In primary FSGS, a genetic predisposition may underlie the susceptibility to a "second hit," whereby viral factors or other immune stimuli lead to the initiation of disease. Mutations in podocyte genes may also predispose to FSGS induced by such secondary causes as obesity, systemic hypertension, and infectious agents, allowing multifactorial podocyte stress. For example, mutations in myosin heavy chain 9 *(MYH9)* were initially identified as a major risk factor for FSGS in patients of African ancestry.[26] Subsequent genetic mining of populations at risk for FSGS identified *APOL1* gene, rather than *MYH9*, as the major risk gene for FSGS and chronic hypertensive arterionephrosclerosis among patients of African descent.[27] *APOL1* encodes for apolipoprotein L-1. The gene is located along the same stretch of chromosome 22 and is in linkage disequilibrium with *MYH9.* G1 and G2 mutations in *APOL1* are protective against infection by *Trypanosoma brucei*, the parasite that

causes African sleeping sickness. Similar to the gene for sickle cell disease, which confers selective advantage against malaria, this genetic mutation became prevalent in a population because it was protective against an infectious pathogen. Although *APOL1* is present in preglomerular arterioles and podocytes,[28] it remains unclear how sequence variations in *APOL1* mechanistically cause glomerulosclerosis.

Viral Induction of Focal Segmental Glomerulosclerosis

Although a number of studies have noted a relationship between prior viral infection with parvovirus or other viruses and FSGS, in particular collapsing FSGS, the data have been far from consistent.[29] By contrast, the role of human immunodeficiency virus (HIV) infection in the pathogenesis is well established (see Chapter 58).

Drug-Induced Focal Segmental Glomerulosclerosis

A number of drugs and medications have been associated with the FSGS phenotype, including heroin, lithium, pamidronate, sirolimus, and interferons alpha, beta, and gamma[30] (see Box 18-1). Heroin has been associated with the nephrotic syndrome and FSGS (heroin nephropathy), although its incidence is decreasing in the modern era.[31] Pamidronate, a bisphosphonate used to prevent bone resorption in myeloma and metastatic tumors, has been associated with both collapsing FSGS and MCD.[32] Stabilization of renal function and resolution of nephrotic syndrome may follow withdrawal of the offending medication (e.g., interferon, heroin, pamidronate). Long-term anabolic steroid abuse among bodybuilders has been associated with the development of FSGS. Many of these individuals also consume high-protein diets and potentially injurious supplements, including growth hormone. Mechanisms of glomerular injury include potential direct toxic effects of anabolic steroids on glomerular cells and adaptive responses to elevated lean body mass.[33]

Structural Maladaptation Leading to Focal Segmental Glomerulosclerosis

Many secondary forms of FSGS are mediated by adaptive structural-functional responses.[1,5,7] These adaptive forms include patients with congenital reduction in the number of functioning nephrons and acquired reduction of nephron numbers, whereas other secondary forms are associated with hemodynamic stress placed on an initially normal nephron population (see Box 18-1). *Obesity-related glomerulopathy* (ORG) is increasingly common worldwide and may be associated with metabolic syndrome, including hypertension, diabetes, and hyperlipidemia. ORG usually lacks full nephrotic syndrome and has a low risk of progression to ESRD.[25] Secondary FSGS resembling ORG has been reported in nonobese, highly muscular patients with elevated body mass index due to bodybuilding.[34] Low birth weight associated with prematurity and reduced nephron endowment may also lead to glomerular hypertrophy, with secondary FSGS developing in adolescence or adulthood.[35] Biopsy specimens with secondary adaptive FSGS typically show glomerulomegaly and perihilar lesions of segmental sclerosis and hyalinosis. These conditions resemble experimental models of renal ablation in which the surgical reduction in renal mass causes functional hypertrophy of remnant nephrons with increased glomerular plasma flows and pressures. Whereas these changes are initially "adaptive," the resultant hyperfiltration and increased glomerular pressure become "maladaptive" and serve as mechanisms for progressive glomerular damage.[7,8]

Pathogenesis of Progressive Renal Failure in Focal Segmental Glomerulosclerosis

Although much attention has been focused on the pathogenetic basis for proteinuria in FSGS, the segmental and eventual global glomerulosclerosis in association with interstitial fibrosis and tubular atrophy clearly underlie the progression to renal failure. The etiology of glomerulosclerosis and its progressive nature are discussed in Chapter 79. Podocytes in some forms of FSGS, such as the collapsing variant, display a dysregulated phenotype with dedifferentiation, proliferation, and apoptosis.[36] Such biopsy samples have altered podocyte expression of cell cycle–related proteins.[37] In renal biopsy specimens of patients with FSGS, the expression levels of transforming growth factor (TGF) β1, thrombospondin-1, and TGF-β2 receptor proteins and messenger RNAs are all increased, as are podocyte markers of the phosphorylated Smad2/Smad3 signaling pathway.[38] Thus, pathways that promote podocyte depletion and overproduction of extracellular matrix converge to produce a sclerosing phenotype.

EPIDEMIOLOGY

Studies of patients who have had a kidney biopsy show an increasing prevalence of FSGS in both adults and children in a number of countries on different continents.[39] In some countries, such as Brazil, FSGS is currently the most common primary renal disease.[40] An analysis of the prevalence of ESRD in the United States caused by FSGS during a 21-year period shows an increase from 0.2% in 1980 to 2.3% in 2000, and FSGS is the most common primary glomerular disease leading to ESRD.[5,6] Although some of this change in prevalence may relate to changes in biopsy practice or disease classification, a real increase is likely in the frequency of FSGS.

Primary FSGS is slightly more common in males than in females, and the incidence of ESRD due to FSGS in males of all races is 1.5 to 2 times higher than in females. The incidence in both children and adults is higher in blacks than in Caucasians.[1] In the United States, FSGS is the most common cause of idiopathic nephrotic syndrome in adult African Americans.[6] African Americans had a fourfold greater risk of ESRD from FSGS than Caucasians did. Even in an almost entirely Caucasian U.S. population, a clear major increase in the incidence of FSGS has been documented over a 30-year period,[41] whereas this has not been the case in some Caucasian populations in Europe.[42]

CLINICAL MANIFESTATIONS

Patients with primary FSGS present with asymptomatic proteinuria or full nephrotic syndrome.[1-3] In children, 10% to 30% of patients with asymptomatic proteinuria are detected on routine checkups and sports physical examinations; in adults, asymptomatic detection occurs at military induction examinations, obstetric checkups, and insurance or employment physical examinations. The incidence of nephrotic-range proteinuria at onset in children is 70% to 90%, whereas only 50% to 70% of adults with FSGS present with nephrotic syndrome. Secondary forms of FSGS associated with hyperfiltration, such as remnant kidney and ORG, typically have lower levels of proteinuria, and many such patients have subnephrotic proteinuria and a normal serum albumin concentration.[25,34]

Hypertension is found in 30% to 50% of children and adults with FSGS at diagnosis. Microhematuria is found in 25% to 75% of these patients, and a decreased GFR is noted at presentation in 20% to

30%.[1-3] Daily urinary protein excretion ranges from less than 1 to more than 30 g/day. Proteinuria is typically nonselective. Complement levels and other serologic test results are normal. Occasional patients will have glycosuria, aminoaciduria, phosphaturia, or a concentrating defect indicating functional tubular damage as well as glomerular injury.

Different histologic patterns of FSGS may display different clinical features. When patients with the tip variant of FSGS were compared to those with MCD or FSGS not otherwise specified (NOS), their clinical features were more similar to those of MCD.[43] Those with tip variant typically manifested abrupt clinical onset of full nephrotic syndrome (almost 90%), shorter time course from onset to renal biopsy, more severe proteinuria, and less chronic tubulointerstitial disease than in FSGS NOS. The cellular variant also typically presents with greater proteinuria and higher incidence of nephrotic syndrome than FSGS NOS. Compared with FSGS NOS, the collapsing variant usually presents with greater proteinuria, more full-blown nephrotic syndrome, and lower GFR.[44,45]

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

Before biopsy, patients with FSGS may be confused with any patient who has glomerular disease or nephrotic syndrome with negative serologic test results. Tests for permeability factors are not available in routine clinical practice. In children with FSGS, most of whom present with nephrotic syndrome, the major differential will be between MCD and other variants of corticosteroid-resistant nephrotic syndrome. In adults with subnephrotic proteinuria, the differential includes almost all glomerular diseases without positive serologic results. In adults with nephrotic syndrome, membranous nephropathy (MN) and MCD may present in an identical manner, and only a renal biopsy will clarify the diagnosis. Focal sclerosing lesions caused by other glomerulopathies (e.g., segmental scarring from chronic glomerulonephritis) must be excluded pathologically. Moreover, because the defining glomerular lesion of FSGS is focal and may be confined to deeper juxtamedullary glomeruli early in the disease, it may not be sampled on renal biopsy. A large glomerular sample of more than 20 glomeruli for light microscopy increases the likelihood of identifying the diagnostic segmental lesions.

Even after the diagnosis of FSGS is established, the primary (idiopathic) form must be distinguished from secondary forms by careful clinicopathologic correlation (see Box 18-1). In general, many forms of adaptive FSGS have lower levels of proteinuria than primary FSGS, a lower incidence of hypoalbuminemia, and on biopsy, lesser degrees of foot process effacement. In patients younger than 25 years and in those with a family history of FSGS, genetic screening for mutations in podocin, nephrin, or other podocyte genes may be useful (see Chapter 19).

PATHOLOGY

The pathologic manifestations of FSGS are heterogeneous, both qualitatively and with respect to the location of lesions within the glomerular tuft. A classification of FSGS by histologic variants (Box 18-2)[46] can be applied to both primary and secondary forms of FSGS (Box 18-1). Subtypes include *classic,* or NOS; *perihilar* variant, in which more than 50% of glomeruli with segmental lesions display hyalinosis and sclerosis involving the vascular pole region; *cellular* variant, manifesting endocapillary hypercellularity; *collapsing* variant, in which at least one glomerulus has global collapse and overlying visceral cell hypertrophy and hyperplasia; and *tip* variant, with segmental lesions involving the tubular pole. This working classification has been applied successfully to retrospective and prospective series of renal biopsies. Other, more controversial histologic variants of FSGS include FSGS with diffuse mesangial hypercellularity and C1q nephropathy (see Chapter 28). Some believe that these are distinct disease entities with unique clinicopathologic features; others believe these are merely subgroups of FSGS.[47,48]

Morphologic Variants of Focal Segmental Glomerulosclerosis

1. FSGS, not otherwise specified (NOS; also known as classic FSGS)
2. FSGS, perihilar variant
3. FSGS, cellular variant
4. FSGS, collapsing variant (also known as collapsing glomerulopathy)
5. FSGS, tip variant

Box 18-2 Morphologic variants of focal segmental glomerulosclerosis (FSGS).

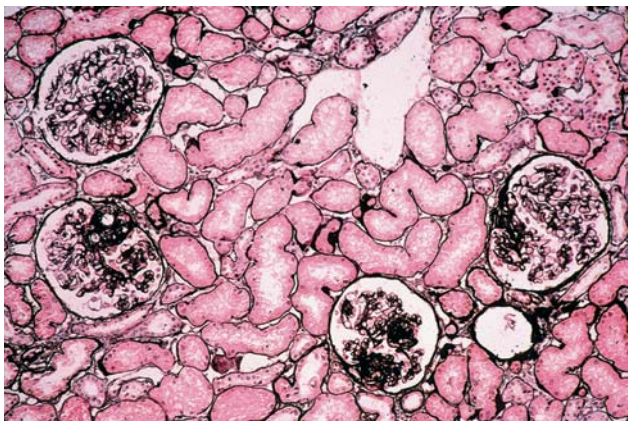

Figure 18-1 Focal segmental glomerulosclerosis, not otherwise specified (FSGS NOS). A low-power view shows four glomeruli with discrete lesions of segmental sclerosis involving a portion of the tuft. The adjacent nonsclerotic capillaries are unremarkable. In this example, there is no evidence of tubulointerstitial injury. (Jones methenamine silver stain; magnification ×100.)

Classic Focal Segmental Glomerulosclerosis (FSGS Not Otherwise Specified)

Classic FSGS, also called FSGS NOS, is the common generic form of the disease. FSGS NOS requires exclusion of the other, more specific subtypes described later. It is defined by accumulations of extracellular matrix (ECM) that occlude glomerular capillaries, forming discrete segmental solidifications (Fig. 18-1).[46] There may be hyalinosis (plasmatic insudation of amorphous glassy material beneath the GBM), endocapillary foam cells, and wrinkling of the GBM (Fig. 18-2). Adhesions or synechiae to Bowman capsule are common, and overlying visceral epithelial cells often appear swollen and form a cellular "cap" over the sclerosing segment. Glomerular lobules unaffected by segmental sclerosis appear normal on light microscopy, except for mild podocyte swelling. Tubular atrophy and interstitial fibrosis are commensurate with the degree of glomerulosclerosis. Immunofluorescence (IF) typically reveals focal and segmental granular deposition of IgM, C3, and more variably C1 in the distribution

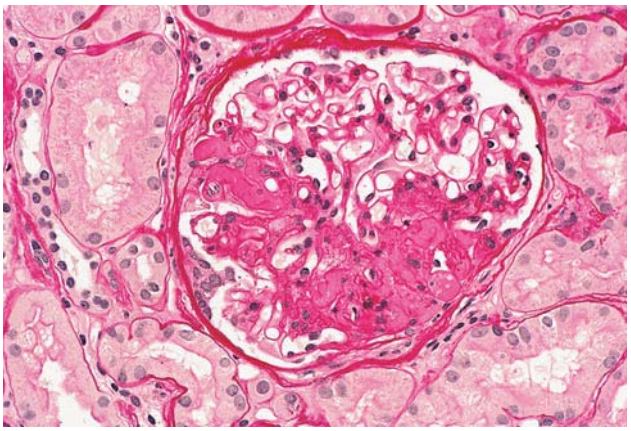

Figure 18-2 Focal segmental glomerulosclerosis, not otherwise specified. The lesions of segmental sclerosis display increased extracellular matrix and hyalinosis. There is adhesion to Bowman capsule without significant podocyte hypertrophy. The nonsclerotic capillaries have glomerular basement membranes of normal thickness and mild podocyte swelling. (Periodic acid–Schiff [PAS] reaction; ×400.)

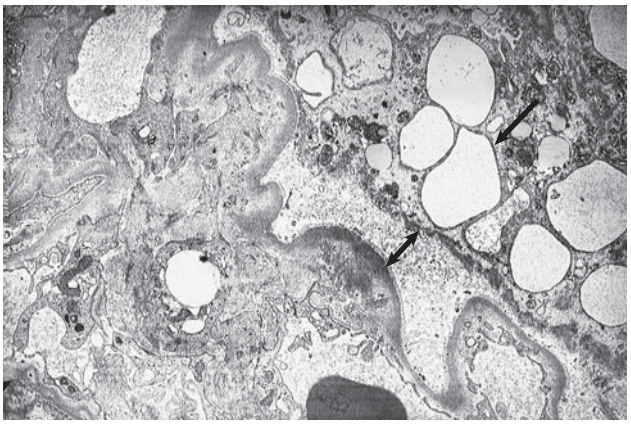

Figure 18-4 Focal segmental glomerulosclerosis, not otherwise specified. Electron micrograph illustrates the lesion of segmental sclerosis with obliteration of the glomerular capillaries by increased extracellular matrix with wrinkled and retracted glomerular basement membranes. The overlying podocytes are detached, with complete effacement of foot processes *(double-headed arrow)* and numerous electron-lucent intracellular transport vesicles *(arrow)*. (×2500.)

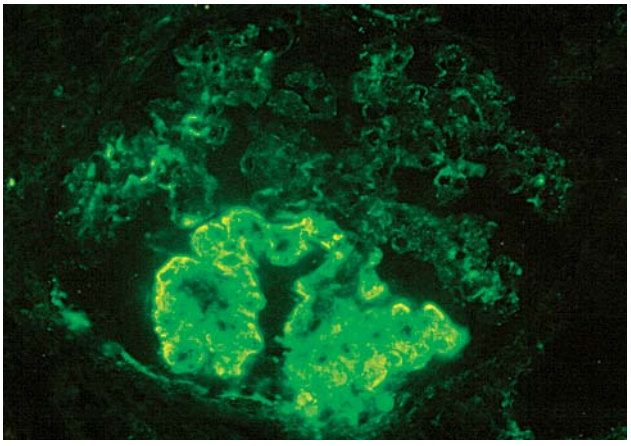

Figure 18-3 Focal segmental glomerulosclerosis, not otherwise specified. The lesions of segmental sclerosis contain deposits of IgM corresponding to areas of increased matrix and hyalinosis. Weaker staining for IgM is also seen in the adjacent mesangium. (Immunofluorescence micrograph; ×400.)

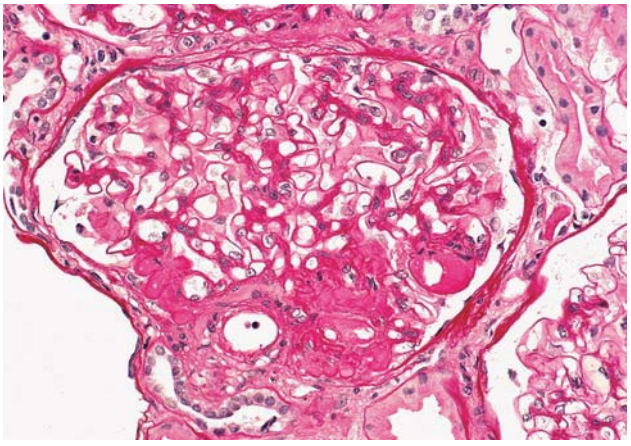

Figure 18-5 Focal segmental glomerulosclerosis (FSGS), perihilar variant. A discrete lesion of segmental sclerosis and hyalinosis is located at the glomerular vascular pole (i.e., perihilar). The glomerulus is hypertrophied. The patient had secondary FSGS in the setting of solitary kidney as a result of contralateral renal agenesis. (PAS; ×250.)

of the segmental glomerular sclerosis (Fig. 18-3). Nonsclerotic glomeruli may have weak mesangial staining for IgM and C3. On electron microscopy (EM), segmental sclerotic lesions exhibit increased ECM, wrinkling and retraction of the GBM, accumulation of inframembranous hyaline, and resulting narrowing or occlusion of the glomerular capillary lumina (Fig. 18-4). No immune-type electron-dense deposits are found. Overlying the segmental sclerosis, there is often podocyte detachment with parietal cell coverage. The adjacent nonsclerotic glomerular capillaries show foot process effacement with variable microvillous transformation (slender projections resembling villi along the surface of podocytes). This is the most frequent variant and may occur in primary or secondary forms of FSGS, including genetic forms.

Perihilar Variant of Focal Segmental Glomerulosclerosis

The perihilar variant is defined as perihilar hyalinosis and sclerosis involving more than 50% of glomeruli with segmental lesions.[34] This category requires exclusion of the cellular, tip, and collapsing variants. Podocyte hyperplasia is uncommon. Although the perihilar variant may occur in primary FSGS, it is particularly frequent in secondary forms of FSGS mediated by adaptive structural-functional responses, where it is typically accompanied by glomerular hypertrophy (glomerulomegaly) and has relatively mild foot process effacement (Fig. 18-5). In this setting, reflex dilation of the afferent arteriole and the greater filtration pressures at the proximal end of the glomerular capillary bed may favor the development of lesions at the vascular pole.[5,7]

Cellular Variant of Focal Segmental Glomerulosclerosis

The cellular variant is characterized by focal and segmental endocapillary hypercellularity that may mimic a form of focal proliferative glomerulonephritis.[49] Glomerular capillaries are segmentally occluded by endocapillary hypercellularity, including foam cells, infiltrating leukocytes, karyorrhectic debris, and hyaline (Fig. 18-6).

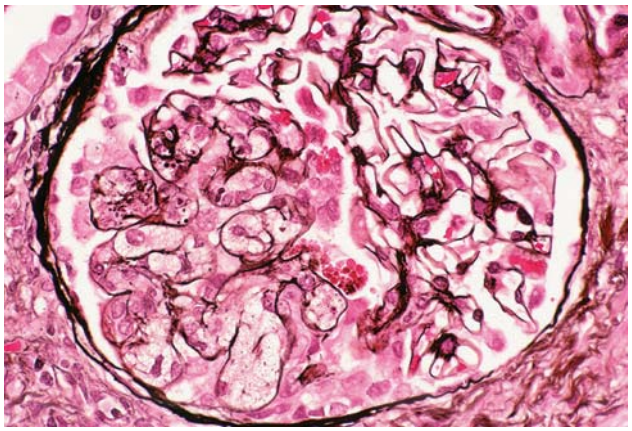

Figure 18-6 Focal segmental glomerulosclerosis, cellular variant. The glomerular capillary lumina are segmentally occluded by endocapillary cells, including foam cells, infiltrating mononuclear leukocytes, and pyknotic debris. The findings mimic a proliferative glomerulonephritis because of the hypercellularity and absence of extracellular matrix material. There are hypertrophy and hyperplasia of the overlying visceral epithelial cells, some of which contain protein resorption droplets. (Jones methenamine silver; ×400.)

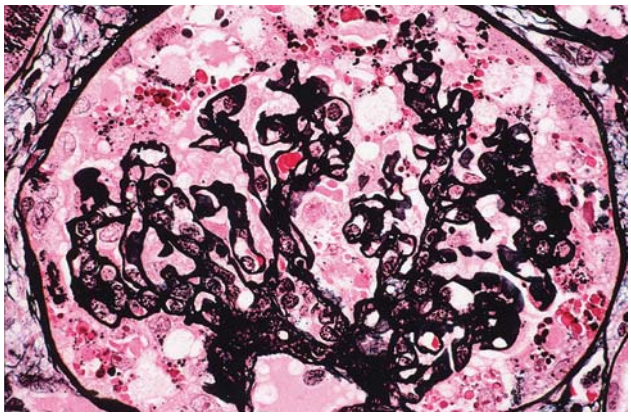

Figure 18-8 Focal segmental glomerulosclerosis, collapsing variant. In this example, exuberant proliferation of glomerular epithelial cells forms a pseudocrescent that obliterates the urinary space. The pseudocrescent lacks the spindle cell morphology, ruptures of Bowman capsule, or pericellular matrix typically seen in true inflammatory crescents of parietal epithelial origin. (Jones methenamine silver; ×400.)

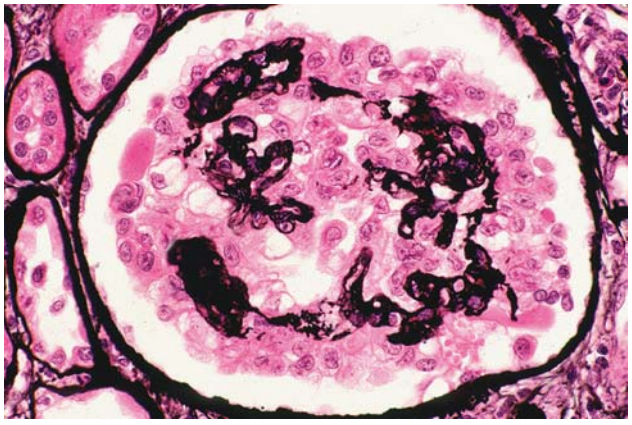

Figure 18-7 Focal segmental glomerulosclerosis, collapsing variant. There is global implosive collapse of the glomerular tuft with obliteration of capillary lumina. The overlying visceral epithelial cells appear hypertrophied and hyperplastic with enlarged nuclei and nucleoli. There are no adhesions to Bowman capsule. (Jones methenamine silver; ×400.)

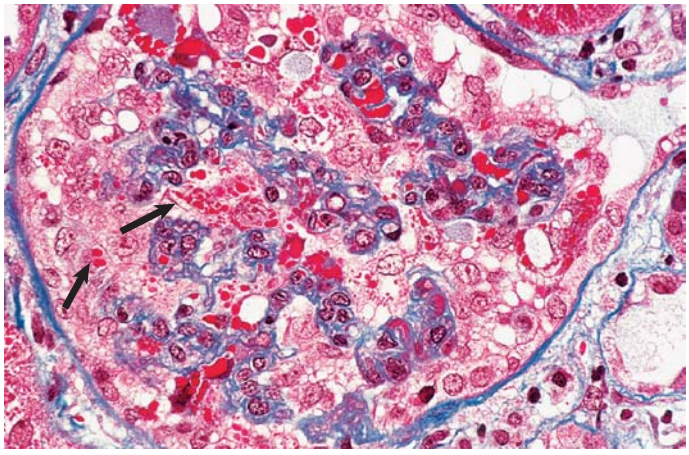

Figure 18-9 Focal segmental glomerulosclerosis, collapsing variant. The crescent-like proliferation of glomerular epithelial cells contains numerous intracytoplasmic vacuoles and trichrome-red protein resorption droplets (*arrows*). (Masson trichrome; ×400.)

There is often hyperplasia of the visceral epithelial cells, which may appear swollen and crowded, sometimes forming pseudocrescents. Foot process effacement is typically severe. This variant requires that tip lesions and collapsing lesions be excluded. Cellular FSGS is thought to represent an early stage in the development of segmental lesions and is usually primary.

Collapsing Variant of Focal Segmental Glomerulosclerosis

The collapsing variant is defined by at least one glomerulus with segmental or global collapse and overlying hypertrophy and hyperplasia of visceral epithelial cells (Fig. 18-7). In these areas, there is occlusion of glomerular capillary lumina by implosive wrinkling and GBM collapse.[44,45] The collapsing lesion is more often global than segmental. Overlying visceral epithelial cells display striking hypertrophy and hyperplasia and express proliferation markers. Glomerular epithelial cells often contain prominent intracytoplasmic protein resorption droplets and may fill Bowman space, forming pseudocrescents (Figs. 18-8 and 18-9). Although visceral cell hyperplasia is found in both the collapsing and the cellular variant of FSGS, collapsing glomerulopathy is distinguished by the absence of endocapillary hypercellularity. Studies suggest that dysregulated podocytes,[36] activated parietal cells (expressing claudin and CD44),[50,51] and progenitor cells (expressing stem cell markers CD133 and CD24)[52,53] that line Bowman capsule contribute to the glomerular epithelial cell hyperplasia. *In vivo* microscopy also has illustrated the ability of parietal cells to rapidly plug sites of podocyte denudation and depletion in FSGS.[54] A major unanswered question is whether cells of Bowman capsular origin have the capacity to differentiate into and replenish mature podocytes.

In collapsing FSGS, there is prominent tubulointerstitial disease, including tubular atrophy, interstitial fibrosis, interstitial edema, and inflammation. A distinctive feature is the presence of dilated tubules forming microcysts that contain loose proteinaceous casts. On EM, there is typically severe foot process effacement affecting both collapsed and noncollapsed glomeruli (Fig. 18-10). Collapsing glomerulopathy may occur as a primary form of FSGS.[44,45] This pattern is also frequently observed in secondary FSGS caused by HIV infection, parvovirus B19 infection, interferon therapy, or pamidronate

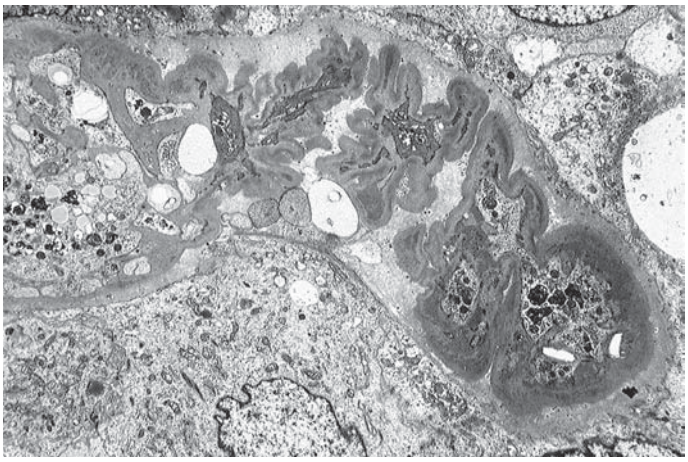

Figure 18-10 Focal segmental glomerulosclerosis, collapsing variant. On electron microscopy, there is tight collapse of the glomerular capillaries with corrugated glomerular basement membrane. The overlying podocytes appear detached and hypertrophied, with complete loss of foot processes. (×2500.)

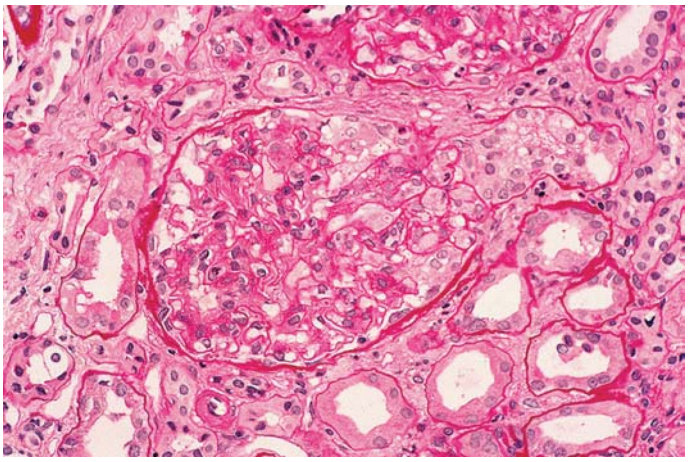

Figure 18-12 Focal segmental glomerulosclerosis, tip lesion variant. A cellular tip lesion displays engorgement of glomerular capillaries by foam cells and adhesion of the involved segment to the origin of the proximal tubule (tubular pole). (PAS; ×250.)

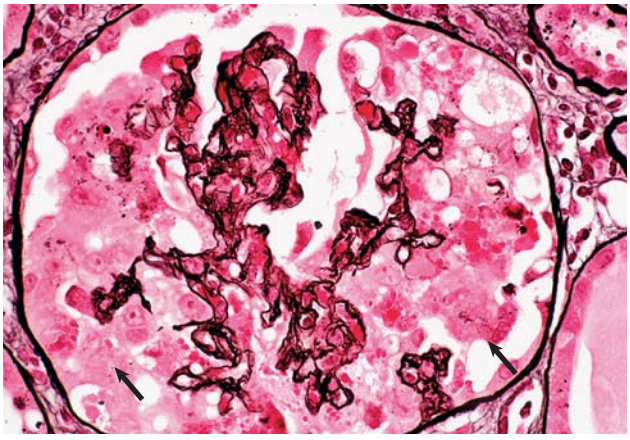

Figure 18-11 Focal segmental glomerulosclerosis, collapsing variant, from pamidronate toxicity. The glomerular tuft is retracted, without appreciable increase in matrix material. The overlying visceral epithelial cells are enlarged and hyperplastic *(arrows),* with numerous intracytoplasmic vacuoles and protein resorption droplets. (Jones methenamine silver; ×400.)

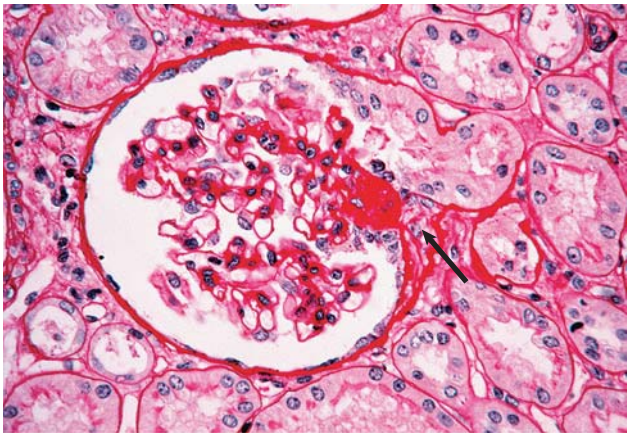

Figure 18-13 Focal segmental glomerulosclerosis, tip lesion variant. A sclerosing tip lesion forms an adhesion to the tubular pole *(arrow)*. (PAS; ×250.)

toxicity[5] (Fig. 18-11). The presence of endothelial tubuloreticular inclusions is helpful to identify collapsing glomerulopathy secondary to HIV-associated nephropathy or interferon therapy.

Tip Variant of Focal Segmental Glomerulosclerosis

The tip variant is defined by the presence of at least one segmental lesion involving the tip domain, or the outer 25% of the tuft next to the origin of the proximal tubule.[43] There is either adhesion between the tuft and Bowman capsule or confluence of swollen podocytes with parietal or tubular epithelial cells at the tubular lumen or neck. The segmental lesions may be cellular or sclerosing (Figs. 18-12 and 18-13). These lesions may evolve more centrally. The presence of perihilar sclerosis or collapsing sclerosis rules out the tip variant. In one study of FSGS tip lesions, biopsy specimens had glomerular tip lesions alone in 26% and glomerular tip lesions plus other peripheral FSGS lesions in the other 74%.[43] The degree of foot process effacement is usually severe. Most cases are primary and resemble MCD in the abrupt onset of nephrotic syndrome, suggesting they may share a similar permeability factor. Higher shear stress and tuft prolapse at the tubular pole are likely to play a role in the morphogenesis of this lesion.[7]

Other Variants of Focal Segmental Glomerulosclerosis

Two histologic variants often included within the FSGS spectrum are FSGS with diffuse mesangial hypercellularity and C1q nephropathy (see also Chapter 28).[5,47,48] FSGS with *diffuse mesangial hypercellularity* has lesions of FSGS on a background of generalized hypercellularity. By IF, there is diffuse mesangial positivity for IgM, with more variable mesangial staining for C3; EM reveals extensive foot process effacement without glomerular electron-dense deposits. This variant occurs almost exclusively in young children.

An idiopathic glomerulopathy, *C1q nephropathy* is defined by dominant or codominant IF staining for C1q, mesangial electron-dense deposits, and light microscopic findings resembling FSGS or MCD with variable mesangial hypercellularity. In one study, 17 patients had a light microscopic appearance of FSGS (including six collapsing and two cellular) and three of MCD.[47] In addition to C1q staining, biopsy specimens may show deposition of other immunoglobulins (particularly IgG) and complement components (C3),

making exclusion of other clinical disease entities important, including lupus nephritis and membranoproliferative glomerulonephritis (MPGN). In C1q nephropathy, electron-dense deposits are typically located predominantly in the paramesangial region subjacent to the GBM reflection. There is variable foot process effacement. The largest series of C1q nephropathy supports that many cases represent a subgroup of primary FSGS or MCD, whereas others are an idiopathic immune complex–mediated glomerulonephritis.[48]

Distinguishing Pathologic Features of Secondary FSGS

Although the pathology of some secondary forms of FSGS resembles closely that of primary FSGS, there are several noteworthy differences. Whereas the light microscopic findings in HIV-associated nephropathy are similar to those of primary collapsing FSGS (Fig. 18-14), tubular microcysts are particularly common (Fig. 18-15).[55] On EM, a major difference is the abundance of tubuloreticular inclusions in the glomerular endothelial cells of HIV-associated nephropathy. These "interferon footprints" consist of 24-nm interanastomosing tubular structures located within dilated cisternae of endoplasmic reticulum (Fig. 18-16). Tubuloreticular inclusions have become less frequent in patients treated with highly active antiretroviral therapy.[55]

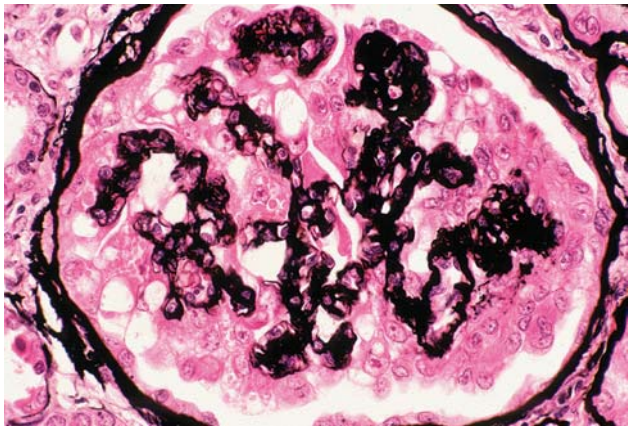

Figure 18-14 Human immunodeficiency virus (HIV)–associated nephropathy. A globally collapsed glomerulus shows marked visceral cell hypertrophy and hyperplasia. (Jones methenamine silver; ×400.)

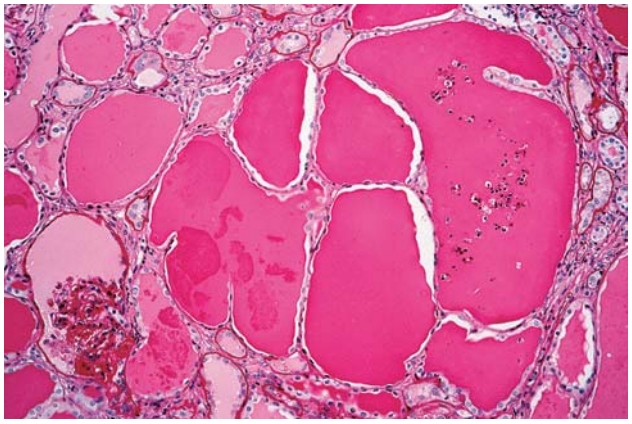

Figure 18-15 HIV-associated nephropathy. At low power, the renal parenchyma contains abundant tubular microcysts with proteinaceous casts. The glomerulus is collapsed with dilated urinary space. (PAS; ×80.)

In secondary adaptive forms of FSGS, renal biopsy typically shows glomerulomegaly and predominantly perihilar lesions of segmental sclerosis and hyalinosis. In secondary FSGS resulting from loss of renal mass, such as from reflux nephropathy or hypertensive arterionephrosclerosis, FSGS is usually seen on a background of extensive global glomerulosclerosis, tubular atrophy, interstitial fibrosis, and arteriosclerosis. In secondary FSGS related to sickle cell disease, glomerular hypertrophy and sclerosis are associated with capillary congestion by sickled erythrocytes and double contours of the GBM resembling those seen in chronic thrombotic microangiopathy. Importantly, in adaptive forms of FSGS, the degree of foot process effacement tends to be relatively mild, affecting less than 50% of the total glomerular capillary surface area, with correspondingly shorter foot process width (Fig. 18-17). In one study, a cutoff of more than 1500 nm for mean foot process width was able to distinguish primary from adaptive FSGS with high sensitivity and specificity.[56]

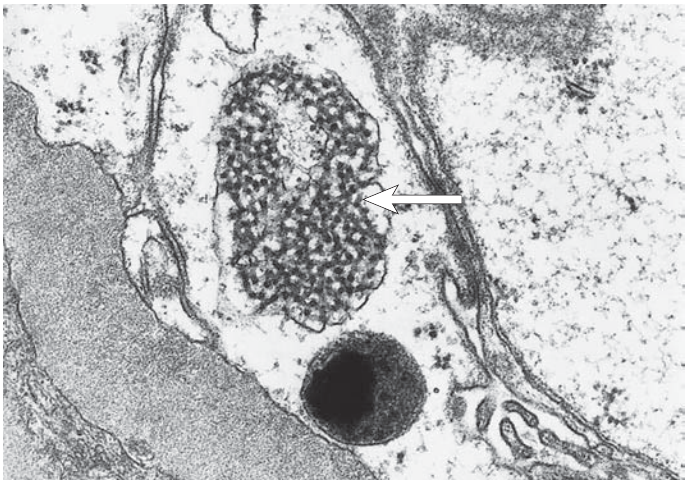

Figure 18-16 HIV-associated nephropathy. The glomerular endothelial cell pictured here contains a large intracytoplasmic tubuloreticular inclusion ("interferon footprint"; *arrow*) composed of interanastomosing tubular structures within a dilated cisterna of endoplasmic reticulum. (Electron micrograph; ×15,000.)

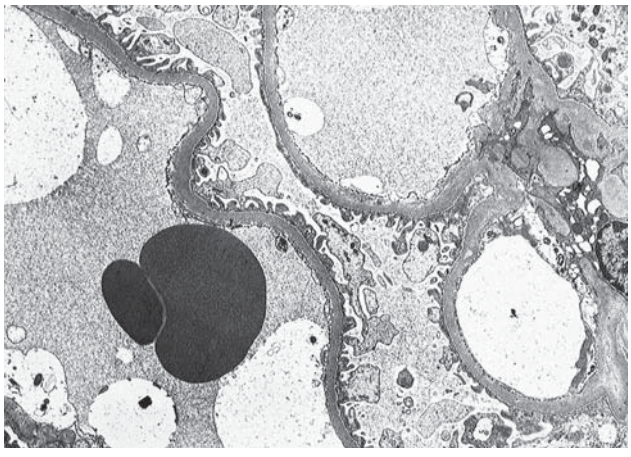

Figure 18-17 Secondary focal segmental glomerulosclerosis (FSGS) from obesity. This patient with morbid obesity had glomerular hypertrophy and predominantly perihilar lesions of segmental sclerosis and hyalinosis on light microscopy. The foot processes show mild effacement involving approximately 20% of the glomerular capillary surface area despite the presence of nephrotic-range proteinuria. This mild degree of foot process effacement is less than that usually seen in primary FSGS. (Electron micrograph; ×2500.)

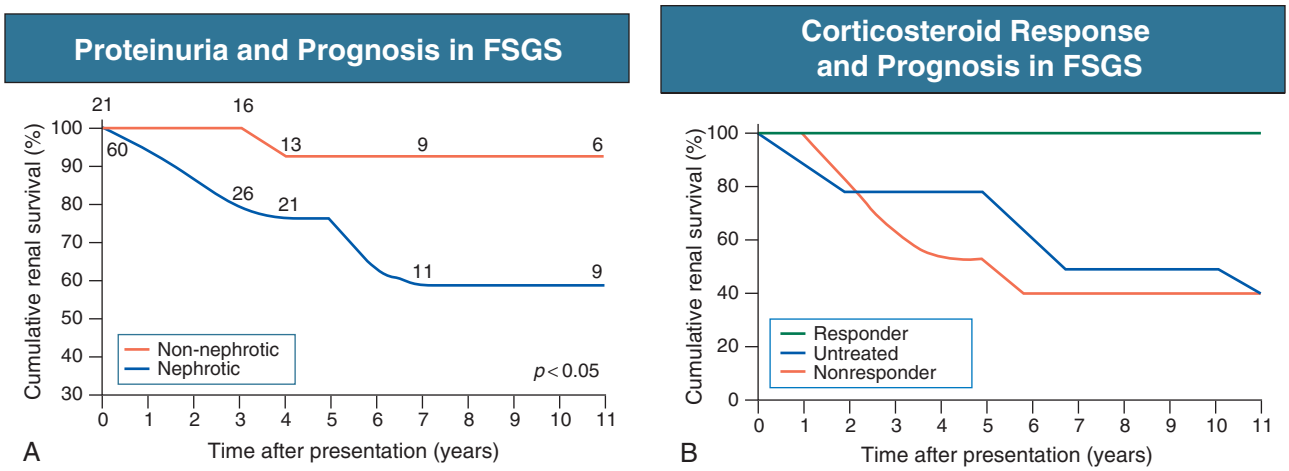

Figure 18-18 Prognosis in primary focal segmental glomerulosclerosis (FSGS). A, The risk for development of renal failure is related to the extent of proteinuria. Those with nephrotic-range proteinuria are much more likely to develop renal failure than those with low-grade proteinuria. The figures indicate the number of at-risk patients at different time points. **B,** Corticosteroid-responsive patients are significantly less likely to develop renal failure than nonresponders and untreated patients. *(Modified from reference 87.)*

Risk Factors for Progressive Renal Disease in Focal Segmental Glomerulosclerosis

Clinical Features at Biopsy
Severity of nephrotic-range proteinuria
Elevated serum creatinine
Black race

Histopathologic Features at Biopsy
Collapsing variant
Tubulointerstitial fibrosis

Clinical Features During Disease Course
Failure to achieve partial or complete remission

Box 18-3 Risk factors for progressive renal disease in FSGS.

NATURAL HISTORY AND PROGNOSIS

The natural history of FSGS is varied.[1-3] Without therapy or response to therapy, the majority of patients with primary FSGS will experience a progressive increase in proteinuria and progression to renal failure. Only 5% to 25% of patients undergo a spontaneous remission of proteinuria.[57] Both unresponsive children and adults have a similar course; most develop ESRD 5 to 20 years from presentation, with approximately 50% of such patients reaching ESRD by 10 years (Fig. 18-18).

Certain epidemiologic, clinical, and histologic findings at diagnosis help predict the long-term course of FSGS patients[1-5] (Box 18-3). African Americans, even when controlled for degree of proteinuria, hypertension, and other features, experience a more rapid progression to renal failure. At biopsy, reduced GFR, greater degrees of proteinuria, and greater degrees of interstitial fibrosis predict a more progressive course.[1] The degree of glomerulosclerosis has been much less consistent as a prognostic finding.[1-5] Patients who experience a remission of proteinuria and the nephrotic syndrome have much better renal survival than those who do not.[1,3,58,59] Even patients with a partial remission of nephrotic syndrome have a lower rate of long-term renal failure.[60]

There is a consensus that outcomes are best for tip variant and worst for collapsing variant of primary FSGS, with intermediate outcome in FSGS NOS.[49,61,62] These differences held true even in a cohort of children and young adults with initially corticosteroid-resistant FSGS.[63] In a comparative series, the percentage of complete and partial remission was greatest for tip lesion (76%), lowest for collapsing variant (13%), and intermediate for cellular (44%), compared with 39% for FSGS NOS. There was a strong inverse correlation between remission rates and progression to ESRD among these subgroups. Accordingly, the percentage ESRD was greatest for collapsing variant (65%), lowest for tip lesion (6%), and intermediate for cellular variant (28%), compared with 35% for FSGS NOS.[49]

TREATMENT

There is still considerable debate about the appropriate treatment of patients with primary FSGS[1-3,5,59] (Fig. 18-19). In part, this relates to confusion between primary and secondary forms of the disease, including unrecognized genetic variants. For example, even after biopsy, it is not always clear whether an obese person with glomerulomegaly, FSGS, and nephrotic-range proteinuria has secondary or primary disease.[18] Moreover, the course of the disease is variable, and only recently have clear prognostic features been defined. Finally, although FSGS is common in adults, there are many therapeutic options with few randomized controlled trials (RCTs) on which to base judgment.

In early studies of FSGS, only 10% to 30% of those treated with corticosteroids for relatively short periods or with other immunosuppressive agents experienced a remission of proteinuria, and the relapse rate was high.[1,59] Thus, many nephrologists considered FSGS to be a resistant disease and did not advocate immunosuppressive treatment. A classic study documented that in Toronto, almost all children with FSGS were treated with immunosuppressives and that 44% experienced a remission.[58] Although the response rate for treated adults was similar (39%), most of the adults never received immunosuppressive therapy.

Use of Corticosteroids

In trials using longer (>6 months) courses of corticosteroids in primary FSGS, the results have been much more rewarding. In adults, therapy is usually with prednisone or prednisolone, 1 mg/kg/day, or 1.5 to 2 mg/kg every other day, for an initial period of 4 to 8 weeks, with subsequent tapering of the dose.[1,3,59] Initial response

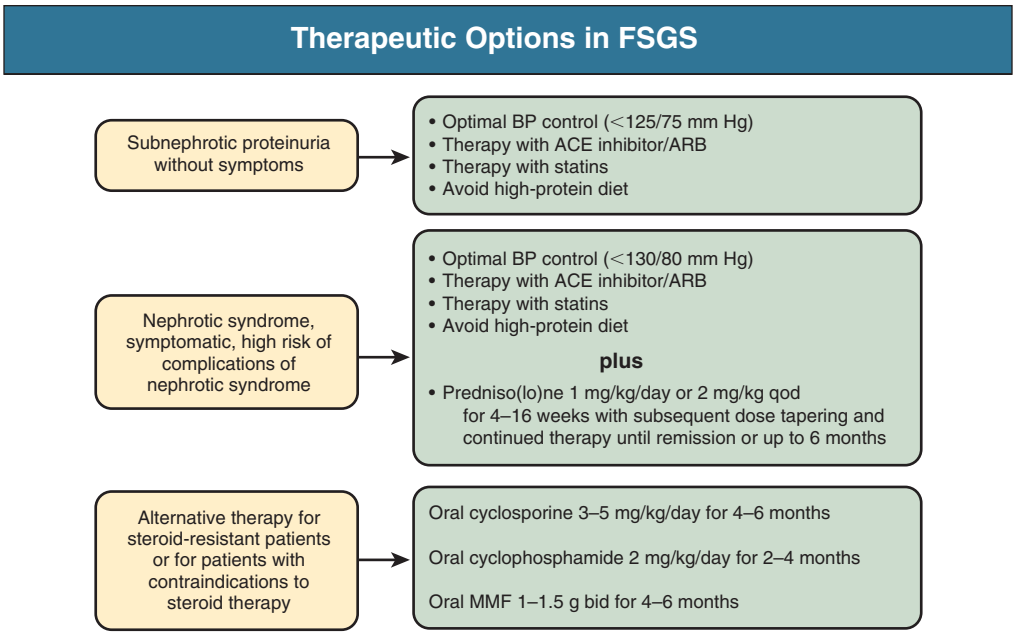

Figure 18-19 Therapeutic options in focal segmental glomerulosclerosis. Treatment of secondary FSGS should be directed at the underlying cause whenever possible. For HIV-associated nephropathy, treatment with highly active antiretroviral therapy (HAART); for pamidronate nephrotoxicity, discontinue the medication; and for obesity-related glomerulopathy, weight loss. *ACE,* Angiotensin-converting enzyme; *ARB,* angiotensin receptor blocker; *BP,* blood pressure; *MMF,* mycophenolate mofetil.

rates range from 40% to 80%. Nephrotic children typically receive an empiric 4- to 6-week course of prednisone (60 mg/m^2 body surface area) before a renal biopsy is performed, in an attempt to effect remissions in those with MCD. In children with biopsy-documented FSGS, 20% to 25% will achieve a complete remission with a short course of corticosteroids, but as many as 50% will remit with more intensive therapy. In adults, although no large RCTs are available, more prolonged use of corticosteroids has led to much higher remission rates of nephrotic syndrome than in earlier studies.[1,3,59,64,65] The median duration of corticosteroid treatment for complete remission to be achieved is 3 to 4 months; most patients respond by 6 months. Most clinicians would treat all nephrotic primary FSGS patients and those at risk of progressive disease with a prolonged course (6 to 9 months) of daily or every-other-day corticosteroid therapy or other immunosuppressive medication in the hope of inducing a remission of nephrotic syndrome and preventing eventual ESRD.[65] Kidney Disease: Improving Global Outcomes (KDIGO) study guidelines recommend initial prednisone therapy in nephrotic patients with primary FSGS, with the high dose to be continued for a minimum of 4 weeks and a maximum of 16 weeks, with a slow taper over 6 months after achieving complete remission.[66]

Other Immunosuppressive Agents

For many years, either chlorambucil or cyclophosphamide combined with corticosteroids was the treatment of choice for corticosteroid-resistant FSGS.[1,67] One uncontrolled trial in children using combined intravenous pulse corticosteroids and long-term immunosuppression with corticosteroids and cytotoxics found a 60% complete remission rate and a 16% partial remission rate of the nephrotic syndrome and a low rate of progression to renal failure.[68] However, recent KDIGO guidelines specifically suggest that cyclophosphamide not be given to children with corticosteroid-resistant nephrotic syndrome, and to use alternative medicines such as calcineurin inhibitors (CNIs) or mycophenolate.[66] In adults with FSGS treated with oral cyclophosphamide or chlorambucil, pooled data show a high response rate for patients with corticosteroid dependence or intolerance, but a remission rate of less than 20% for corticosteroid-resistant patients.[59]

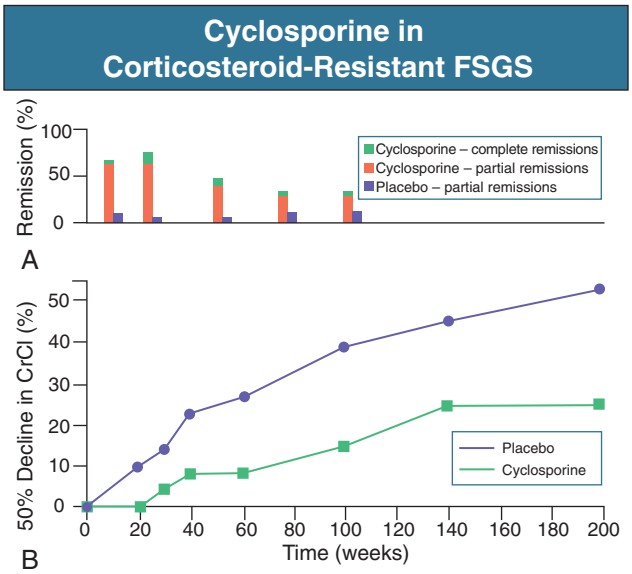

Figure 18-20 Cyclosporine in corticosteroid-resistant focal segmental glomerulosclerosis (FSGS). Randomized controlled trial of 6 months of treatment with prednisolone and either cyclosporine or placebo. **A,** Cyclosporine induces a partial or complete remission significantly more often than placebo. **B,** Cyclosporine treatment results in a lower rate of decline in renal function than with placebo, even after 4 years; *CrCl,* creatinine clearance. *(Modified from reference 70.)*

A number of studies have used low-dose cyclosporine, 3 to 6 mg/kg/day for 2 to 6 months, to treat corticosteroid-resistant FSGS[69,70] (Fig. 18-20). Complete plus partial remission rates of 60% to 70% have been achieved versus only 17% to 33% in the placebo groups. In North America, steroid-resistant adult FSGS patients randomized

to either cyclosporine with low-dose corticosteroids or the same low dose of corticosteroids alone for a 6-month period exhibited a much higher remission rate (12% complete and >70% complete or partial) in the group treated with cyclosporine.[70] Despite relapses after the cyclosporine was discontinued, at the end of long-term follow-up, there were still significantly more remitters in the treated group. The percentage of patients with reduction of GFR during 4 years was significantly less in the treated group. Nevertheless, because there is a high relapse rate when cyclosporine is discontinued, many clinicians use a 1-year course with slow taper in patients who have had a favorable reduction of proteinuria with cyclosporine.[1,59]

Although data are more limited with tacrolimus and there are no RCTs, the results have been similar.[71,72] Because the major side effects of nephrotoxicity, hypertension, and hyperkalemia are the same for both cyclosporine and tacrolimus, choice may depend on cosmetic and other, less severe adverse side effects (e.g., gum swelling, tremor, hirsutism). Tacrolimus has been effective in some patients who are resistant to or intolerant of cyclosporine.

A multicenter German collaborative study compared the efficacy and safety of corticosteroids plus cyclosporine with corticosteroids plus chlorambucil in corticosteroid-resistant nephrotic adults with FSGS.[73] Total and partial remission rates were similar (~20% full and 40% to 50% partial remissions), and the addition of chlorambucil to the regimen did not improve outcome.

Whether cyclosporine is equivalent or superior to corticosteroids as first-line therapy for FSGS has never been documented. However, some clinicians use cyclosporine as first-line therapy in patients at high risk of corticosteroid complications, such as those with concurrent diabetes or morbid obesity.[5]

Mycophenolate mofetil (MMF; mycophenolic acid) has been used successfully in several uncontrolled series of FSGS patients.[74,75] A multicenter prospective RCT compared cyclosporine and a regimen of oral MMF plus dexamethasone in 138 children and young adults up to age 40 who had corticosteroid-resistant FSGS.[76] The partial or complete remission rates were not significantly different (46% in cyclosporine group; 33% in MMF-dexamethasone group). KDIGO guidelines now recommend MMF and dexamethasone for corticosteroid-resistant patients who do not tolerate CNIs.[66]

The use of sirolimus has been controversial because the drug was reported to induce proteinuria and FSGS lesions in kidney transplant patients. In one series, sirolimus was associated with worsening of renal function, episodes of acute renal failure, and no remissions of the nephrotic syndrome.[77] In another series with 21 corticosteroid-resistant FSGS patients, 19% experienced a complete remission, 38% a partial remission.[78] Given the controversy about toxicity, sirolimus is not recommended for the treatment of FSGS. Plasma exchange, which is successful in treating some patients with recurrent FSGS in the renal allograft (see Chapter 108), has not proved useful in patients with disease in their native kidneys.[20] A study of low-density lipoprotein apheresis and prednisone in corticosteroid- and cyclosporine-resistant children with primary FSGS achieved a remission in 7 of 11 patients.[79]

Rituximab has been used in several studies of small numbers of FSGS patients.[80] It has proved more successful for steroid-dependent than steroid-resistant patients.[81]

Corticotropin (ACTH) has been beneficial in small numbers of FSGS patients resistant to multiple other immunosuppressives, but it also has not been formally studied in large RCTs.[82]

Galactose, a monosaccharide sugar, has been shown to have a high affinity for CLC1 permeability factor.[83] In single cases with FSGS resistant to multiple immunosuppressive regimens, long-term galactose therapy normalized CLC1 and dramatically reduced proteinuria.[84]

Other Therapeutic Interventions

The role, if any, of corticosteroids and other immunosuppressives in the treatment of patients with subnephrotic levels of proteinuria and little damage on renal biopsy is unclear. Most nephrologists would not use corticosteroids to treat FSGS patients with subnephrotic proteinuria. Most would treat all FSGS patients who have no contraindications with angiotensin-converting enzyme (ACE) inhibitors or angiotensin receptor blockers (ARBs) as well as statins, similar to other progressive glomerular diseases. Clearly, optimal blood pressure control itself is also critical to slow or to prevent the progression of the disease (see also Chapter 80).

Another area of active research is the use of agents to prevent renal fibrosis in patients with FSGS. Pirfenidone, an oral TGF-β inhibitor, was used in 21 patients with FSGS and a declining GFR.[85] Pirfenidone slowed the loss of kidney function over time without altering either blood pressure or proteinuria. A study using an antibody to TGF-β is ongoing in FSGS patients.

For patients with secondary forms of FSGS, attempts to treat the actual cause of the FSGS should be the initial step in management. Patients with FSGS secondary to obesity and heroin nephropathy have had remission of proteinuria after weight reduction or cessation of heroin use, respectively. In patients with HIV-associated nephropathy, therapy with highly active antiretroviral drugs and blockers of the renin-angiotensin system has proved useful (see Chapter 58). The role of immunosuppressives has not yet been documented in RCTs in any form of secondary FSGS. In all forms of secondary FSGS, supportive therapy as outlined in Chapter 80 is essential to prevent progressive renal disease in this population. In patients with primary idiopathic or a secondary form of FSGS who remain nephrotic, control of fluid retention and edema can be managed with salt restriction and diuretics (see Chapter 15).

TRANSPLANTATION

Approximately 40% of patients with primary FSGS who develop ESRD and undergo renal transplantation develop recurrent FSGS in the allograft[86] (see Chapter 108). Children with FSGS and patients who manifest with more severe proteinuria and a more rapid course to renal failure in their native kidneys are at greater risk of recurrence in the allograft. Those who have lost a prior allograft because of recurrent FSGS are at highest risk of recurrence. Recurrence in the allograft may be seen immediately after transplantation, supporting the existence of a circulating factor, or years later. Interestingly, the histologic variant of recurrent FSGS was the same as that documented in the native kidney in 81% of cases, validating the fidelity of the histologic subclassification.[11] Plasma exchange has been used successfully to induce remissions of the proteinuria associated with recurrence, but the results are more favorable in children than in adults. Rituximab has been used in some patients for recurrent FSGS, with varied outcomes.

CHAPTER 19

Inherited Causes of Nephrotic Syndrome

Gentzon Hall and Michelle P. Winn

Inherited nephrotic syndromes are rare diseases that present with nephrotic syndrome and varying degrees of renal impairment, but at times may also present with subnephrotic proteinuria. Inherited disease may manifest *in utero* or shortly after birth, as in congenital nephrotic syndromes, or later in life with proteinuria and pathologic findings consistent with focal segmental glomerulosclerosis. FSGS as the cause of nephrotic syndrome in adults is increasing according to North American (but not European) biopsy studies, and some believe that up to 18% of FSGS cases are caused by hereditary disorders.[1] Autosomal dominant and recessive renal diseases result from defects in podocytes, the slit diaphragm, and the glomerular basement membrane (GBM). These primary renal disorders by definition do not recur after kidney transplantation. In children, syndromic conditions may be seen in which mutations in transcription factors involved in the development of multiple organ systems also affect renal morphogenesis and result in glomerulopathy. Further insight into these hereditary diseases has been elucidated through animal models, in which mutations in corresponding proteins often result in FSGS and proteinuria. Understanding these mechanisms not only provides better insight into abnormalities involved in idiopathic proteinuric kidney diseases but also allows the possible development of molecular drug targets that may improve the course of the renal disease and delay progression.[2-4]

AUTOSOMAL RECESSIVE DISEASES

Congenital Nephrotic Syndrome of the Finnish Type

In 1956, Hallman described a disorder of massive proteinuria *in utero* in the Finnish population. Congenital nephrotic syndrome of the Finnish type (CNF) or nephrotic syndrome type 1 (NPHS1) is an autosomal recessive disease. It has an incidence of 1 in 8200 births in Finland and has been reported less frequently in other ethnicities. The placenta is larger than the child at birth, and the baby is usually born prematurely. Affected children will have as much as 30 g of proteinuria daily, massive edema, hypoalbuminemia, and hyperlipidemia. On light microscopy, kidneys typically have cystic dilation of the proximal tubules and diffuse mesangial sclerosis (Fig. 19-1). Effacement of podocyte foot processes and loss of the glomerular slit diaphragm are seen with electron microscopy.[2]

The product of the mutated *NPHS1* gene, nephrin, is specifically expressed in podocytes, localized to the slit diaphragm between podocyte foot processes.[3] Nephrin is a transmembrane protein belonging to the immunoglobulin superfamily with an intracellular, transmembrane, and extracellular domain. The extracellular domain forms the zipper-like structure of the slit diaphragm; the short intracellular domain interacts with the podocyte proteins podocin and CD2-associated protein (CD2AP). The most common mutations in nephrin are termed Fin-major and Fin-minor and account for 95% of the disease, but more than 50 other mutations in nephrin have been reported.[4] *NPHS1* knockout mice have massive proteinuria, have no slit diaphragm, and die within 24 hours of birth.[5]

Patients with CNF do not respond to cytotoxic therapy or corticosteroids. Angiotensin-converting enzyme (ACE) inhibitors and nonsteroidal anti-inflammatory drugs (NSAIDs) have no effect on reducing proteinuria in those with the Fin-major mutation, but there are some reports of efficacy of these agents in those with other mutations in nephrin. The ultimate goal of treatment of CNF is renal transplantation because without this approach, mortality is almost 100%. Because of overwhelming urinary loss of protein, affected infants without the Fin-major mutation may require medical nephrectomy with ACE inhibitors and NSAIDs, followed by renal replacement therapy before transplantation.

Corticosteroid-Resistant Nephrotic Syndrome

In children with nephrotic syndrome of unknown etiology, 90% respond to corticosteroids. Of the remaining 10%, many have corticosteroid-resistant nephrotic syndrome. Multiple hereditary forms have been identified. Mutations of *NPHS2,* which encodes the essential slit diaphragm protein podocin, cause an autosomal recessive disease seen mostly in children younger than 5 years.[6] Affected children have nephrotic-range proteinuria, extrarenal complications of massive proteinuria (see Chapter 15), and rapid progression to end-stage renal disease (ESRD). On light microscopy, the renal lesions vary along the spectrum of minimal change disease to FSGS.[4] Podocin is a hairpin-shaped transmembrane protein specifically expressed in podocytes[2] (Fig. 19-2). Podocin localizes to the foot processes and seems to be involved in podocyte structure as well as in intracellular signaling, with the recruitment of nephrin and CD2AP to microdomains along the slit diaphragm.[4]

Corticosteroid-resistant nephrotic syndrome attributed to the *NPHS2* mutation affects children between 3 months and 5 years of age. The age when the disease manifests seems to depend on the specific podocin mutation. The presence of at least one podocin mutation that codes for a stop codon or in patients homozygous for the R138Q mutation results in renal disease at about age 2 years. Two missense podocin mutations cause disease just before 5 years. Furthermore, studies demonstrate podocin mutations in some adult-onset FSGS. These patients must have two podocin mutations, one of which must be the podocin R229Q mutation.[7]

Another cause of corticosteroid-resistant nephrotic syndrome is a mutation in the phosphatase receptor type O (PTPRO), also called glomerular epithelial protein 1 (GLEPP1).[8] PTPRO is a 150-kD transmembrane protein expressed on the apical membrane surface of podocytes. PTPRO deficiency has been demonstrated to alter podocyte structure and cause foot process flattening. Homozygous donor splice-site mutations result in skipping of *PTPRO* exon 16 or 19. Patients with *PTPRO* mutations present in the first decade of life with resistant nephrotic syndrome. In immunohistochemical

analyses, the exon 16 mutation did not produce a change in the staining pattern of *PTPRO* in biopsy specimens, whereas the *PTPRO* staining with the exon 19 deletion biopsy specimens was completely absent, consistent with a lack of protein expression secondary to degradation of the messenger RNA product. Ultrastructural analyses of biopsy specimens revealed podocyte foot process effacement and microvillous transformation consistent with findings in the *PTPRO*$^{-/-}$ mouse model. The specific effects of the *PTPRO* mutations in podocytes are unknown.[8,9]

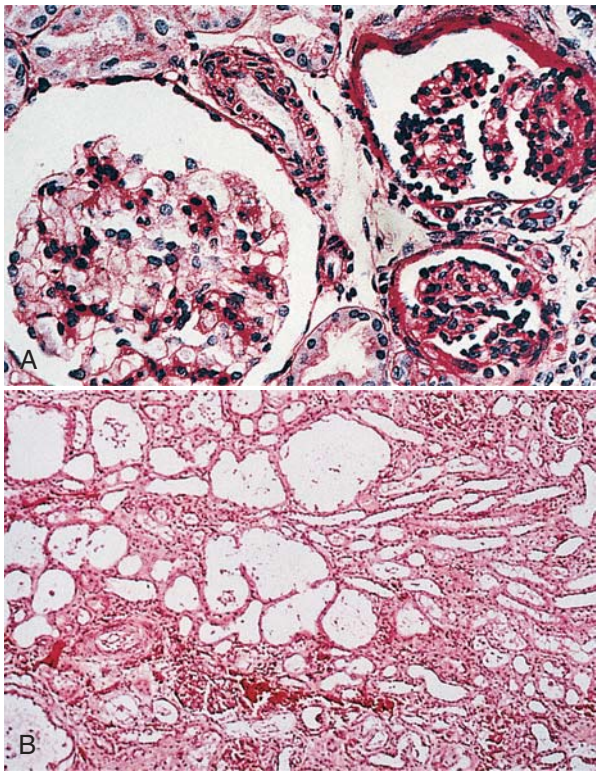

Figure 19-1 Congenital nephrotic syndrome, Finnish type. A, Diffuse mesangial thickening and partially collapsed glomeruli. **B,** Microcystic dilation of the tubules. (**A,** Periodic acid–Schiff reaction; magnification ×260; **B,** hematoxylin-eosin stain; ×150.) *(Modified from reference 30.)*

Isolated Diffuse Mesangial Sclerosis

Diffuse mesangial sclerosis is a pathologic finding in some patients with early-onset nephrotic syndrome. It occurs either "syndromic," when it is associated with a particular clinical syndrome, or "isolated." The isolated disease presents as nephrotic syndrome in the first month of life with rapid progression to ESRD. Light microscopy shows podocyte hypertrophy, mesangial matrix expansion, thickened basement membranes, and decreased size of glomerular capillary lumina. Some cases have shown response to cyclosporine.[10] Diffuse mesangial sclerosis is inherited in an autosomal recessive pattern (Table 19-1). The causative gene *PLCE1* encodes phospholipase C epsilon 1 (PLCε1). PLCε1 is a phospholipase involved in the generation of diacylglycerol and inositol 1,4,5-trisphosphate, which are intracellular second messengers (see Fig. 19-2). A *PLCE1* knockout model in zebrafish revealed edema and pathologic characteristics of nephrotic syndrome during development. The mechanism of disease from the *PLCE1* mutation is not clear, but evidence shows that it interacts with a guanosine triphosphatase (GTPase)–activating protein involved in podocyte development and interaction with nephrin. *PLCE1* is not the only gene responsible for isolated diffuse mesangial sclerosis. More genetic causes are under investigation.[10]

Autosomal Recessive Familial Focal Segmental Glomerulosclerosis

In 2011, mutations of *MYO1E,* which encodes the Myo1E protein, a nonmuscle class I myosin with important functions in the regulation of podocyte cytoskeletal dynamics, were identified as causes of nonsyndromic autosomal recessive FSGS.[11] Mutations of *MYO1E* resulted in early-onset ESRD secondary to FSGS. These mutations have been associated with presentation between 1 and 9 years of age.

Autosomal Recessive Nephrotic Syndromes

Disease	Gene	Protein	Clinical Presentation	Mechanism of Disease
Congenital nephrotic syndrome of Finnish type	*NPHS1*	Nephrin	Proteinuria *in utero* (at times >30 g), large placenta, resistant to conventional therapy; transplant is only treatment.	Mutation in nephrin leads to loss or malfunction of slit diaphragm.
Corticosteroid-resistant nephrotic syndrome	*NPHS2*	Podocin	Clinical manifestations and age of onset of proteinuria vary; resistant to corticosteroids, generally progresses to FSGS	Mutation in podocin leads to loss or malfunction of slit diaphragm.
	PTPRO (GLEPP1)	PTPRO (GLEPP1)	Childhood-onset corticosteroid-resistant nephrotic syndrome; FSGS on biopsy	Unclear, but *PTPRO* mutation results in severe podocyte foot process effacement, swelling, and vacuolization as well as mesangial hypercellularity and focal sclerosis.
Isolated diffuse mesangial sclerosis	*PLCE1*	PLCε1	Nephrotic syndrome in first year of life; rapid progression to ESRD	Unclear, but *PLCE1* mutation results in abnormal podocyte differentiation, possibly through nephrin; other mutations exist not attributable to *PLCE1.*
Corticosteroid-resistant FSGS	*MYO1E*	Myo1E	Corticosteroid-resistant FSGS; early onset between 6 and 18 years of age	*MYO1E* mutation is associated with corticosteroid-resistant FSGS characterized by basement membrane thickening and multilamination as well as podocyte foot process effacement and microvillous transformation; overexpression of *MYO1E* A159P mutant in human podocyte line resulted in mislocalization of Myo1E and CD2AP.

Table 19-1 Autosomal recessive nephrotic syndromes. *ESRD,* End-stage renal disease; *FSGS,* focal segmental glomerulosclerosis; *GLEPP1,* glomerular epithelial protein 1; *Myo1E,* myosin 1E; *PLCE1,* phospholipase C epsilon 1; *PTPRO,* protein tyrosine phosphatase receptor, type O.

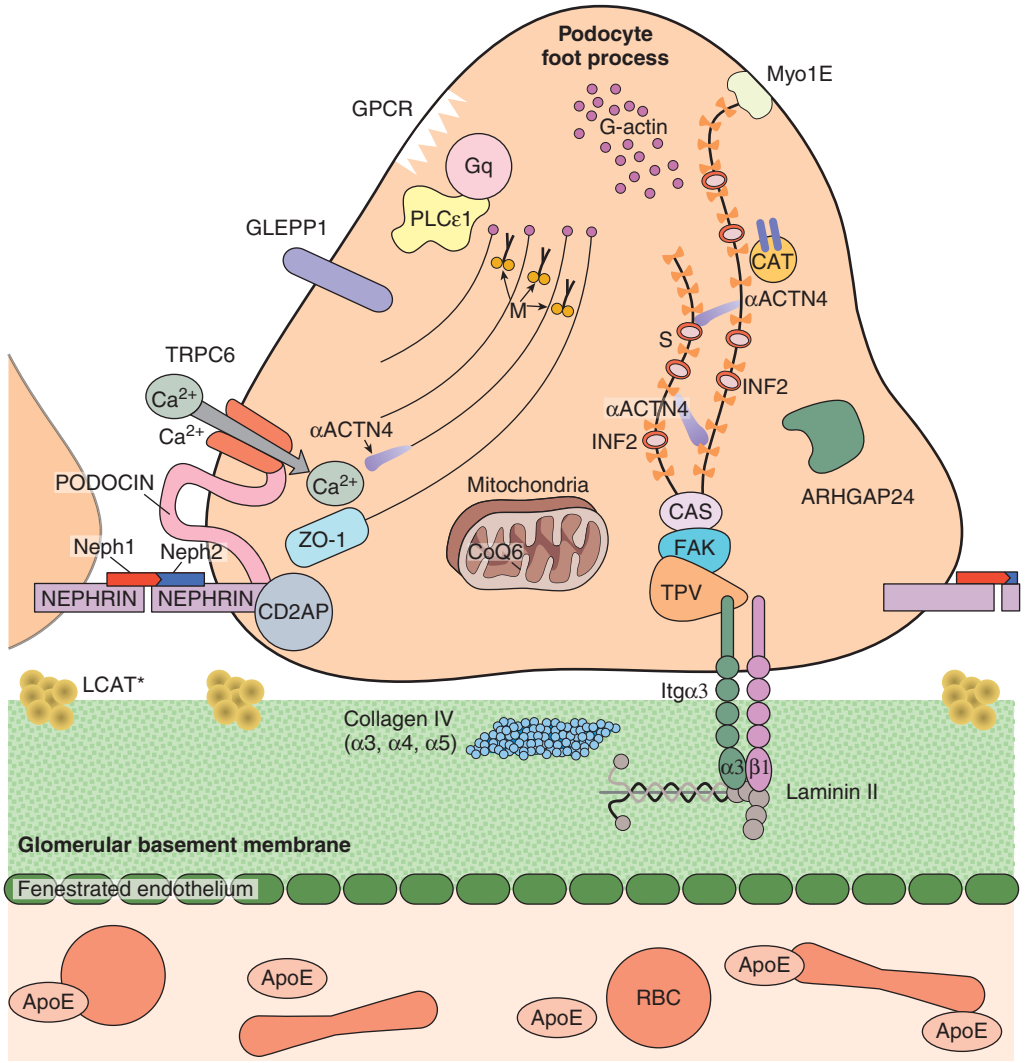

Figure 19-2 Podocyte foot process structure and proteins involved in hereditary nephrotic syndromes. The podocyte contains F-actin, myosin *(M)* and actin-binding proteins synaptopodin *(S)* and α-actinin-4; *αACTN4* is mutated in FSGS type 1. The slit diaphragm contains proteins that include nephrin, podocin, and CD2AP. Nephrin is mutated in congenital nephrotic syndrome of the Finnish type and podocin in corticosteroid-resistant nephrotic syndrome. Zona occludens 1 *(ZO-1)* is a cell-to-cell junction protein. The phospholipase PLCε1 is an enzyme identified as a cause of diffuse mesangial sclerosis. Angiotensin receptor, type 1 is an example of a G-protein coupled receptor *(GPCR)* and can activate TRPC6 via signals transmitted through the G-protein subunit Gq. A *TRPC6* mutation in FSGS type 2 results in increased calcium (Ca^{2+}) transients. Arhgap24 modulates the activity of the cytoskeletal regulator Rac1. Coenzyme Q10 biosynthesis monooxygenase 6 (CoQ6) is an essential component of the mitochondrial respiratory transport chain that is required for the biosynthesis of CoQ10. Talin, paxillin, and vinculin *(TPV)* are connected to laminin-11 via $\alpha_3\beta_1$ integrin dimers and are involved in anchoring the podocyte to the glomerular basement membrane (GBM). Myo1E is a mediator of F-actin filament organization. The protein phosphatase receptor type O (PTPRO, or *GLEPP1*) may regulate podocyte structure and function via its interaction with CD2AP. *INF2* is mutated in FSGS 5 and is a regulator of F-actin assembly. The *LAMB2* mutation is responsible for Pierson syndrome and results in diffuse mesangial sclerosis. Lecithin–cholesterol acyltransferase *(LCAT*)* deficiency leads to lipid deposits in the GBM. Laminated apolipoprotein deposits *(ApoE)* are found in the capillaries in lipoprotein glomerulopathy. *LMX1B* and *WT1* (not shown) are transcription factors mutated in syndromic proteinuric renal diseases. Catenins *(CAT),* p130Cas *(CAS),* and focal adhesion kinase *(FAK)* are structural proteins. *(Modified from reference 31.)*

Clinical signs and symptoms include nephrotic-range proteinuria and microhematuria, as well as hypoalbuminemia and edema. Renal biopsy findings are consistent with FSGS. Treatment with corticosteroids, ACE inhibitors, and cyclosporine A can result in partial remission, although some patients progress to ESRD. *In vitro* studies showed overexpression in a conditionally immortalized podocyte cell line that resulted in mislocalization of Myo1E and its interaction partner CD2AP. Also, targeted *MYO1E* knockout in mice produced basement membrane thickening and podocyte foot process effacement. Myo1E protein is postulated to be important in the regulation of tension development in podocyte foot processes, which may affect their ability to counterbalance variations in the glomerular capillary intraluminal pressure and maintenance of slit diaphragm integrity.[11]

AUTOSOMAL DOMINANT DISEASES

Autosomal Dominant Familial Focal Segmental Glomerulosclerosis

In contrast to inherited nephrotic syndromes that present in childhood, there are familial proteinuric kidney diseases that manifest in adolescence through adulthood. Most of these are inherited in an autosomal dominant manner (Table 19-2). Typical pathology reveals the glomerular changes of FSGS, and there is variability in the rate of progression of renal impairment. Genetic mutations have been identified, and mechanisms of FSGS in sporadic forms can be elucidated from increasing understanding of these familial cases.[12] Mutations of *ACTN4* cause an autosomal dominant form of FSGS. The

Autosomal Dominant Nephrotic Syndromes				
Disease	**Gene**	**Protein**	**Clinical Presentation**	**Mechanism of Disease**
FSGS type 1	*ACTN4*	α-Actinin-4	Slow progression to ESRD; generally presents in adulthood with proteinuria	Mutation in *ACTN4* results in abnormal assembly-disassembly of actin and podocyte structural abnormalities.
FSGS type 2	*TRPC6*	TRPC6	Proteinuria seen in late adolescence to adulthood; 60% progress to ESRD by 10 years	Mutation in *TRPC6* leads to increased calcium transients, which may result in disruption of podocyte structure or function.
FSGS type 5	*INF2*	INF2	Moderate proteinuria seen in late adolescence to adulthood; occasional microscopic hematuria and hypertension	Mutation in *INF2* causes mislocalization of the protein.
FSGS	*ARHGAP24*	Arhgap24	FSGS	*ARHGAP24* mutations cause increased podocyte membrane ruffling and hypermotility through potentiation of Rac1 activity *in vitro.*

Table 19-2 Autosomal dominant nephrotic syndromes. *Arhgap 24,* RhoA-activated Rac1 GTPase-activating protein 24; *ESRD,* end-stage renal disease; *FSGS,* focal segmental glomerulosclerosis; *INF2,* inverted formin 2; *TRPC6,* transient receptor canonical, type 6.

product of this gene is α-actinin 4, which is expressed in podocytes and cross-links with F-actin filaments in the foot processes (see Fig. 19-2). The mutation in *ACTN4* is believed to be a gain-of-function mutation, leading to increased cross-linking of F-actin with α-actinin 4, resulting in dysregulation of actin assembly and disassembly in the podocyte. It was recently found that the relaxation frequency from actin of mutant *ACTN4* was an order of magnitude lower than wild-type α-actinin 4. The resultant structural abnormality is believed to cause proteinuria, renal dysfunction, and subsequent glomerulosclerosis. This has been supported in murine studies; mice with mutated α-actinin 4 with high affinity for F-actin have an FSGS-like phenotype, and mice deficient in α-actinin 4 have abnormal podocytes and develop ESRD.[2,4] Patients with *ACTN4* mutations have variable age at onset and progression of renal disease.

Various mutations of the transient receptor potential cation channel, subfamily C, member 6 *(TRPC6)* have been identified as a cause of autosomal dominant FSGS.[12] TRP channels are involved in various biologic processes, including cell growth, mechanosensation, vasoregulation, and cation entry into cells. The P112Q missense mutation results in a gain of function, with increased calcium influx presumably leading to glomerular dysfunction.[2,4] Disease manifests in the third and fourth decades of life. As many as 60% of affected individuals will progress to ESRD in 10 years. In contrast to other known mutations that result in structural podocyte and slit diaphragm abnormalities, such as podocin, nephrin, and α-actinin 4, this is the first ion channel to be implicated as a cause of hereditary nephrotic syndrome and FSGS. Furthermore, there is increased expression of wild-type TRPC6 in human proteinuric kidney diseases, animal models of kidney injury, and cultured podocytes exposed to complement and antipodocyte antibodies, highlighting the role of TRPC6 in podocyte function and in the pathogenesis of various forms of kidney disease.[13]

Originally identified through its interaction with CD2 in T lymphocytes, the widely expressed protein CD2AP has been implicated in proteinuric renal disease. *CD2AP*-deficient mice die of renal failure at 6 to 7 weeks of age. On histologic examination, foot process effacement and glomerulosclerosis are seen. CD2AP does localize to the slit diaphragm and has been shown to interact with nephrin and podocin (see Fig. 19-2).[4] A corresponding disease in humans caused solely by *CD2AP* mutations has not yet been clearly established.[14]

Mutations in the formin gene *INF2* cause autosomal dominant FSGS.[15] All mutations are located in the diaphanous inhibitory domain of INF2. Individuals in these families present in early adolescence or adulthood with moderate proteinuria that progresses to ESRD. Some individuals also present with microscopic hematuria and hypertension. Pathology shows typical FSGS, although electron microscopy also shows prominent actin bundles within the foot processes. INF2 protein is a member of the formin family. These proteins regulate actin and accelerate actin polymerization. INF2 is widely expressed throughout the body and in podocytes. When transfected into podocytes, mutant *INF2* constructs exhibited different localization patterns than wild-type INF2.

In 2011, a novel missense mutation in the Rac1 regulatory protein Arhgap24 was identified as a cause of autosomal dominant FSGS. RhoA-activated Rac1 GTPase-activating protein (Arhgap24) is recognized as an essential modulator of podocyte actin cytoskeletal dynamics through the modulation of Rac1 GTPase activity.[16] Targeted *ARHGAP24* knockout in mouse podocytes impairs Rac1 deactivation and promotes podocyte motility. The Q158R variant led to impaired inhibition of Rac1 activation when overexpressed in cultured human embryonic kidney cells. The specific effects of the *ARHGAP24* mutation in podocytes have not been elucidated.[16]

SYNDROMIC PROTEINURIC RENAL DISEASE

Denys-Drash and Frasier Syndromes

Denys-Drash syndrome (DDS) and Frasier syndrome are rare diseases manifested with early onset of congenital nephrotic syndrome and male pseudohermaphroditism (Table 19-3). Both are associated with the development of urogenital tumors: nephroblastoma or Wilms tumor in DDS and gonadoblastoma in Frasier syndrome. Patients with DDS have a high incidence of severe hypertension and rapid progression to ESRD. The glomerular lesion of DDS is diffuse mesangial sclerosis, and patients progress to ESRD by age 3 years. In Frasier syndrome, male pseudohermaphrodites typically present as phenotypic females with amenorrhea or nephrotic syndrome, or both. The nephrotic syndrome may be slowly progressive, usually over 10 years, and is typically corticosteroid resistant; the pathologic lesion is FSGS. The patients develop ESRD in the second or third decade of life, with most cases occurring at puberty. Some cases present in much younger children.[17] Rarely, an XX karyotype with a less severe phenotype may not be identified clinically as Frasier syndrome and presents only with renal disease. The gene responsible for both DDS and Frasier syndrome has been localized to chromosome 11p13. The gene product is the Wilms tumor suppressor (WT1), which is a transcription factor involved in gonad and kidney development. WT1 seems to downregulate the expression of a number of genes involved in normal embryonic development of the urogenital system. Therefore, the decreased expression or lack of expression of

Syndromic Proteinuric Renal Diseases					
Disease	**Inheritance**	**Gene**	**Protein**	**Clinical Presentation**	**Mechanism of Disease**
Denys-Drash and Frasier syndromes	AD	*WT1*	WT1	Male pseudohermaphroditism, early nephropathy, and Wilms tumor in Denys-Drash; later onset of nephropathy, FSGS, and gonadoblastoma in Frasier syndrome	Mutation in *WT1* results in abnormal urogenital development.
Nail-patella syndrome	AD	*LMX1B*	LMX1B	Skeletal, nails, eyes, and renal abnormalities; variable renal disease from benign proteinuria to nephrotic syndrome	Mutation in *LMX1B* results in abnormal regulation of podocyte genes.
Pierson syndrome	AD	*LAMB2*	Laminin β2 chain	Microcoria, diffuse mesangial sclerosis, onset shortly after birth	Abnormal GBM is caused by mutations in adult form of laminin.
Galloway-Mowat syndrome	AR	Unknown	Unknown	Microcephaly, abnormal cerebral gyral patterns, seizures, cranial dysmorphia, and glomerulopathy	Mechanism unknown
Congenital nephrotic syndrome	AR	*ITGA3*	Itgα3	Early onset; disease characterized by interstitial lung disease, epidermolysis bullosis, and congenital nephrotic syndrome	*ITGA3* mutations result in disruption of GBM architecture and failure of podocyte foot process attachment.
Corticosteroid-resistant nephrotic syndrome	AR	*COQ6*	CoQ6	Early onset; syndrome characterized by sensorineural deafness, fibrosis, and podocyte foot process effacement; FSGS and diffuse mesangial sclerosis on biopsy	*COQ6* mutations result in impaired Q10 biosynthesis and podocyte apoptosis; effects can be partially ameliorated with coenzyme Q10 supplementation.

Table 19-3 Syndromic proteinuric renal diseases. *AD,* Autosomal dominant; *AR,* autosomal recessive; *CoQ6,* coenzyme Q6; *FSGS,* focal segmental glomerulosclerosis; *GBM,* glomerular basement membrane; *Itgα3,* integrin α_3; *LMXB1,* LIM-homeodomain transcription factor b1; *WT1,* Wilms tumor 1.

WT1 seen in DDS and Frasier syndrome leads to the clinical manifestations,[2,14] as supported by *WT1* knockout mice, who lack kidneys and gonads.[17]

Nail-Patella Syndrome

Nail-patella syndrome (hereditary onycho-osteodysplasia; Fong syndrome) is an autosomal dominant disease involving abnormalities of the skeleton, nails, eyes, and kidneys. Affected patients have nail dysplasia, absence of or poorly developed patellas, dysplasia of the iliac horns and elbows, cataracts, glaucoma, and glomerulopathy.[2] Chapter 48 discusses nail-patella syndrome in detail.

Pierson Syndrome

In 1963, Pierson and colleagues described cases of congenital nephrotic syndrome with distinct eye abnormalities.[18] In this rare syndrome, patients present with hypoplasia of the ciliary body and iris, resulting in fixed narrowing of the pupil (microcoria) as well as massive proteinuria at birth and rapid progression to ESRD. Most die before 2 months of age. Diffuse mesangial sclerosis exemplifies the renal pathology findings in the Pierson syndrome. The resultant mutation is in *LAMB2*, which codes for the laminin β2 chain. *LAMB2* is present in the normal GBM, and the mutation results in abnormal formation of the GBM as well as abnormal differentiation of podocyte foot processes (see Fig. 19-2). *LAMB2* knockout mice demonstrate congenital nephrosis with abnormalities of the retinal and neuromuscular junctions.[2,18]

Galloway-Mowat Syndrome

In 1968, two siblings with nephrotic syndrome, hiatal hernia, and abnormal development of the central nervous system were described by Galloway and Mowat.[19] The Galloway-Mowat syndrome is inherited in an autosomal recessive pattern. The currently recognized clinical features include microcephaly, abnormal cerebral gyral patterns, seizures, psychomotor retardation, cranial dysmorphia, and glomerulopathy. The renal disease generally presents as the nephrotic syndrome within the first few months of life, with rapid progression to ESRD. Most affected children die before age 6 years. Based on the time of biopsy, renal findings on light microscopy include diffuse mesangial sclerosis, mesangial proliferation, FSGS, cystic microdilation of tubules, and normal-appearing glomeruli. Electron microscopy reveals irregular thickening of the GBM and effacement of podocyte foot processes. The genetic abnormality has not been found, but because of multiple reports of the same disease in siblings, the Galloway-Mowat syndrome is presumed to be a familial disorder.[20]

Glomerulopathy Associated with Abnormalities in Lipid Metabolism

Nephrotic-range proteinuria, edema, hypoalbuminemia, lipiduria, and hyperlipidemia are hallmarks of the nephrotic syndrome. However, the hyperlipidemia is thought to be caused by urinary losses of cholesterol and albumin, resulting in increased hepatic synthesis of low-density lipoproteins, very-low-density lipoproteins, and lipoprotein(a).[21] However, some rare proteinuric kidney diseases are caused by abnormal metabolism of lipids, resulting in deposition of lipids in glomeruli and subsequent nephrotic syndrome (Table 19-4).

Lipoprotein glomerulopathy presents in adulthood with proteinuria and often nephrotic syndrome, with rapid progression to renal failure. Light microscopy reveals extensive deposition of laminated lipid thrombi in glomerular capillaries (Fig. 19-3). The lipid deposits contain apolipoproteins A, B, and E (see Fig. 19-2). Because of studies of affected kindreds, particularly in Japan, it is thought to be

Glomerular Diseases Associated with Lipid Abnormalities in Lipid Metabolism					
Disease	**Inheritance**	**Gene**	**Protein**	**Clinical Presentation**	**Mechanism of Disease**
Lipoprotein glomerulopathy	Unknown	*Unknown*	Apolipoprotein E	Type III hyperlipidemia, nephrotic syndrome, renal failure, and deposition of lipid thrombi in glomerular capillaries	Abnormal lipid metabolism and deposition in various tissues
LCAT deficiency	Autosomal recessive	*LCAT*	LCAT	Anemia, corneal opacities, low HDL, elevated LDL, proteinuria, and progressive renal failure	Abnormal lipid metabolism and deposition in various tissues

a hereditary disease. The *APOE* mutation is believed to be in apolipoprotein E because these patients also have a type III hyperlipidemia, characterized by elevated intermediate-density lipoproteins and apolipoprotein E. Treatment with lipid-lowering drugs such as fibric acid derivatives has shown some benefit.[22] Missense mutations of the antitrypanosomal serum factor apolipoprotein L1 *(APOL1)* have been associated with an increased risk for sporadic FSGS, human immunodeficiency virus–associated nephropathy (HIVAN), as well as hypertension-associated ESRD in blacks. Although *in vitro* analyses demonstrate enhanced trypanosomolytic activity of the *APOL1* mutants, insights into the mechanisms promoting kidney disease remain unclear.[23]

Lecithin–cholesterol acyltransferase (LCAT) deficiency is an autosomal recessive disease characterized by anemia, corneal opacities, decreased high-density lipoprotein level, elevated low-density lipoprotein level, proteinuria, and often nephrotic syndrome with progressive renal failure. LCAT disease generally presents in adulthood and is slow in onset. Light microscopy reveals irregular thickening of the glomerular capillaries with "vacuolization" of the capillary basement membranes caused by lipid droplets (Fig. 19-4). This is the "foamy" appearance characteristic of LCAT deficiency. Mesangial and basement membrane electron-dense lamellar structures are also seen and are unique to this disorder. Patients with LCAT deficiency respond poorly to treatment.[24]

Nephrotic Syndrome Associated with Specific Mutations

In 2012, mutations of *ITGA3,* which encodes the transmembrane integrin α_3 receptor subunit (ITGA3), were reported.[25] ITGA3 is known to play a critical role in the transmission of mechanosensory and biochemical signals between the extracellular and intracellular fluid compartments. *ITGA3* mutations cause a syndrome of congenital nephrotic syndrome, interstitial lung disease, and epidermolysis bullosa. ITGA3 staining was absent in biopsy specimens and was associated with profound irregularities of the basement membrane architecture in the kidney, lungs, and epidermis. Two additional mutations were also identified in two unrelated subjects.[25]

Mutations of the coenzyme Q10 biosynthesis monooxygenase 6 *(COQ6)* cause corticosteroid-resistant nephrotic syndrome and sensorineural deafness. CoQ6 is an evolutionarily conserved and ubiquitously expressed monooxygenase that is necessary for the biosynthesis of CoQ10. CoQ10 is an essential lipophilic antioxidant required for the proper functioning of the mitochondrial electron transport chain. Compound heterozygous truncating or nonsense mutations and homozygous missense mutations of *COQ6* were associated with cyclosporine A–dependent nephrotic syndrome or diffuse mesangial sclerosis.[25a] All mutations segregated in a manner consistent with autosomal recessive inheritance. All the affected children manifested proteinuria by 6 years of age and progressed to ESRD by age 9. Five died in early childhood, and 7 of the 11 patients had biopsy-proven FSGS. In addition, sensorineural deafness was detected in all nine affected individuals screened. In complementary *in vitro* analyses, targeted knockdown of *COQ6* was found to induce apoptosis in a podocyte cell line. This was partially ameliorated with CoQ10 supplementation. Similar results were observed with *COQ6* knockout in zebrafish.[25a]

GENETIC TESTING

Children with a family history of corticosteroid-resistant nephrotic syndrome or after failure of an initial treatment course of corticosteroids should undergo renal biopsy and should be considered for

genetic testing. Mutations in the recessive genes that encode nephrin *(NPHS1)*, podocin *(NPHS2)*, phospholipase Cε1 *(PLCE1)*, WT1 *(WT1)*, and laminin β2 *(LAMB2)* cause proteinuric renal disorders in children. *NPHS1*, *NPHS2*, *LAMB2*, and *WT1* mutations are responsible for 85% of glomerular disease seen in the first 3 months of life and 66% in the first year, and these certainly should be the first tests sent in screening of children for inherited conditions.[7] Diffuse mesangial sclerosis is seen with mutations in *NPHS1*, *PLCE1*, *LAMB2*, and *WT1*. FSGS is seen with mutations in *NPHS2*. The Galloway-Mowat syndrome can have either diffuse mesangial sclerosis or FSGS-like changes, but the genetic defect is not known. Further testing will be determined by the patient's presentation. In most cases of syndromic disease, the clinical characteristics will dictate which genetic tests are necessary and may narrow the analysis to one or two genes. For example, in a patient with pseudohermaphroditism and renal disease, *WT1* mutations are likely, and *LAMB2* testing can be done in those with congenital nephrotic syndrome and microcoria. Inherited nephrotic syndrome in adults generally presents as FSGS and is believed to be responsible for up to 18% of cases identified in those older than 18 years.[1]

In patients with suspected syndromic or nonsyndromic nephrotic syndrome, we recommend pursuit of genetic testing if (1) test results are likely to aid in the diagnosis, (2) test results are likely to alter clinical management or inform discussions of prognosis, or (3) the test result from the presenting affected individual will likely provide data on risk in other family members.[26] In patients with congenital or infantile nephrotic syndrome, or in patients with disease onset after age 1 year who also have a positive family history, and/or a diagnosis of corticosteroid-resistant nephrotic syndrome, screening for autosomal recessive (AR) and autosomal dominant (AD) causes of nephrotic syndrome should be performed (Fig. 19-5).[26]

At present, limited genetic testing for inherited FSGS and nephrotic syndromes is available worldwide, but this is likely to change in the near future. Testing may be expensive but is covered by some insurance companies or subsidized by some hospitals. For idiopathic FSGS, the current KDIGO (Kidney Disease: Improving Global Outcomes) guidelines recommend against routine genetic testing. This is not a graded recommendation but does take into account that according to currently available prevalence data from selected case series, less than 10% of all cases of corticosteroid-resistant nephrotic syndrome are caused by FSGS and less than 2% of all cases of nephrotic syndrome are probably the result of single-gene defects.[27] In this regard, consideration of the associated cost of currently available genetic testing versus benefit should be reviewed with patients and families. The highest probability of detecting a genetic lesion is in infants and children and those with a family history of FSGS or nephrotic syndrome.

CLINICAL MANAGEMENT OF INHERITED NEPHROTIC SYNDROME

Angiotensin receptor blockers (ARBs) and ACE inhibitors are considered appropriate treatment for all individuals (children and adults) with nephrotic syndrome. Lipid-lowering medications are also recommended because adults with nephrotic syndrome have hyperlipidemia and may have increased risk of cardiovascular disease. No randomized clinical trials have been done on immunosuppressant and chemotherapeutic therapy in inherited nephrotic syndromes, but anecdotal data report that these agents may delay the progression of kidney disease in patients with familial forms of disease.[28] Cyclosporine is generally used for initial treatment in FSGS

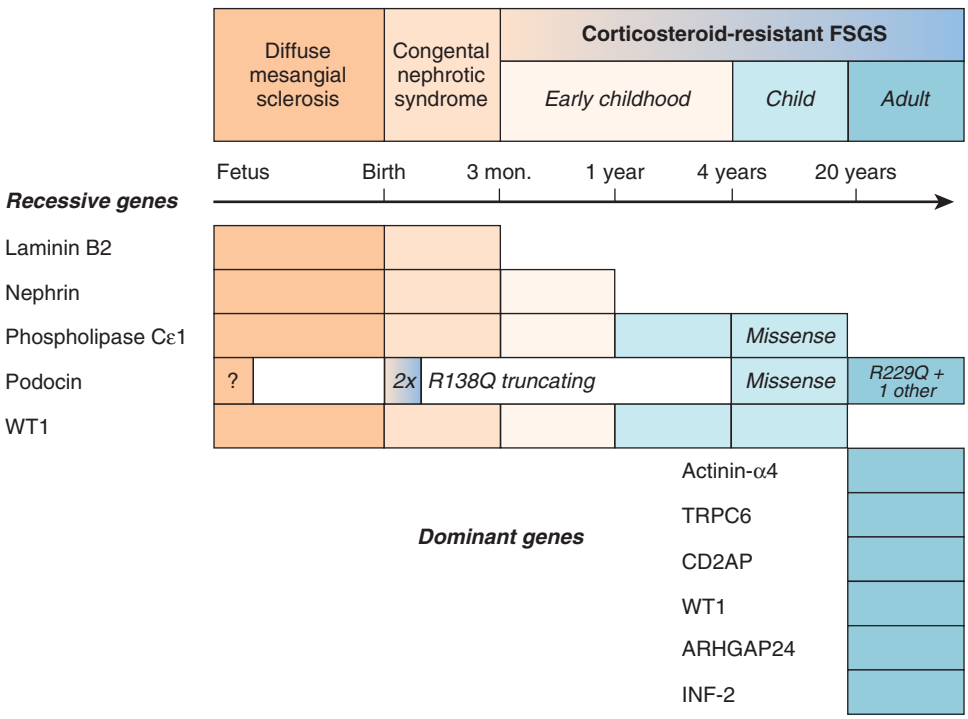

Figure 19-5 Inheritance patterns of nephrotic syndromes. Autosomal recessive diseases generally present early in life as diffuse mesangial sclerosis or congenital nephrotic syndrome. In early childhood, mutations in proteins encoding nephrin *(NPHS1)*, podocin *(NPHS2)*, Wilms tumor suppressor *(WT1)*, and phospholipase Cε1 *(PLCE1)* will also cause disease. Podocin mutations result in disease at different times based on the particular mutation with disease in young adults as well. Autosomal dominant conditions present later in life and have been described in families with FSGS with mutations in *ACTN4* (encoding α-actinin 4), *TRPC6, WT1, INF2,* and *ARHGAP24. CD2AP* mutations are suspected, but have not been described as a sole cause of disease in humans. *(Modified from reference 7.)*

not responsive to corticosteroids (see Chapter 18) and may be appropriate in inherited forms as well. When effective in the treatment of inherited nephrotic syndromes, it may reflect the favorable effects of cyclosporine on the podocyte actin cytoskeleton by a mechanism that may involve blockade of calcineurin phosphatase–mediated dephosphorylation of synaptopodin, which leads to cytoskeletal stabilization.[29]

These disorders result from inherited abnormalities in renal developmental or structural proteins, so there should be no recurrence of the original condition after transplantation because the donor kidney presumably is from a patient without a genetic renal disease (see Chapter 108). However, the reported recurrence rate of nephrotic syndrome in those with inherited disorders is misleading because chronic allograft nephropathy can present with an FSGS-like phenotype. Similarly, reports of recurrence in patients with podocin mutations exist, but given the complex inheritance pattern, with some diseases manifesting in children and others in adults, these are difficult to interpret. More recent data suggest a low recurrence rate of nephrotic syndrome in the transplant in those with *NPHS2* mutations.[7] Reappearance of the nephrotic syndrome in congenital nephrotic syndrome of the Finnish type is not truly a "recurrence" but thought to be caused by antinephrin autoantibodies and not a *de novo* nephrin mutation in the transplanted kidney. Therefore, transplantation is not discouraged in those with congenital nephrotic syndromes, and their postsurgical management should not differ from usual clinical care. In fact, data suggest that patients with inherited nephrotic syndromes and FSGS may have better transplant survival outcomes than those with idiopathic disease.

CHAPTER 20

Membranous Nephropathy

David J. Salant and Daniel C. Cattran

DEFINITION

Membranous nephropathy (MN) is an immune complex glomerular disease in which immune deposits of IgG and complement components develop predominantly or exclusively beneath podocytes on the subepithelial surface of the glomerular capillary wall. Podocyte injury resulting from the immune deposits increases glomerular permeability to plasma proteins, which results in proteinuria and potentially, nephrotic syndrome.[1,2] In about 75% to 80% of patients, MN occurs in the absence of any identifiable cause or initiating event and is known as *idiopathic* or *primary* MN. Various conditions have been identified in association with MN, some of which are likely to be causal and some of which probably represent only associations[1] (Table 20-1). Primary MN is an organ-specific autoimmune disease. It is the most common cause of primary nephrotic syndrome in older (>60 years) Caucasian adults, but the age range is broad, and patients may present for the first time in their teenage years.[3]

The term *membranous* refers to thickening of the glomerular capillary wall on light microscopy of a renal biopsy, but the entity now referred to as membranous nephropathy is defined by immunofluorescence and electron microscopy. These techniques reveal diffuse, finely granular immune deposits on immunofluorescence and electron-dense deposits in the subepithelial space that are now regarded as pathognomonic of MN. Consequently, MN is a pathologic diagnosis made in patients with proteinuria whose glomeruli exhibit these immune deposits without associated hypercellularity or inflammatory changes.[2]

ETIOLOGY AND PATHOGENESIS

Experimental Membranous Nephropathy

Much of what we know about the pathogenesis of MN derives from observations in animal models.[4,5] Studies of the Heymann nephritis model of MN in rats in the late 1970s established that the subepithelial immune deposits form *in situ* when circulating antibodies bind to an intrinsic antigen in the glomerular capillary wall. The antigen was subsequently identified as *megalin,* a large (~600 kD) transmembrane receptor of the low-density lipoprotein receptor family expressed on the basal surface of rat podocytes.[6] Binding of circulating antimegalin antibodies induces capping and shedding of the antigen-antibody complexes, where they bind to the underlying glomerular basement membrane (GBM), resist degradation, and persist for weeks or months as immune deposits characteristic of MN (Fig. 20-1, *A*). Proteinuria in this model is caused by complement-fixing antibodies in the immune deposits that overcome local complement regulatory mechanisms and activate complement *in situ.* The primary mechanism involves sublethal podocyte injury induced by the complement membrane attack complex C5b-9, which triggers a cascade of structural and functional changes, including oxidative injury, calcium influx, activation of cytosolic phospholipase A_2, production of arachidonic acid metabolites and cytokines, endoplasmic reticulum stress, DNA damage, and disruption of the actin cytoskeleton[7] (Fig. 20-2). Podocyte foot process effacement is likely the result of the collapse of the actin cytoskeleton and loss of cell-GBM adhesion complexes, and the loss and displacement of slit diaphragms is associated with the onset of severe, nonselective proteinuria. Podocyte injury is also responsible for the production of new extracellular matrix (ECM) proteins that are laid down between and around the immune deposits, giving rise to the characteristic "spikes" and GBM thickening that are hallmarks of MN.

Another mechanism of subepithelial immune deposit formation involves planted antigens[5] (Fig. 20-1, *B*). This is best exemplified by animal models immunized with cationized bovine serum albumin (cBSA). The cBSA binds to negatively charged residues in the GBM, where it serves as a target for circulating anti-BSA antibodies. As in the Heymann nephritis model, podocyte injury and proteinuria result from local complement activation.

Human Membranous Nephropathy

Evidence has recently been obtained that both fixed and planted antigen mechanisms are involved in human MN (see Fig. 20-1). The first demonstration that circulating antibodies reactive with an intrinsic podocyte antigen may be involved in MN was provided by an unusual case of antenatal MN induced by the transplacental passage of alloantibodies to neutral endopeptidase (NEP), a known podocyte protein.[8] The mother of the affected child was found to be deficient in NEP and had been immunized during a previous pregnancy and, like subsequent cases, produced complement-fixing anti-NEP alloantibodies. Although antibodies to anti-NEP do not account for primary MN, alloantibodies probably explain the development of de novo MN after renal transplantation and MN in the setting of chronic graft-versus-host disease after allogeneic hematopoietic stem cell transplantation (see Table 20-1). The predominant autoimmune system responsible for primary MN is that associated with autoantibodies directed at the M-type phospholipase A_2 receptor (PLA_2R) on podocytes.[9] Circulating anti-PLA_2R antibodies are detectable in the serum of 75% to 80% of patients with primary MN from all ethnic groups and are rarely found in secondary MN.[10,11] The antibodies are predominantly IgG4 and, as in the Heymann nephritis model, the antigen (PLA_2R) and antibodies (anti-PLA_2R) co-localize in the immune deposits in primary (but not in secondary) MN.[9,12,13] PLA_2R is a transmembrane protein of the mannose receptor family[14] (Fig. 20-3). Although it has been shown to undergo constitutive endocytosis and is involved in the production of eicosanoids, reactive oxygen species, DNA damage, and cellular senescence, its role in podocytes is unknown. Reactivity to certain intracellular antigens, including aldose reductase, SOD2, and enolase, has been detected in primary MN and may contribute to the progression of podocyte injury.[15] The best evidence of a planted antigen mechanism in MN is that described in a subset of children

Classification and Causes of Membranous Nephropathy		
Primary		
Anti-PLA_2R associated (70%-80%) Idiopathic (20%-30%)		
Secondary	**Common**	**Uncommon**
Autoimmune diseases	Class V lupus nephritis	Rheumatoid arthritis Autoimmune thyroid disease IgG4-related systemic disease Anti-GBM and ANCA-associated crescentic glomerulonephritis
Infections	Hepatitis B	Hepatitis C virus (HCV) Human immunodeficiency virus (HIV) Syphilis Schistosomiasis
Malignancy	Solid tumors (colon, stomach, lung, prostate)	Non-Hodgkin lymphoma Chronic lymphocytic leukemia (CLL) Melanoma
Drugs or toxins	Nonsteroidal anti-inflammatory drugs and cyclooxygenase-2 (COX-2) inhibitors	Mercury-containing compounds Gold salts D-Penicillamine, bucillamine
Miscellaneous		Sarcoidosis Anticationic bovine serum albumin
Alloimmune		
Graft-versus-host disease following hematopoietic stem cell transplantation *De novo* membranous nephropathy in renal allograft Fetomaternal alloimmunization to neutral endopeptidase		

Table 20-1 Classification of conditions and agents associated with membranous nephropathy. The list excludes conditions for which only a single case has been reported or the lesions were atypical of membranous nephropathy. *ANCA,* Antineutrophil cytoplasmic antibody; *GBM,* glomerular basement membrane.

with MN who have been exposed to cBSA, presumably in bottled milk. In such cases, as in the animal models, the cBSA localizes in the GBM, where it forms complexes with circulating anti-BSA.[16] Planted antigens may also be responsible for immune deposition in class V (membranous) lupus nephritis and hepatitis B virus (HBV)–associated MN.

The resolution of MN depends on remission of the immune response, the extent of podocyte damage, and expansion of the GBM. In cases in which immunologic remission occurs before extensive podocyte loss and GBM remodeling, complete recovery is possible. On the other hand, proteinuria may persist for several weeks or months until the normal architecture is restored. Once there is extensive podocyte loss, severe proteinuria persists despite immunologic remission and glomerular sclerosis, tubular atrophy, and interstitial fibrosis may ensue.

EPIDEMIOLOGY AND GENETICS

Membranous nephropathy may occur at any age and in all ethnic groups, but primary MN is more common in men than in women (2:1) and is rare in children. Primary MN has its peak incidence during the fourth and fifth decades of life (Box 20-1). In comparison,

Clinical Features of Membranous Nephropathy
Rare in children: less than 5% of total cases of nephrotic syndrome
Common in adults: 15% to 50% of total cases of nephrotic syndrome, depending on age; increasing frequency after 40
Males > females in all adults groups
Caucasians > Asians > African Americans > Hispanics
Nephrotic syndrome in 60% to 70%
Normal or mildly elevated blood pressure at presentation
"Benign" urinary sediment
Nonselective proteinuria
Tendency to thromboembolic disease*
Other features of secondary causes: infection, drugs, neoplasia, systemic lupus erythematosus

Box 20-1 Clinical features of membranous nephropathy. *Deep venous thrombosis, renal vein thrombosis, and pulmonary embolism.

MN in childhood is more often secondary (e.g., caused by HBV). Primary MN is the most common cause of nephrotic syndrome in nondiabetic Caucasian adults, with an estimated annual incidence of 8 to 10 cases per 1 million population in Western countries. Although association with certain human leukocyte antigen (HLA) class II immune response genes indicated a genetic predisposition,[17-21] primary MN is not a familial disease, except in rare patients with more than one affected family member.[22] The genetic predisposition became more evident after the discovery of PLA_2R as the major antigen, when studies from Korea and Taiwan documented a significant association with non-synonymous single-nucleotide polymorphisms (SNPs)[23,24] in the first C-type lectin-like domain (CTLD) of PLA_2R (Fig. 20-3), a region that is known to undergo conformational changes, as well as another in CTLD7. A subsequent genome-wide association study conducted by a European consortium revealed strong associations with a noncoding SNP in *PLA2R1* (rs4664308) and another in HLA-DQA1 (rs2187668), a member of HLA class II that includes isoforms that predispose carriers to autoimmunity.[25] Although each of these two associated SNPs was significant alone, the odds ratio of MN was almost 80 in individuals who were homozygous for both HLA-DQA1 and *PLA2R1* variants. Other genetic associations have been reported and may contribute to the severity or likelihood of MN progression.[5]

CLINICAL AND SEROLOGIC MANIFESTATIONS

From 70% to 80% of all patients with MN present with the nephrotic syndrome.[26,27] The remaining 20% to 30% present with subnephrotic asymptomatic proteinuria (<3.5 g/24 h). Proteinuria is nonselective. Microscopic hematuria is common (30% to 40%), but red blood cell (RBC) casts are rare and suggest a different glomerular pathologic process. In primary MN, serologic tests for anti-PLA_2R are positive in 75% to 80% of cases,[9,10,28] whereas serum complement levels are normal despite evidence of intraglomerular complement activation, and serologic markers (e.g., antinuclear antibodies, ANCA, rheumatoid factor) are normal or absent. At diagnosis, only 10% to 20% of MN patients have hypertension. Renal function is usually normal at presentation, with only a small fraction (<10%) presenting with renal impairment (Table 20-2). These presenting features can be modulated by age or preexisting hypertension; tubulointerstitial and vascular changes on biopsy may be related to these factors rather than

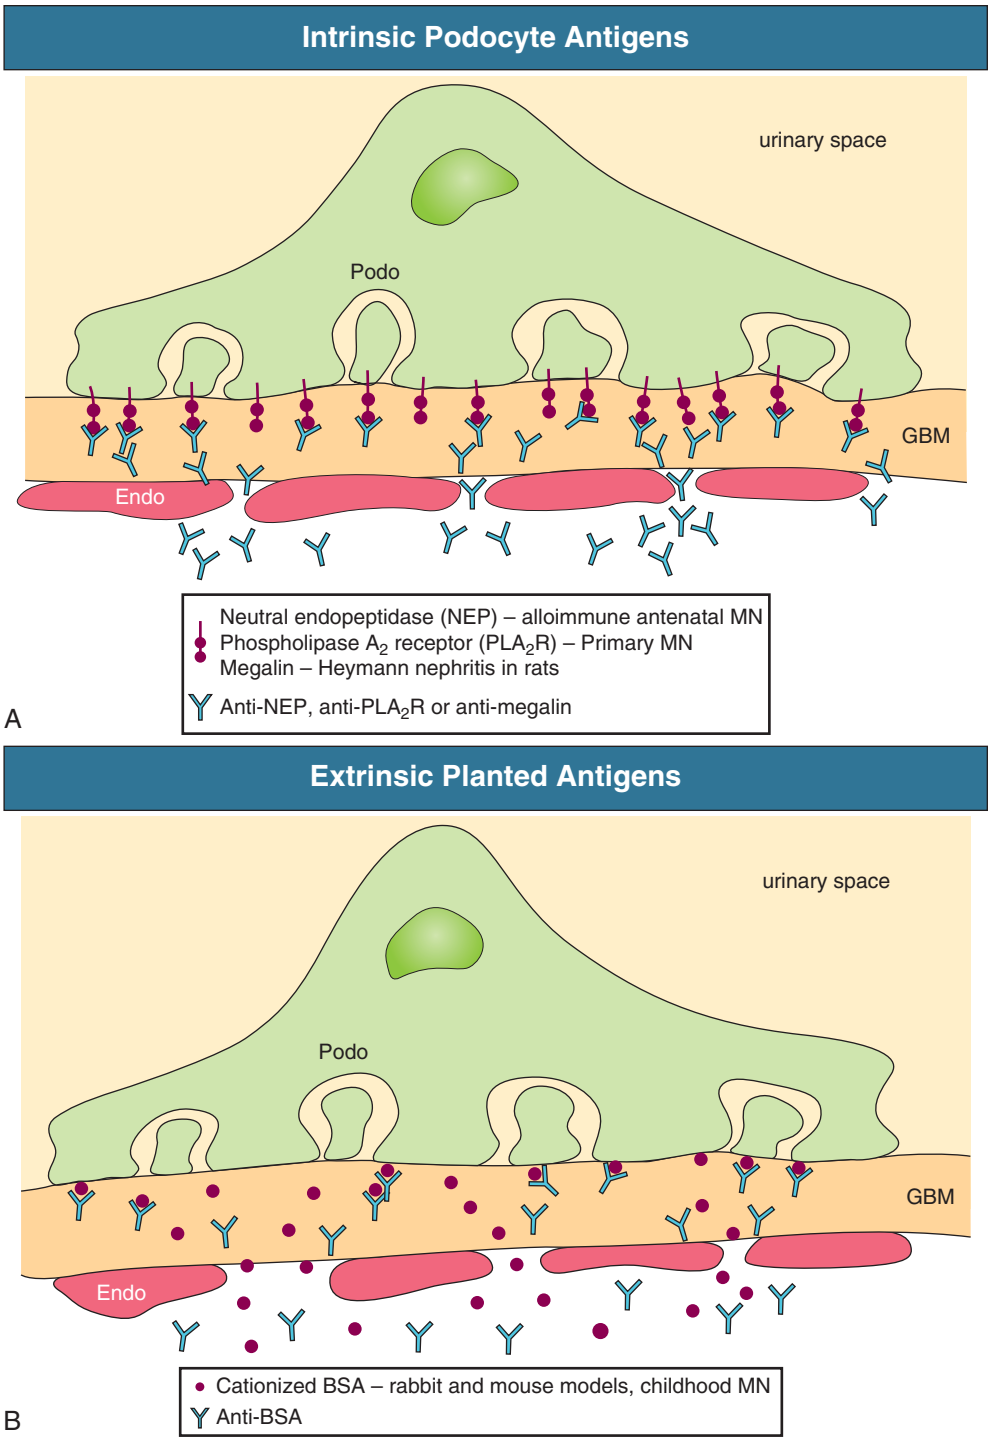

Figure 20-1 Mechanisms of in situ immune complex formation in experimental and human membranous nephropathy (MN). A, Circulating antibodies may cross the glomerular capillary wall and bind to podocyte *(Podo)* antigens exposed on the foot process, as in Heymann nephritis in rats (megalin), alloimmune MN (neutral endopeptidase), and primary MN (PLA_2R). *Endo,* Glomerular endothelial cell; *GBM,* glomerular basement membrane. **B,** Certain extrinsic antigens such as cationized bovine serum albumin *(BSA)* may bind to sites in the GBM and serve as planted antigens and form deposits with circulating antibody.

to the severity of the MN.[29] This is supported by recent evidence that age *per se* does not influence the rate of progression in MN, but does influence the GFR at presentation. Other complications related to the nephrotic syndrome include dyslipidemia, which probably contributes to the increased cardiovascular risk, and a high prevalence (10% to 40%) of thromboembolic events, including renal vein thrombosis.

Recent large MN databases have indicated clinically relevant thromboembolic events occur in the range of 10% of nephrotic MN patients, most frequently in the first 1 to 2 years after presentation.[30,31]

PATHOLOGY

The earliest pathologic feature of MN is the formation of subepithelial immune complexes of IgG and complement along the outer surface of the capillary wall in which glomeruli appear histologically normal and therefore may be mistaken for minimal change nephrotic syndrome, if only light microscopy is performed. MN begins with the formation of immune complexes at the interface of the podocyte and GBM, with subsequent changes in the podocyte, deposition of new extracellular matrix material between and around the immune deposits, thickening of the GBM (membranous change), and in some

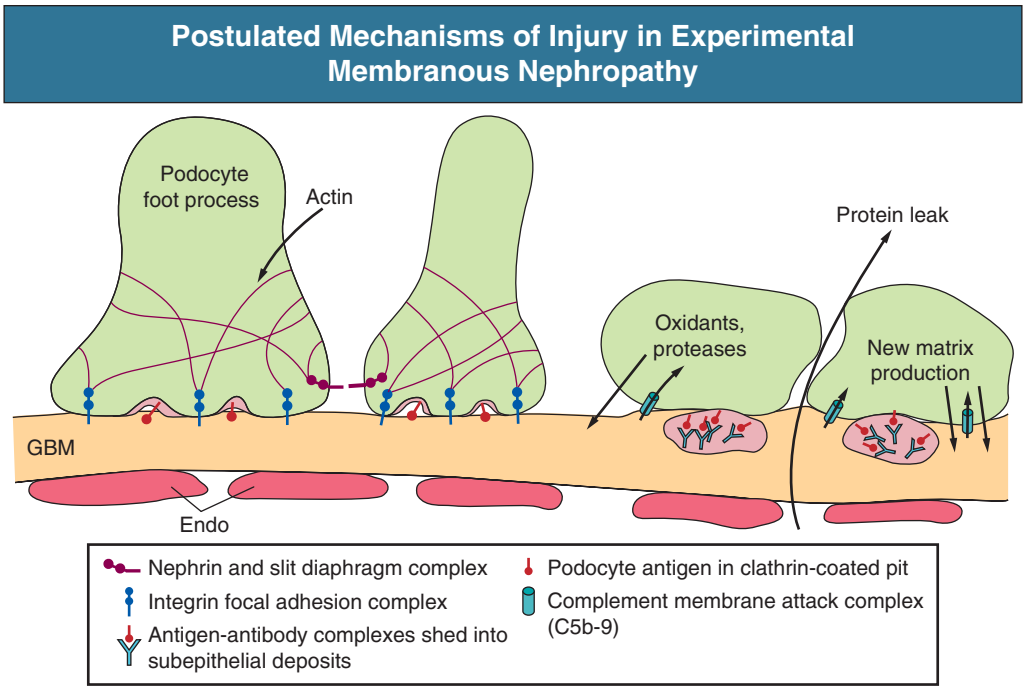

Figure 20-2 Postulated mechanisms of injury in experimental membranous nephropathy. Antibodies against a podocyte antigen in clathrin-coated pits on the foot processes (left podocyte) form complexes that are shed to form deposits in the subepithelial space (right podocytes) and induce complement activation leading to formation of C5b-9. Insertion of C5b-9 is insufficient to cause lysis but stimulates the podocyte to release a host of inflammatory mediators. Disruption of the actin cytoskeleton causes altered cell-matrix adhesion and loss or displacement of slit diaphragms, leading to foot process effacement and loss of the filtration barrier to protein. New matrix production by the damaged podocytes expands the GBM between and around the deposits. *Endo,* Glomerular endothelial cells.

cases, focal glomerulosclerosis, tubular atrophy, and interstitial fibrosis.[2,27]

Light Microscopy

In the earliest stages of MN, the glomeruli and interstitium appear normal on light microscopy, and the diagnosis is made by immunohistology and electron microscopy (Fig. 20-4, *A*). The next stage of MN involves a homogeneous thickening of the capillary wall, seen with light microscopy in sections stained with hematoxylin and eosin or with periodic acid–Schiff (PAS) reagent (Fig. 20-4, *B*). On silver methenamine staining, early projections of the GBM between deposits may be detected in a characteristic spike-like configuration (see Fig. 20-4, *C*). Later, lucencies may develop in the GBM as immune deposits are resorbed, resulting in craters within the thickened GBM.

Leukocyte infiltration is absent in glomeruli in MN, probably because chemotactic products of complement activation follow filtration forces into the urinary space rather than diffusing backward into the capillary lumen, and the intervening GBM prevents immune adherence mechanisms from being operative. As a result, the pathologic lesion of MN is characterized only by changes in podocytes and basement membrane, without associated glomerular hypercellularity.

The podocyte response to this form of injury includes effacement of foot processes visible only by electron microscopy. In general, there are no visible mesangial or endothelial cell abnormalities. The presence of significant mesangial hypercellularity suggests immune deposit formation in the mesangium and is more consistent with a secondary MN, such as class V lupus nephritis (see Chapter 26). In some patients with heavy proteinuria and progressive disease, glomeruli exhibit reduced podocyte numbers and areas of focal sclerosis that are similar to the appearance of secondary focal segmental glomerulosclerosis (FSGS; see Chapter 18). These patients often have a more rapidly progressive course and a poor response to therapy. These sclerotic lesions may be a consequence of glomerular hypertrophy accompanied by an inability of terminally differentiated podocytes to proliferate,[32] leading to areas of denuded GBM, attachment to Bowman capsule, and subsequent capillary collapse. As in all glomerular diseases, tubulointerstitial injury is common and correlates with both renal function and the level of proteinuria. Some studies suggest that the long-term outcome correlates in general with the severity of the tubulointerstitial damage (see Chapter 79).

Immunohistology

The pattern of granular glomerular capillary wall staining for IgG in MN is characteristic and easily recognizable by immunohistology (Fig. 20-5). Positive staining for IgG marks the finely granular subepithelial deposits, which are present on the outer surface of all capillary walls.[2] The predominant IgG subclass in primary MN is IgG4.[33-35] Positive staining for IgG1 or IgG3, IgA, or IgM or significant staining in the glomerular mesangium suggests lupus or other causes of secondary MN as an underlying mechanism.[33-37] Kappa and lambda light-chain staining are typically equal but rare cases of MN due to monoclonal IgG, including anti-PLA_2R have been reported.[38] Complement C3 is also present in most cases of active disease and usually reflects staining for C3c, a breakdown product of C3b that is rapidly cleared. Consequently, positive C3 staining probably reflects active, ongoing immune deposit formation. When sought, staining for C5b-9 is generally present as well, consistent with the proposed pathogenetic role of C5b-9 in this disease.[4] Strong C1q staining is not typically found in primary MN (<20% of cases)[33,39,40] and is more common in lupus-associated MN.[40] Positive staining for C4d in the

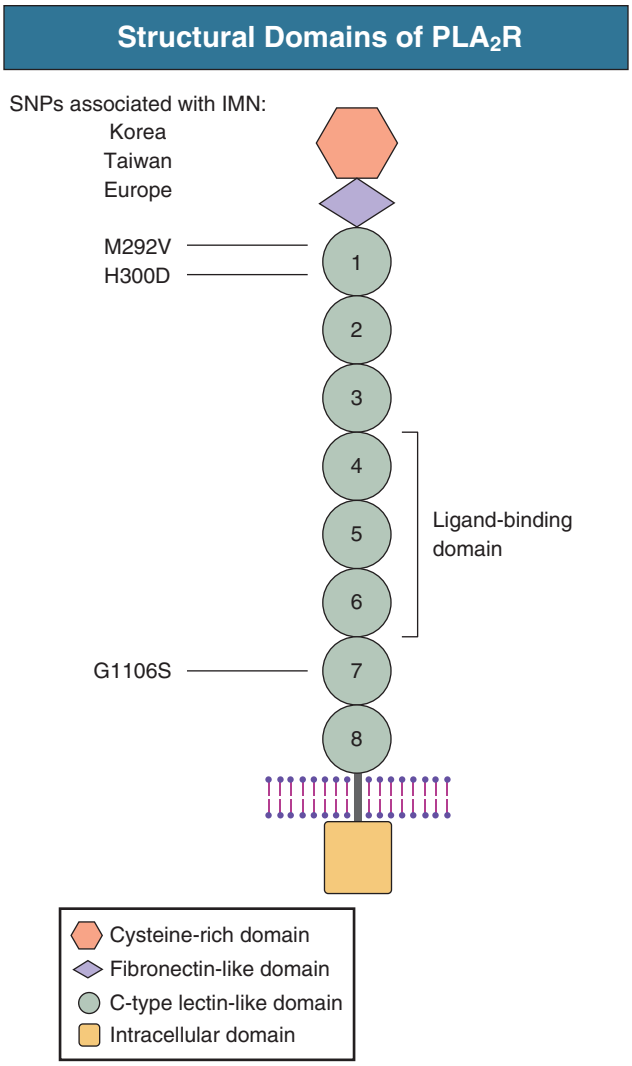

Figure 20-3 Structural domains of phospholipase A_2 receptor (PLA_2R). The M-type phospholipase A_2 receptor is a transmembrane protein and receptor for secretory PLA_2 (CTLD5). The N-terminal region from the cysteine-rich domain through CTLD4 of other members of the mannose receptor family is known to exist in extended or folded configurations. PLA_2R is involved in the production of eicosanoids, reactive oxygen species, DNA damage and cellular senescence. Its role in podocytes is unknown. *SNPs,* Single-nucleotide polymorphisms.

absence of C1q is another feature of primary MN[41,42] and may be consistent with activation of the mannose-binding lectin pathway of complement.[43] Although not used in routine clinical practice, another feature that helps distinguish primary and secondary MN is the presence of PLA_2R staining in the immune deposits in a pattern that co-localizes with IgG in anti-PLA_2R-associated MN but not in secondary MN.[9,12,44] Thus, several histopathologic features help distinguish primary and secondary forms of MN (Table 20-3).

Electron Microscopy

The presence of subepithelial electron-dense deposits by electron microscopy (EM) parallels IgG staining. In primary MN, immune deposit formation occurs in a subepithelial distribution; subendothelial deposits are not seen and mesangial deposits are rare (Table 20-3). These deposits in early stages of the disease process are homogeneous and may even be confluent in some areas, with overlying podocyte foot process effacement and little change in the underlying

Diagnosis and Management of Patients with Membranous Nephropathy

Patient Groups	Test
All patients	Blood pressure Renal function (serum creatinine and creatinine clearance) Urine protein excretion (24-hour urine or urine protein-creatinine ratio) Serum albumin Serum cholesterol, including LDL-HDL ratio Urinalysis Renal biopsy Anti-PLA_2R
Associated disease	Hepatitis B (HBs antigen) Hepatitis C (HCV antibody) Antinuclear antibody (ANA), anti–double-stranded DNA (hallmark of systemic lupus erythematosus) Complement C3, C4 (usually normal in idiopathic MN)
Select Patients	
With suspected thromboembolic events, flank pain, hematuria, acute renal failure	Renal venous Doppler ultrasound Contrast CT, MRI
With sudden decrease in renal function, development of active urine sediment	Anti-GBM antibody Antineutrophil cytoplasmic antibody (ANCA) Assess for interstitial nephritis
Suggestive symptoms or age >50 years	Cancer screening (see text)

GBM (stage I). As the disease persists, basement membrane material is laid down between the deposits and corresponds to the spikes seen on light microscopy with use of a silver methenamine stain and are easily visible by EM (stage II; Fig. 20-6, *A*). Later, the spikes extend and the deposits may become surrounded by new basement

membrane–like material (stage III; Fig. 20-6, *B*). In stage IV disease, the basement membrane is overtly thickened, the deposits incorporated in it become more lucent, and the spikes are less apparent (stage IV; Fig. 20-6, *C*). Although clearly reflecting the duration of disease, these GBM changes do not correlate well with clinical manifestations or outcome. The overlying podocyte foot processes are effaced with condensation of the actin cytoskeleton; the filtration slits between the foot processes may be occluded; and in those still open, the slit diaphragms may be displaced or disrupted. Microvillous changes of the podocyte membrane are common, as are protein reabsorption droplets within podocytes and proximal tubular cells. The presence of tubuloreticular inclusions in the endothelial cells is strongly suggestive of lupus-associated MN, although these may rarely be found in primary MN as well.[45]

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

When the initial presentation includes the nephrotic syndrome, the differential diagnosis includes minimal change disease (MCD), FSGS, membranoproliferative glomerulonephritis pattern of injury (either MPGN type I or dense deposit disease [DDD]), amyloidosis, light-chain deposition disease, lupus nephritis, and diabetic nephropathy. In the 20% to 25% of patients whose initial presentation is asymptomatic non-nephrotic proteinuria, the differential is even more extensive.[46] Although clinical clues in proteinuric patients may increase the likelihood of one specific histologic pattern over another,

Glomerular capillary wall with discrete, electron-dense deposits on the subepithelial surface of the basement membrane *(BM)* corresponding to granular deposits of IgG detected by immunofluorescence microscopy (corresponding to light micrograph in *B*). There are diffuse, granular immune complex deposits *(white asterisks)* along outer surface of the capillary wall, with effacement of overlying podocyte foot processes. Small extensions of BM between deposits *(arrows)* are also evident and represent the projections that are seen as spikes by light microscopy with silver methenamine staining. *CL,* Capillary lumen; *GEC,* glomerular epithelial cell. **B,** More advanced (stage III) MN. Two glomerular capillary loops show involvement of the BM by the immune complex deposition *(arrows).* There is prominent membrane synthesis surrounding and incorporating these deposits into the BM (corresponding to spikes seen on silver-stained histologic preparations). Overlying cells continue to demonstrate widespread effacement of foot processes. **C,** Morphologically advanced (stage IV) MN. Capillary BM is diffusely thickened; scattered electron-dense immune deposits *(arrows)* are present throughout its thickness, in addition to scattered subepithelial deposits. Overlying GECs continue to demonstrate effacement of foot processes. *US,* Urinary space. (Original magnifications ×18,000.) *(Courtesy C. E. Alpers.)*

confirmation that MN is the underlying cause of nephrotic syndrome generally requires a kidney biopsy. However, the diagnosis can be made with a high degree of confidence with a positive serologic test for anti-PLA_2R under circumstances in which a biopsy cannot be performed. On the other hand a negative test for anti-PLA_2R does not exclude the diagnosis of idiopathic MN.

Secondary MN represents 20% to 30% of all cases (see Table 20-1); the most common causes are systemic lupus, hepatitis B, malignant neoplasms, and drugs. In addition to a careful history and physical examination, appropriate laboratory evaluation for potential secondary causes should include a complement profile, antinuclear antibodies, hepatitis serology, chest radiography, stool testing for occult blood, mammography in women, and prostate-specific antigen testing with digital rectal examination in men. In women age 20 to 50, a high index of suspicion is warranted for underlying lupus.[47] This diagnosis can be particularly difficult to make because the majority of these patients have no systemic symptoms, and serologic markers of systemic lupus erythematosus are often absent. Membranous lupus accounts for 8% to 27% of cases of lupus nephritis[47] (see Chapter 26).

In adults, regardless of age, malignant neoplasia is an important secondary cause of MN (see Table 20-1). The colon, kidney, and lung are the most common primary sites, and in some patients, the tumor may not have been discovered at presentation with renal disease. Although it is hypothesized that antigens derived from the tumor account for deposit formation and injury in glomeruli, very few tumor-related antigens have actually been demonstrated.

Hepatitis B virus–associated MN is also a common secondary cause in countries where HBV is endemic. It can affect both adults and children who are chronic carriers of HBV (positive HBsAg, HBcAg, and usually HBeAg).[48] This can occur with or without a history of overt liver disease. In children, HBV-associated MN most often presents as the nephrotic syndrome and usually follows a benign course.[49] In adults, progressive renal impairment is a more common outcome. Hypocomplementemia is present in approximately 50% of MN patients with HBV.

Membranous nephropathy secondary to drugs usually resolves after discontinuation of the offending agent.[50,51] The time to resolution, however, varies significantly, from as early as 1 week (e.g., for NSAIDs) to several years for gold or D-penicillamine. Many other renal disorders have been seen in association with or superimposed on MN, including IgA nephropathy, FSGS, crescentic glomerulonephritis (GN) (anti-GBM disease, ANCA vasculitis), acute interstitial nephritis, and diabetic nephropathy.

Preliminary data suggest that the absence of circulating autoantibody to PLA_2R and the pattern of antigen expression of PLA2 at the glomerular level on biopsy favor a secondary etiology of the MN.[12]

CLINICAL COURSE, OUTCOMES, AND COMPLICATIONS

The clinical course of MN varies widely. Spontaneous remissions in proteinuria have been reported in up to 30% of patients. As the severity of proteinuria at presentation increases, the frequency of spontaneous remission appears to decrease. Female gender and lower-grade (non-nephrotic) proteinuria at presentation are the only two features associated with a higher likelihood of spontaneous remission.[19] This is likely to produce a bias in renal survival because the majority of studies reporting 10-year outcomes in untreated patients have included those with subnephrotic proteinuria (<3.5 g/24 h). For example, one study reported a 72% renal survival at 8 years for 100 untreated patients, but 37% of the patients were non-nephrotic at presentation, and more than 50% had less than 5 g/day.[20] In addition, deaths were excluded from the kidney survival analysis. Even so, there was a 25% end-stage renal disease (ESRD) rate by 8 years and almost 50% by 15 years. Thus, patients presenting with less than 3.5 g/day of proteinuria, no RBC casts, no hypertension, normal renal function, and no systemic features suggestive of a secondary cause have a relatively benign prognosis. If no renal biopsy is performed, these patients must be monitored, because up to 50% are likely to develop nephrotic-range proteinuria at some time in the disease course, most within the first 2 years after presentation.

In summary, although the majority of MN patients do reasonably well long term, MN is still the second or third leading cause of ESRD in patients with primary GN. The factor still missing from most MN survival data is the much higher-than-expected mortality from cardiovascular disease or thromboembolic events seen in patients who remain nephrotic. When another renal condition is superimposed on MN, there is often an associated acceleration in the rate of deterioration in renal function. The most common conditions to consider in this setting are drug-induced interstitial nephritis, superimposed crescentic GN including anti-GBM disease, and renal vein thrombosis.

Patients with primary MN who develop ESRD are generally suitable candidates for kidney transplantation, although the disease may recur in up to 50% (see Chapter 108).[52] Recurrence may be asymptomatic and found only on protocol biopsy, but those with recurrence of nephrotic syndrome have a high rate of graft loss. A positive serologic test for anti-PLA_2R at transplantation may forecast early recurrence.[53,54]

Predictors of Poor Outcome

Given the wide variation in the natural history of MN, markers that predict individual outcome would be valuable. Testing for circulating anti-PLA_2R autoantibody has the potential to be critical in this domain as a monitoring tool of MN immunologic activity changing in advance of the classic laboratory parameters.[28,55] Table 20-4 lists the more traditional factors associated with progression and the strength of those associations. Both age and gender influence outcome, with male sex and increasing age associated with a higher risk for renal failure. However, both have limitations.[56] Age seems to be related to the underlying pathologic process at presentation rather than the severity of disease, because age does not influence rate of deterioration in function, and the gender of the patient seems more closely related to the severity of proteinuria at presentation rather than representing an independent risk factor for progression. The severity of chronic changes seen on the biopsy specimen (i.e., degree of glomerulosclerosis, tubulointerstitial fibrosis, and vascular disease) has been associated with a poor prognosis but more closely reflects initial GFR than the subsequent rate of renal functional deterioration.[29] Other pathologic features, including the percentage of glomeruli with glomerulosclerosis and the configuration of the immune deposits (synchronic/single stage or heterogeneous/multistage) on EM, have also been suggested as predictors of both outcome and response to treatment but have not been validated in prospective studies. The degree of renal impairment at presentation has also been found to correlate with long-term renal survival, but a better and more sensitive predictor of long-term prognosis is the ongoing rate of renal function loss, as measured by the decline in creatinine clearance over time.

One of the best models to calculate risk of MN takes into consideration the initial creatinine clearance, the slope of the creatinine clearance during a fixed period, and the lowest level of proteinuria during that observation period[57] (see Table 20-3). This risk score assessment has a reported sensitivity of 60% to 89%, specificity of 86% to 92%, and overall accuracy of 79% to 87%. The model predicts that patients with a normal creatinine clearance at presentation that

Factors Associated with Worse Renal Survival in Membranous Nephropathy

Factors	Predictor	PPV (%)
Clinical Features		
Age	Older > younger	43
Gender	Male > female	30
HLA type	HLA/B18/DR 3/Bffl present	71
Hypertension	Present	39
Serum Levels		
Albumin	<1.5 g/dL	56
Creatinine	Above normal	61
Urine Protein		
Nephrotic syndrome	Present	32
Proteinuria	>8 g for >6 months	66
IgG excretion	>250 mg/day	80
β_2-Microglobulin excretion	>54 μg/mmol creatinine	79
C5b-9 excretion	>7 μg/mg creatinine	67
Biopsy Changes		
Glomerular focal sclerosis	Present	34
Tubulointerstitial disease	Present	48

Table 20-4 Univariate factors associated with worse renal survival in membranous nephropathy. Univariate factors associated with increased likelihood of progression and their positive predictive value *(PPV). (Positive predictive values modified from references 57 and 59.)*

Renal Disease Risk Categories		
Low Risk	**Medium Risk**	**High Risk**
Normal serum creatinine and creatinine clearance plus proteinuria <4 g/day over 6 months of observation	Normal or near-normal creatinine clearance and persistent proteinuria >4 g/day to <8 g/day over 6 months despite maximum conservative treatment	Deteriorating renal function and/or persistent proteinuria >8 g/day for 3 (up to 6) months of observation

Table 20-5 Risk categories of renal disease progression in membranous nephropathy.

remains stable during 6 months, and with persistent proteinuria of less than 4 g/24 h, have less than a 5% chance of progression, and only conservative treatment is recommended. In contrast, those patients with proteinuria that remains above 4 g but less than 8 g/24 h during the same time frame have a 55% probability for development of chronic renal impairment; and those with persistent proteinuria above 8 g/24 h have a 66% to 80% probability of progression to chronic kidney disease within 10 years (Table 20-5). Recent data also suggest that a greater than 50% reduction in the baseline proteinuria estimate at 1 year is an independent predictor of spontaneous remission.[58] Other biomarkers, including urinary α_1-microglobulin, β_2-microglobulin, IgM, and IgG have also been strongly associated with MN progression.[59] These markers measured together at a single time point have a higher positive predictive value than proteinuria alone, but none has yet been validated in an independent data set. However, there is increasing evidence of a relationship to the autoantibody titer. Most recently, for example, high levels of anti-PLA_2R antibodies were found to be associated with active disease and a higher risk of declining renal function than lower levels during follow-up.[28]

Relapse After Complete Remission or Partial Remission

Relapse from a complete remission occurs in approximately 25% to 40% of MN cases with an unpredictable time line. Relapses have been reported up to 20 years after the primary remission. However, the great majority of patients will relapse only with subnephrotic-range proteinuria and will maintain stable long-term kidney function with conservative management alone.[60] In contrast, the relapse rate is as high as 50% in those achieving only a partial remission. Achievement of either a complete or a partial remission, however, significantly slows progression and increases renal survival. A recent review of 348 nephrotic MN patients documented a 10-year renal survival in patients with a complete remission of 100%; with partial remission, 90%; and with no remission, only 45%.[61]

TREATMENT

Nonimmunosuppressive Therapy

Conservative management of MN is directed at control of edema, hypertension, hyperlipidemia, and proteinuria and is similar to that used for nephrotic syndrome of any etiology (see Chapter 15). Blood pressure control is important for both renal and cardiovascular protection. For patients with proteinuria of more than 1 g/day, the target for blood pressure is 125/75 mm Hg unless contraindicated for clinical reasons.[62] Numerous studies have shown that angiotensin-converting enzyme (ACE) inhibitors and angiotensin receptor blockers (ARBs) are cardioprotective and can reduce proteinuria and slow progression of renal disease in both diabetic and nondiabetic patients with chronic nephropathy (see Chapter 80). A recent meta-analysis of the largest renal protection trials using ACE inhibitors showed that the degree of protection is closely correlated to the degree of proteinuria reduction. None of these studies has focused on the specific effect of renin-angiotensin system (RAS) blockade in MN. In secondary analyses, the number of patients with MN has been small, and although the use of ACE inhibitors has been associated with significant improvement in some series, their antiproteinuric effect was modest (<30% reduction in proteinuria) in others.[63] When effective, the benefit of RAS blockade occurs early, usually within the first 3 months of initiation of treatment. Even patients at low risk for progression (proteinuria <4 g/24 h) should be treated with ACE inhibitors or ARBs because this may reduce proteinuria and offer additional renal protection, with minimal risk of significant adverse effect. Patients must also follow a low-salt diet (1.5 to 2 g sodium/day) to achieve the maximum benefit from RAS blockade.

Proteinuria is also an independent risk factor for cardiovascular morbidity and mortality. When the proteinuria is in the nephrotic range, there is a clear increase in cardiovascular risk, with a threefold to fivefold increase in both coronary events and death rates in this population.[64] Patients with significant proteinuria almost always have elevated serum cholesterol and triglyceride levels. Although not proven, we recommend the use of statins to reduce low-density lipoprotein cholesterol to 100 mg/dl (2 mmol/l) or lower[65,66] (see Chapters 80 and 82).

It is recommended that both RAS blockade and lipid control be initiated early in the MN patients, although reaching a goal of complete remission or even partial remission in patients at higher risk of progression (with persistent proteinuria >5 g/24 h) with conservative treatment alone is unlikely. Dietary protein intake may be restricted to 0.8 g/kg/day of high-quality protein,[25] with additional dietary protein (gram per gram) to correct for urinary losses. Dietary protein restriction has been associated with reduced proteinuria (15% to 25%) and a slowing in renal disease progression, but has never been shown to induce a complete remission or to add to effects obtained with RAS blockade. Protein restriction must be carefully monitored in nephrotic patients to avoid malnutrition.

Patients with severe nephrotic syndrome are at increased risk for thromboembolic complications (see Chapter 15). Retrospective reviews have shown that prophylactic anticoagulation is beneficial in reducing fatal thromboembolic episodes in nephrotic patients with MN, without a concomitant increase in the risk of bleeding.[67] No randomized controlled trial (RCT) has ever been done, however, and thus there is no current consensus about prophylactic anticoagulation and no laboratory test that can predict with any accuracy such an event. A thromboembolic event is more likely in certain patients, including those with severe and persistent nephrotic syndrome (proteinuria >10 g/day and/or serum albumin <25 g/l). Two additional recent clinical observations indicate the majority of thromboembolic events occur within the first 2 years of presentation and that there is an increasing likelihood of an event associated with progressively lower levels of serum albumin levels less than 30 g/l.[31] The majority of practicing nephrologists, however, will still wait until a primary thromboembolic event has occurred before using anticoagulants, at least until the level is persistently below 2 g/l, at which point the benefits of prophylactic anticoagulant therapy appear to outweigh the risk.

Other agents that have been tried with modest effects in small numbers of patients with MN include probucol,[68] a lipid peroxidation scavenger, and high-dose intravenous immune globulin, an agent with multiple effects on antibody-mediated tissue injury.[69]

Immunosuppressive Therapy

Several regimens using a variety of immunosuppressive agents have been shown to be successful in reducing proteinuria in MN patients. Many questions remain unresolved, however, including duration of conservative therapy while awaiting a spontaneous remission, determination of when to initiate immunosuppressive therapy, most effective and safest of the available agents, and duration of treatment before futility is assessed.[70] Many of these issues, based on clinically available evidence, are discussed in the recent KDIGO clinical practice guidelines for glomerulonephritis.[71]

The current evidence would support that specific immunosuppressive drug therapy should not be considered unless the patient has had persistent nephrotic-range proteinuria (>4 g/day) and unless the proteinuria has not declined more than 50% from baseline, over a minimum observation period of 6 months, despite maximum antihypertensive and antiproteinuric therapy. Other suggested criteria for early intervention are the presence of severe disabling or life-threatening symptoms related to the nephrotic syndrome or a rise in serum creatinine greater than 30% within 12 months documented as related to disease progression and not a complication such as a renal vein thrombosis, transformation to crescentic MN variant, or interstitial nephritis from diuretics. Recent biomarkers data also suggest that persistent, very high levels of the autoantibody to PLA_2R might be an indication for early intervention.[28]

Corticosteroids

In the three RCTs of corticosteroids in primary MN treatment, the overall consensus has been no significant long-term beneficial effect on proteinuria, rate of disease progression, or renal survival.[72,73] The use of oral corticosteroids as a single agent for the treatment of MN is therefore not recommended. The one exception may be the East Asian (Japanese) population, in whom long-term observational studies have indicated improvement in both proteinuria and renal function preservation with use of corticosteroids as monotherapy.[74]

Cytotoxic Agents Combined with Corticosteroids

In patients at moderate risk of progression, a significant benefit has been described with the combination of a daily oral dose of a cytotoxic agent (cyclophosphamide or chlorambucil) alternating monthly with corticosteroids: methylprednisolone pulses, 1 g intravenously daily for 3 days at the start of months 1, 3, and 5, followed by oral prednisone, 0.5 mg/kg/day for 27 days for 6 months.[75-77] Complete or partial remission of the nephrotic syndrome was seen in almost 80% of treated patients, a threefold to fourfold increase compared with the control group. Both progression rate and renal survival were significantly improved. Both treatment regimens were remarkably safe, although relapses were seen within 2 years in 30% of the treatment group. Similar results were obtained in an RCT ($n = 93$) using this same regimen to treat MN patients of Asian (East Indian) ethnicity.[40] Because the results of a cyclophosphamide-based regimen were similar to one based on chlorambucil,[78] cyclophosphamide is most often used because of a better safety profile.

The most recent RCT in MN studied a select population of 108 patients with documented deteriorating renal function (>20% decline in GFR within 3 to 24 months of study entry).[79] The combination of corticosteroids and a cytotoxic drug (chlorambucil) showed better protection against progressive kidney disease than placebo or cyclosporine. A difficult study to complete, trial entry took 10 years, and of the 108 patients entered, only 42% had 1 year of data, and less than 20% had 3 years of data. There were 117 severe adverse events reported, usually hematologic issues in the chlorambucil group and renal function deterioration in the cyclosporine group and infections in both groups. Statistically, there was a small benefit in terms of preventing further progression in the chlorambucil/corticosteroid group (60% progressed) versus no difference between the cyclosporine compared to the placebo group (80% progressed), a 20% differential. However, the very high dropout rate and inability to manage these therapies safely in MN patients with significantly declining renal function should give pause to applying any of these options under these conditions.[79]

One smaller RCT ($n = 26$) using intravenous cyclophosphamide in patients at high risk of progression (mean creatinine 2.3 to 2.7 mg/day; proteinuria 11 g/day) noted no statistical differences in proteinuria, remission rate, or rate of decline of renal function between the corticosteroid-alone and the combined-treatment group.[80] However, this RCT used monthly intravenous doses of cyclophosphamide rather than the oral regimen used in the Italian and Indian studies and in the recent UK trial.

In older, smaller studies, these cytotoxic agents, even with appropriate adjustments in dose, have produced variable effects on outcome and significant adverse events in a high percentage of patients.[81-83] The most recent longer-term studies in high-risk patients prospectively studied 65 patients with MN and serum creatinine concentration above 1.5 mg/dl treated with oral cyclophosphamide for 12 months and corticosteroids (same as previous regimen).[84-86] Renal survival was 86% after 5 years and 74% after 7 years. Partial remission occurred in 86% of the patients. The relapse rate was similar to earlier cytotoxic-corticosteroid regimens, 30% at 5 years. Treatment-related complications were significant and occurred in two thirds of patients, mainly bone marrow suppression and infections. The majority of adverse events could be managed by dose reduction, although some required permanent discontinuation of treatment.

A recent meta-analysis showed that the use of alkylating agents was associated with higher remission rates (partial or complete remission), but no statistical benefit of cytotoxic drug therapy was demonstrated compared with placebo in rates of ESRD or death.[87] The difficulty with this type of analysis is that the end point of renal survival is far beyond the termination point of most clinical trials. The latest UK study, for example, had few patients still in follow-up after 3 years in any of the three treatment groups, so it was not possible to demonstrate any effect on long-term preservation of renal function.

In summary, cyclophosphamide used in combination with corticosteroids appears to be effective in the treatment of patients with nephrotic-range proteinuria due to primary MN, especially if renal function is well preserved at initiation of therapy. This combination may work even in those with impaired renal function, but the supporting data are much less compelling, adverse effects are higher, and the likelihood of benefit is reduced, especially in patients with advanced renal failure (GFR <30 ml/min).[86] The favorable effects are maintained beyond the 1-year treatment period, but relapse rates approach 35% by 2 years. The adverse effects of long-term cyclophosphamide therapy are the major drawbacks to the universal application of this treatment. These include increased susceptibility to infections, anemia, thrombocytopenia, nausea, vomiting, sterility, and over time, malignant disease. Evidence from the vasculitis literature suggests that the incidence of cancer is increased at a much lower level of exposure than previously considered; the standardized incidence ratio was increased in a number of malignant neoplasms with total cyclophosphamide exposure as low as 36 g (~100 mg/day for 1 year).[88]

Calcineurin Inhibitors

Early uncontrolled studies using the calcineurin inhibitor (CNI) cyclosporine suggested an initial benefit but a high relapse rate.

Cyclosporine may reduce proteinuria not only through its immunosuppressive effects but also by direct effects on the podocyte. In a single-blinded RCT, 51 patients with corticosteroid-resistant MN were treated for 6 months with cyclosporine (2 to 5 mg/kg) plus low-dose prednisone and compared with placebo plus prednisone.[89] Complete remission and partial remission were seen in 75% of cyclosporine-treated patients versus 22% of the placebo controls. Cyclosporine was well tolerated, with no adverse events requiring discontinuation of treatment. However, 38% relapsed within 6 months of discontinuation of treatment.

Only one RCT has used cyclosporine in patients with high-grade proteinuria and progressive renal failure.[90] Both proteinuria and rate of renal function loss were reduced with cyclosporine compared with placebo and when the treatment group was compared to their status 6 months before starting cyclosporine. This improvement in proteinuria was sustained for up to 2 years after cyclosporine was discontinued. The entry criteria included documented GFR decline and high-grade proteinuria, but in contrast to the UK study, the cyclosporine was introduced at a lower dose and slowly increased to minimize toxicity (mean treatment dose 3.5 mg/kg/day). Treatment with longer-term cyclosporine (i.e., 12 months) has resulted in a higher rate of complete remission and partial remission (84%). In addition, persistence of remission was maintained with doses of cyclosporine as low as 1 to 2 mg/kg, although relapses were still common if the cyclosporine level fell below 100 ng/ml. Time to remission with use of cyclosporine varies from a few weeks to several months. This suggests that if no significant reduction in proteinuria (<30%) is noted within 3 to 4 months, a change in therapy should be considered.

Significant adverse effects seen with cyclosporine include hypertension, gingival hyperplasia, gastrointestinal complaints, muscle cramps, and most important, nephrotoxicity, which depends on both dose and duration of treatment. Patients at particular risk are those with initial impaired renal function, especially if accompanied by extensive intrarenal vascular disease or chronic tubulointerstitial damage on biopsy.

In a recently completed 12-month RCT (n = 48), tacrolimus monotherapy was compared with a control group (conservative therapy only).[91] Proteinuria remission was 76% with tacrolimus versus 35% in the control group, and progression rate was also substantially slowed by the CNI. The relapse rate after stopping of the drug, however, approached 50% by the end of 2 years of follow-up.

In summary, both cyclosporine and tacrolimus have been shown to be effective in reducing proteinuria in RCTs of MN. Although relapses are common after short exposure (6 to 12 months), a longer exposure time and lower maintenance doses of CNI can be used to maintain the partial remission state. No studies using CNIs have been of sufficient duration to confirm that maintenance of remission in proteinuria prolongs renal survival. Side effects are substantial, with the major concern being nephrotoxicity. This is particularly common if the medication is not introduced at a low dose and slowly increased until an effective drug level is reached. Clinical experience indicates increased potential for nephrotoxicity with the CNIs if the level of renal function is low (GFR <40% of normal), if there is a high degree of interstitial or vascular pathology accompanying the membranous lesion, or if the patient's renal function is rapidly deteriorating.[71,79]

Mycophenolate Mofetil

Studies using mycophenolate mofetil (MMF) in MN patients report conflicting results. However, even in the most optimistic study, although initial response was high (used in combination with prednisone), the relapse rate within months approached 50%. The most pessimistic study (the only RCT), compared with conservative management only, showed no difference in remission rates in MN patients.[92,93] Follow-up was limited and numbers in the latter study were small, but the reason for the marked differences between these two trials is not clear. In a small, retrospective study in corticosteroid-resistant Asian MN patients, a higher response with MMF was observed, with partial remission rate approaching 50%, possibly related to the ethnic characteristics of the population studied. The role of MMF in the treatment of MN is currently uncertain.

Rituximab

In several pilot studies, rituximab, despite substantial variations in the dose and timing of the drug, consistently reduced proteinuria by 60% to 70%.[94-97] The response rate to rituximab in patients who previously failed immunosuppressive therapy was similar to patients receiving the drug as first-line therapy. A delayed response in proteinuria reduction was seen, similar to cytotoxic therapy, with remissions continuing to occur up to 12 months after the last rituximab infusion. The anti-PLA_2R antibody was measured in both the Mayo Clinic cohorts, and a decline in titer preceded proteinuria reductions by as long as 3 months and was associated with patients subsequently achieving a partial or complete remission compared to those with no change in titer.[55] The relapse rate with rituximab, however, may be significantly less than with CNI or cytotoxic-based regimens. The best predictor of which patients will respond to rituximab is unknown, although the absence of interstitial disease on the biopsy specimen may improve response rate; an RCT is needed. The results of a recently initiated RCT comparing rituximab to cyclosporine are required before widespread use of this agent is advocated, given the high cost and unknown long-term toxicity of rituximab in patients with MN.

Eculizumab

Eculizumab is a humanized anti-C5 monoclonal antibody designed to prevent the cleavage of C5 into its proinflammatory byproducts. An RCT in 200 patients with MN that compared eculizumab with placebo during a total of 16 weeks showed no significant effect on proteinuria or renal function, but effective complement inhibition was not achieved.

Adrenocorticotropic Hormone

Two small studies have reported the use of an intramuscular long-acting synthetic form of adrenocorticotropic hormone (ACTH) in MN.[98,99] The exact mechanism of action of this agent in MN is unknown but likely unrelated to corticosteroid effects because corticosteroids alone are not beneficial in MN. A dose escalation study showed prolonged remission in the majority of MN patients treated with the synthetic form of ACTH, 1 to 2 mg weekly intramuscularly for a year. In a small RCT (n = 32) with a similar dose regimen, ACTH was compared to a standard cytotoxic plus corticosteroids regimen. The remission rate was the same in the two groups, 80% to 90%, but the relapse rate in the ACTH group was lower, 14% versus 30%, after a follow-up of 1 year. Side effects of ACTH were few and included fluid retention, sleep disturbances, and bronze skin discoloration. Potassium supplementation was required in the majority of patients in one trial.[99]

Treatment Summary

Control of proteinuria, specifically achieving either complete or partial remission of the nephrotic syndrome, is associated with prolonged renal survival and a slower rate of renal disease progression in patients with MN. Supportive or conservative care

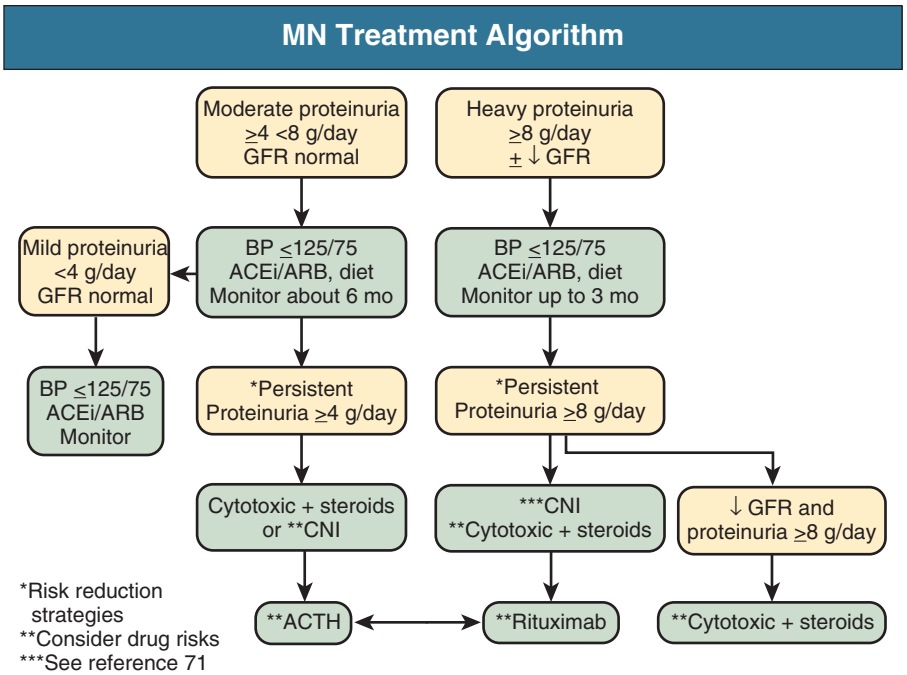

Figure 20-7 Algorithm for treatment of the patient with membranous nephropathy (MN). Details of possible therapies are discussed in the text. *ACEi,* Angiotensin-converting enzyme inhibitor; *ACTH,* adrenocorticotropic hormone; *ARB,* angiotensin receptor blocker; *BP,* blood pressure; *CNI,* calcineurin inhibitor; *GFR,* glomerular filtration rate.

should be provided to all patients first, including diuretics, antihypertensive agents such as ACE inhibitors and ARBs (potentially renal protective), and lipid-lowering agents, with lifestyle modifications such as salt restriction, weight normalization, and smoking cessation (see Chapter 80). In MN patients who require disease-specific therapy, the choice of agents remains controversial. Figure 20-7 outlines a suggested management algorithm based on the level and persistence of proteinuria.

Both cytotoxic-corticosteroid combinations and CNIs have proved effective in reducing proteinuria in moderate or high-risk MN patients. The physician, in concert with the patient, must take into account all risk/benefit factors to arrive at the best decision about which of these therapies should be used first. These approaches are not mutually exclusive and can be used in sequence if the first one chosen does not succeed in inducing a remission, or if adverse effects are untenable. Ideally, the approach should leave 2 to 3 months between treatment regimens to help immune system recovery. Alternatively, a second course of the same immunosuppressive regimen could be used, but at the potential cost of cumulative toxicity, or another treatment regimen may be indicated if the patient's risk profile has changed. Although the risks of malignancy from alkylating agents are reduced by limiting treatment to 6 months (especially with the alternating regimen), tobacco smokers are at increased risk of bladder and lung cancer and might be candidates for an alternative treatment regimen. In addition, men wanting to procreate are advised to bank sperm before treatment with alkylating agents.

Preliminary evidence on the use of rituximab or long-acting ACTH suggests that both may be effective and are safer than current regimens, but both need to be assessed further before being widely recommended. Patients with severe renal impairment (GFR <30 ml/min), especially if the MN course has been slowly progressive and histopathology indicates significant interstitial fibrosis and glomerular obsolescence, are less likely to benefit from immunosuppressive therapy, and the risks of treatment may favor conservative therapy as the best option for these patients.

CHAPTER 21

Membranoproliferative Glomerulonephritis and Cryoglobulinemic Glomerulonephritis

Francesco P. Schena and Charles E. Alpers

DEFINITION

Membranoproliferative glomerulonephritis (MPGN), or mesangiocapillary glomerulonephritis, is characterized by persistent antigenemia and circulating immune complexes, diffuse proliferative lesions involving both the mesangium and the peripheral capillary walls, and widening of the capillary loops, often with a double-contoured appearance expressing a capillary wall remodeling. MPGN may be idiopathic, but primary MPGN is increasingly recognized as a diagnosis of exclusion, with many previously "idiopathic" cases now found to be secondary to chronic infections, cryoglobulinemia, or systemic autoimmune disorders that result in aberrant immune complex formation.

On the basis of electron microscopy (EM) findings, MPGN has been traditionally classified into three categories. Type I was characterized by immune deposits in the subendothelial space and in the mesangium. Type II, now known as *dense deposit disease* (DDD), was characterized by dense deposits within the mesangium and in the basement membranes. Type III was considered a variant of type I (see Pathology). However, a more modern classification has emerged of MPGN based on underlying pathogenetic mechanisms. In this approach, which we follow in this chapter, MPGN is used to describe an immune complex disorder that includes most of those cases formerly considered MPGN type I and some cases of MPGN type III of Burkholder type. Cases of the former MPGN type II (DDD) and type III of Strife and Anders type are considered part of the spectrum of diseases now called *C3 glomerulopathies,* discussed separately in Chapter 22. Some cases formerly considered MPGN type I, in which deposits of complement (C3) are detected but not immunoglobulin, are also best considered as belonging to the class of C3 glomerulopathies, although evidence of alternative complement pathway dysregulation may not always be available for these cases.[1]

ETIOLOGY AND PATHOGENESIS

Membranoproliferative glomerulonephritis denotes a pattern of injury that is similar, whether the disease is primary or not. Therefore, the histologic diagnosis of MPGN should initiate a search for secondary causes[2] (Table 21-1). In older adults (>30 years), MPGN is frequently associated with cryoglobulinemia and hepatitis C virus (HCV) infection.

Membranoproliferative GN is most likely to occur in the setting of chronic immune complex diseases, for example, when the host cannot eliminate a foreign antigen effectively despite a humoral response. This may account for the MPGN observed with chronic blood-borne viral (hepatitis C and hepatitis B), bacterial (endocarditis, infected ventriculoatrial shunt), and malarial infections (see Chapter 57). A histologic pattern resembling MPGN can also be observed in chronic immune complex diseases such as lupus. Chronic immune complex disease and MPGN may also occur if the host has a defect in clearing immune complexes, as in complement deficiency, or when the reticuloendothelial system is impaired, as occurs with liver or splenic disease. Hereditary deficiencies of the classical pathway of complement (C1q, C2, C4) and of C3 may predispose to lupus and bacterial infections, then to development of MPGN. The disease is also associated with some malignant neoplasms, especially chronic lymphocytic leukemia (CLL) and lymphoma.

Membranoproliferative GN results from the glomerular deposition of immune complexes or from *in situ* immune complex formation (see Chapter 16). These complexes preferentially localize in the mesangium and subendothelial space of the capillary walls. Once localized, they typically activate complement through the classical pathway, leading to the generation of chemotactic factors (C5a), opsonins (C3b), and the membrane attack complex (C5b-9), with corresponding lowering of circulating C3 and C4 serum levels. In some patients, complement activation may be enhanced by C4 nephritic factors; in other cases, activation of complement may occur by the mannose-binding lectin (MBL) pathway[3] (Fig. 21-1). Complement activation results in the release of chemotactic factors that promote leukocyte accumulation and direct recruitment of leukocytes by engagement of Fc receptors present on these cells (Fig. 21-2). These features likely are important in the influx of monocytes, a noteworthy feature of MPGN. Leukocytes release oxidants and proteases, mediating capillary wall damage and proteinuria and a decrease in glomerular filtration rate. Cytokines and growth factors released by both exogenous and endogenous glomerular cells lead to mesangial proliferation and matrix expansion.

Cryoglobulins (i.e., immunoglobulins) precipitate in the cold and are categorized as types I to III (Table 21-2). The mixed cryoglobulinemias (types II and III) are most often associated with MPGN and have been strongly associated with chronic HCV infection in up to 80% to 90% of patients with cryoglobulinemic vasculitis.[4] The non-HCV cases have been associated with other infections (chronic hepatitis B, bacterial endocarditis), autoimmune diseases (systemic lupus), and other immunologic disorders (notably postinfectious GN). CLL may also be associated with cryoglobulinemia and MPGN, but cases of CLL and lymphoma also have been associated with MPGN in the absence of cryoglobulinemia.[5]

Many patients with HCV infection and cryoglobulinemia have an IgM-κ monoclonal antibody with rheumatoid factor (RF) activity. Complexes of this IgM RF can be found with anti-HCV and IgG, along with HCV peptides, and HCV RNA can be found in cryoprecipitates from patient serum. It has been postulated that the IgM is produced by dysregulated B cells infected with HCV. Cryoglobulinemia does not develop until many years (often >10) after HCV infection; but by the time chronic active hepatitis or cirrhosis

Etiology of Membranoproliferative Glomerulonephritis and Dense Deposit Disease	
Type	**Secondary Causes**
MPGN Type I	
With mixed (type II or III) cryoglobulinemia	Hepatitis C virus (70%-90% of patients) Other infections: bacterial endocarditis, chronic hepatitis B viral infection Collagen vascular disease: systemic lupus erythematosus, Sjögren syndrome Malignancy: chronic lymphocytic leukemia, non-Hodgkin lymphoma
Without cryoglobulinemia	Bacterial infections: endocarditis, abscess, infected ventriculoatrial shunt Viral infections: hepatitis B, C, and G; human immunodeficiency virus; hantavirus Malarial *(Plasmodium malariae)* Collagen vascular disease (systemic lupus erythematosus, hypocomplementemic urticarial vasculitis) Hereditary complement deficiency (C1q, C2, C4, or C3) Acquired complement deficiency (presence of C4 nephritic factor) Chronic liver disease: especially associated with hepatitis B or C infection, chronic schistosomal infection, with splenorenal shunt for liver fibrosis, and with α_1-antitrypsin deficiency Sickle cell disease Malignancy: chronic lymphocytic leukemia, lymphoma, thymoma, renal cell carcinoma
Dense Deposit Disease (MPGN Type II)	
Associated with C3 nephritic factor (C3 Nef)	With or without partial lipodystrophy and retinal abnormalities
Associated with factor H defect	Inherited mutations of factor H (deficiency) Autoantibodies to factor H
MPGN Type III	
	Secondary causes similar to MPGN type I (hepatitis C or B, and others)

Table 21-1 Etiology of membranoproliferative glomerulonephritis.

develops, as many as 30% to 40% of patients will have circulating cryoglobulins or other evidence of cryoglobulinemia.[6] Most of these patients will not develop renal disease, but in some, possibly those in whom the cryoglobulins have an affinity for fibronectin, the cryoglobulins containing HCV antigens will deposit in glomeruli.[7]

Specific HCV-related proteins have been detected in glomeruli (Fig. 21-3), tubulointerstitium, and vessels in patients with cryoglobulinemic HCV-positive MPGN,[8] although difficulties with the antisera available to detect HCV render such findings controversial. Glomerular HCV deposits have displayed two different patterns: (1) a linear homogeneous deposition along glomerular capillary walls, including endothelial and subendothelial spaces, and (2) a granular appearance on immunofluorescence microscopy with distinct deposits in mesangial and paramesangial areas. IgG, IgM, and C3 deposits have a distribution comparable to those of HCV RNA and core protein deposits, suggesting that in cryoglobulinemic HCV-positive MPGN, deposits consist of HCV-containing immune complexes that may directly contribute to renal damage.[9] Further pathogenetic insight will likely be provided by new murine models, including the transgenic thymic stromal lymphopoietin (TSLP) mouse, which develops mixed cryoglobulinemia and MPGN.[10] Monocytes/macrophages appear to mediate progression of renal damage in this model.[11]

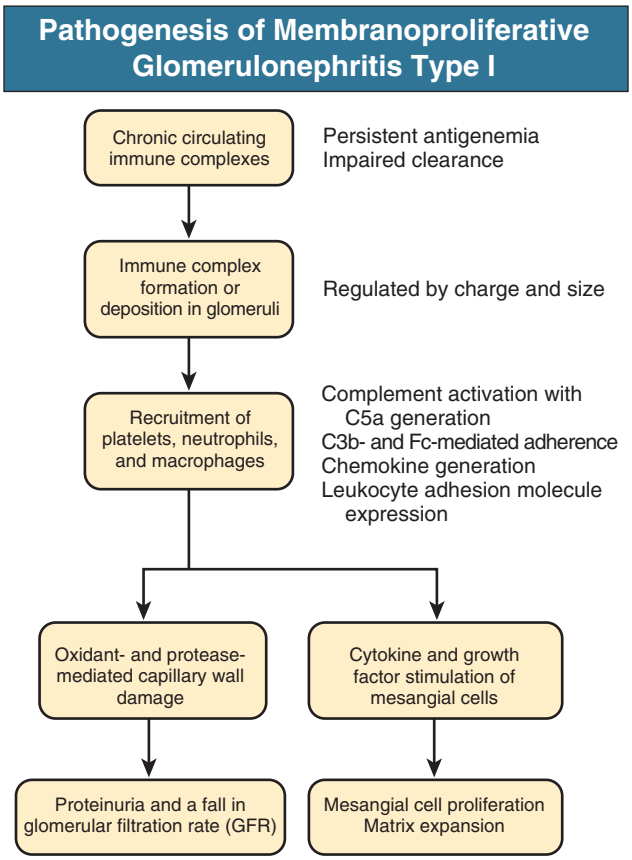

Figure 21-2 **Pathogenesis of MPGN type I.**

EPIDEMIOLOGY

In North America and Europe, MPGN constitutes less than 5% of all primary glomerulopathies. MPGN accounts for 5% to 10% of primary renal causes of nephrotic syndrome in children and adults.[12] Affecting males and females equally, MPGN in the United States is relatively more common in Caucasians than African Americans.

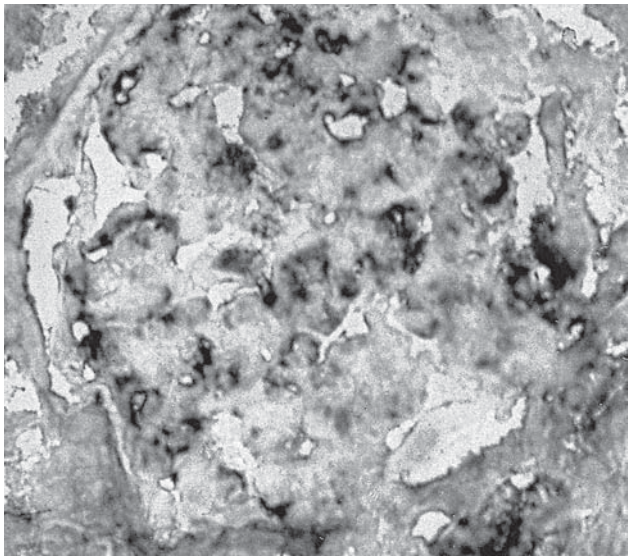

Figure 21-3 **Hepatitis C virus (HCV)–related antigen (c22-3).** In capillary wall of glomerulus from patient with cryoglobulinemic membranoproliferative glomerulonephritis (MPGN). (Light microscopy; magnification ×3100.)

Classification of Cryoglobulins

Type	Composition	Associated Disease
I	Monoclonal IgG, IgA, or IgM	Multiple myeloma (IgG, IgM) Chronic lymphocytic leukemia Waldenström macroglobulinemia (IgM) Idiopathic monoclonal gammopathy Lymphoproliferative disorders
II	Polyclonal IgG and monoclonal IgM (with rheumatoid factor activity)	Hepatitis C virus Neoplasms: chronic lymphocytic leukemia, diffuse lymphoma, B lymphocytic neoplasia Mixed cryoglobulinemia
III	Polyclonal IgG and polyclonal IgM	Infections: viral (hepatitis B and C, Epstein-Barr virus, cytomegalovirus), bacterial (endocarditis, leprosy, poststreptococcal glomerulonephritis), parasitic (schistosomiasis, toxoplasmosis, malaria) Autoimmune disorders: systemic lupus erythematosus, rheumatoid arthritis Lymphoproliferative disorders Chronic liver disease Mixed cryoglobulinemia

Table 21-2 **Classification of cryoglobulins.**

MPGN remains the most common cause of GN in many developing countries, especially in Africa and South America (such as Peru).

The renal biopsy registries show a declining incidence and prevalence of MPGN in the last 40 years in industrialized countries, whereas it remains common in developing countries, where the occurrence of infections is high. The disease may be familial in rare cases, and different histologic lesions may occur in family members.

CLINICAL MANIFESTATIONS

Membranoproliferative GN may present as microhematuria and non-nephrotic proteinuria (35%), as nephrotic syndrome with minimally depressed renal function (35%), as a chronically progressive GN (20%), or as a nephritic syndrome with rapidly deteriorating renal function with proteinuria and red blood cell casts (10%). Hypertension is present in 50% to 80% of patients, occasionally so severe that the presentation may be confused with that of malignant hypertension.

Pediatric Population

When presenting in childhood, primarily between ages 8 and 14 years, MPGN is usually idiopathic. Previously reported series have frequently included both immune complex–mediated MPGN and DDD together in characterizing the features of MPGN in children. Asymptomatic Japanese children diagnosed through a urinalysis screening program at school had lower blood pressure, proteinuria, and serum creatinine concentration than individuals diagnosed after presenting with symptoms.[13] Thus, early identification of the disease by urinary screening may allow early treatment.

Adult Population

When presenting in adults, MPGN is most often associated with cryoglobulinemia and HCV infection. Such patients usually present with the triad of weakness, arthralgias, and purpura. The arthralgias are only rarely accompanied by arthritis, are usually symmetric, and classically involve the knees, hips, and shoulders. The purpura is usually painless, palpable, and nonpruritic, occurring in "crops" that last 4 to 10 days, and preferentially localizes to the extremities (Fig. 21-4). Other manifestations may include ulcerative, vasculitic lesions that classically involve the lower extremities (Fig. 21-4) and buttocks (Fig. 21-5), Raynaud phenomenon, digital necrosis (Fig. 21-6), peripheral neuropathy, hepatomegaly, and rarely signs of cirrhosis (clubbing, spider angiomas, ascites). Although most patients with cryoglobulinemia have a chronic waxing and waning course, occasional patients may have a more fulminant presentation, with congestive heart failure (from an HCV-induced cardiomyopathy), infiltrates in the lung from deposition of cryoglobulins (Fig. 21-7), pulmonary hypertension, severe systemic hypertension, or mesenteric ischemia.

In view of the conditions associated with MPGN, signs of bacterial infection, viral infection, systemic lupus, malignant disease, and chronic liver disease should be sought (see Table 21-1).

Laboratory Findings

Membranoproliferative GN is often associated with depressed complement levels (C3 and total hemolytic complement [CH50]). In immune complex–mediated MPGN and in cryoglobulinemic MPGN, the classical pathway is often activated (with low circulating levels of C3, C4, and CH50). C3 nephritic factor (C3Nef) activity, strongly but not exclusively associated with DDD, is sometimes detected in plasma by the hemolytic test or the C3Nef IgG solid-phase assay.[14] The presence of C3Nef should prompt genetic analyses of complement factors, whereas RFs or cryoglobulins should prompt testing for anti-HCV antibody and HCV RNA. However, MPGN can be associated with HCV infection in the absence of cryoglobulinemia or RFs.[15] Failure to detect the cryoglobulins may result from improper specimen handling or transient cryoglobulinemia; however, in some patients, especially renal transplant recipients, test

Figure 21-4 Purpura in patient with HCV-associated cryoglobulinemia. Raised purpuric lesions are present on the legs of this individual. The differential diagnosis of purpura and renal disease includes cryoglobulinemia, Henoch-Schönlein purpura, vasculitis, and endocarditis.

Figure 21-5 Purpura in patient with HCV-associated cryoglobulinemia. Purpuric lesions are present on the patient's buttocks and thigh. Interestingly, note the purpuric lesions along the superior and inferior elastic border of the undergarment line.

results for cryoglobulinemia may be persistently negative. Serum and urine electrophoresis, immunofixation tests, and free light-chain assays may be required to exclude the presence of a monoclonal gammopathy in older persons. In patients with positive tests, a bone marrow aspiration is necessary for a more precise diagnosis. Tests for autoimmune disease must be included. Clinical or laboratory evidence of liver disease should prompt a search for causes of chronic liver disease, including hepatitis C, hepatitis B, and if appropriate, rare entities such as schistosomiasis and α_1-antitrypsin deficiency. Laboratory tests to detect infection include blood cultures, polymerase chain reaction, and serologic tests for bacterial, viral, and fungal infections.

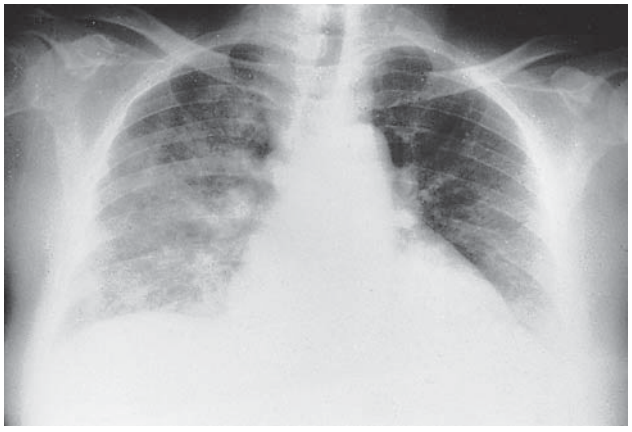

Figure 21-7 Lung infiltration in patient with hepatitis C. Chest radiograph shows nodular infiltrates in the lung secondary to cryoglobulinemic vasculitis in a patient with HCV infection.

PATHOLOGY

On light microscopy, MPGN is classically described as *hypercellular* because of both the influx of circulating leukocytes, in particular monocytes and macrophages, and the intrinsic glomerular cell proliferation, typically mesangial cells, leading to a characteristic accentuation of the normal glomerular lobular architecture[2,16] (Fig. 21-8, *A*). Accumulation of extracellular material, predominantly matrix, contributes further to the frequent mesangial expansion. The glomerular appearance can range from extremely hypercellular to predominantly sclerotic. In its most advanced form, sclerosis can manifest as nodules indistinguishable from diabetic nodular mesangial sclerosis. Silver stain often shows a double contouring of the glomerular basement membrane (GBM) ("tram tracks") as a result of the interposition of mesangial cells, leukocytes, or endothelial cells in the capillary wall with the synthesis of new basement membrane material (Fig. 21-9).

Immunofluorescence in MPGN frequently shows the deposition of IgG, IgM, and C3 in a granular capillary wall distribution (Fig. 21-8, *B*), although the immunoglobulin deposits may be scant. Staining for C3 in a peripheral (lobular) pattern involving capillary walls and mesangial areas is the most constant and strongest pattern, but when present in isolation, should prompt consideration of C3 glomerulopathy (see Chapter 22). Staining for classical pathway complement components (C1q, C4) may also be seen in MPGN. EM reveals discrete immune deposits in the subendothelial portions of the capillary walls and mesangial regions in MPGN, often in association with leukocyte infiltration (Fig. 21-8, *C*). The deposits are often discrete but may be confluent in their involvement of the capillary wall. Deposits can be small and sparse or so large and numerous that they are visible by light microscopy. A separation of the endothelium from the GBM can occasionally be observed, usually with some synthesis of new basement membrane material under endothelial cells that have detached from the original basement membrane. Between these layers (old and new) of basement membranes, interposed cells of mesangial, endothelial, or leukocyte origin may be found, as well as immune deposits and matrix.

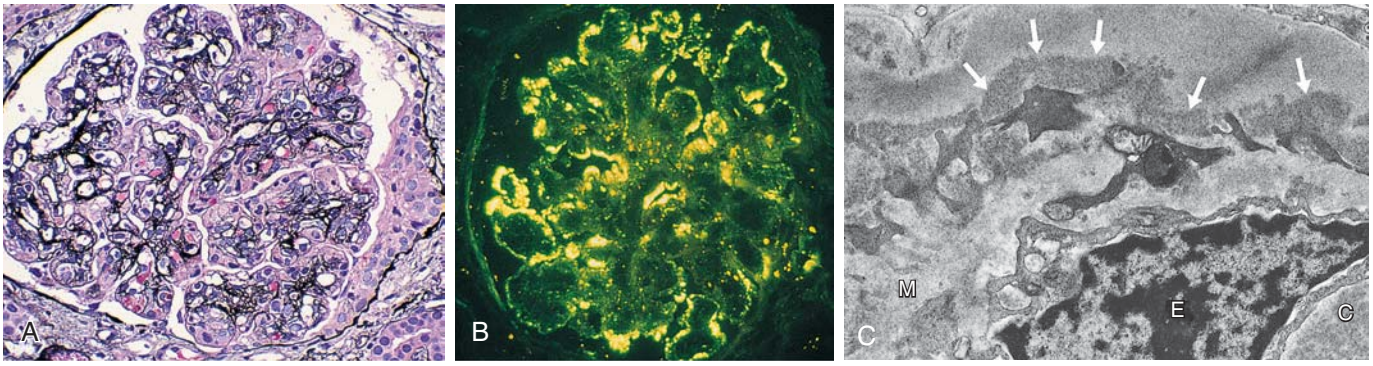

Figure 21-8 Pathology of membranoproliferative glomerulonephritis (MPGN) type I. A, Light microscopy shows a hypercellular glomerulus with accentuated lobular architecture and a small cellular crescent (methenamine silver stain). **B,** Immunofluorescence usually shows discrete, granular staining of the peripheral capillary wall for IgG (seen here) and C3 and occasionally for IgM and earlier complement components (C1q and C4). **C,** Electron microscopy shows numerous subendothelial deposits *(arrows)* between the duplicated basement membrane that extend into the mesangium *(M); C,* capillary lumen; *E,* endothelial cell nucleus.

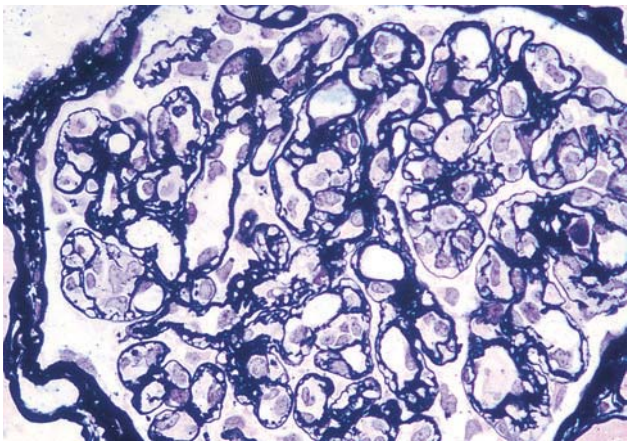

Figure 21-9 "Tram tracks" in MPGN type I. Silver staining shows a double contouring of the glomerular basement membrane (GBM) can be observed in MPGN type I, resembling tram tracks.

Type I and type III MPGN are long-established terms to subclassify MPGN on the basis of pathologic appearance, but these cases form a morphologic continuum and thus are not always separable by light microscopy. Type I and type III MPGN were historically distinguished on the basis of some differences in the location of immune deposits in glomerular capillary walls, as revealed by EM. However, once cases of C3 glomerulopathy have been removed from the category of MPGN, it is doubtful whether this ultrastructural distinction has any value in defining etiology, and it does not modify clinical management. Perhaps 15% of MPGN cases demonstrate both subendothelial and subepithelial deposits associated with minute disruptions of the lamina densa and newly elaborated lamina densa–like material (formerly called MPGN type III). Furthermore, there can be a continuum of subepithelial deposits in MPGN type I and type III from none or scanty to numerous, making it difficult to separate all cases into type I (scanty or no subepithelial deposits) or type III (numerous deposits) categories using this classification system.[17] Therefore, in transitioning to a more pathogenetically based classification system for MPGN, the use of the terms MPGN type I, II, or III is no longer advocated.

Cryoglobulinemic MPGN may appear histologically identical to MPGN type I. However, the cryoprecipitates can occasionally be observed by light microscopy as intracapillary hyaline-like globules (Fig 21-10, *A*), and there is often a more pronounced infiltration of macrophages within capillary lumina. EM may also show highly organized microtubular or finely fibrillar structures consisting of the precipitated cryoglobulins (Fig. 21-10, *B*).

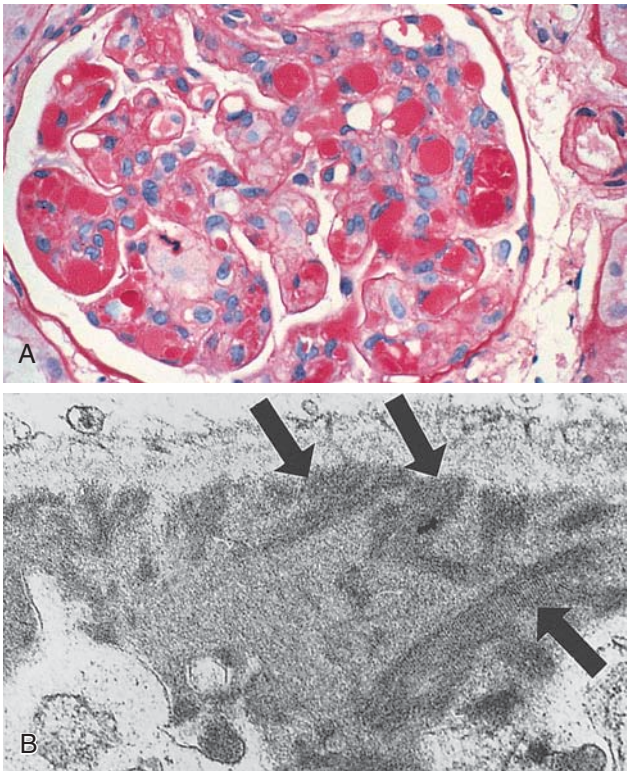

Figure 21-10 Pathology of cryoglobulinemic MPGN. A, Although cryoglobulinemic MPGN may histologically appear similar to MPGN type I (see Fig. 21-8), discrete precipitates of cryoglobulins may occasionally be found occluding individual capillary loops. **B,** In addition, electron microscopy shows organized fibrillar or tubular structures consistent with cryoglobulins *(arrows)*. Diseases that Histologically Resemble Membranoproliferative Glomerulonephritis

- Paraproteinemias: especially fibrillary glomerulonephritis, light-chain nephropathy
- Thrombotic microangiopathies: hemolytic uremic syndrome, scleroderma, radiation nephropathy, malignant hypertension
- Glomerulosclerosis in liver diseases
- Postinfectious glomerulonephritis
- "Transplant" glomerulopathy
- Rare diseases: collagen III glomerulopathy, C1q nephropathy, lipoprotein nephropathy

Box 21-1 Diseases that histologically resemble MPGN.

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

Membranoproliferative GN is diagnosed by renal biopsy in patients presenting with nephrotic or non-nephrotic proteinuria, accompanied by microhematuria, or by nephritic syndrome. On light microscopy, other entities may appear histologically similar, including diffuse lupus nephritis, poststreptococcal GN, the thrombotic microangiopathies, paraproteinemias, and fibrillary GN (Box 21-1). Immunofluorescence and EM are essential for separating these diseases. Systemic lupus usually can be eliminated by serologic testing.

Low complement levels can also be observed in atheroembolic renal disease (low C3 with eosinophilia), in thrombotic microangiopathy, in chronic liver disease (because of decreased synthesis), and in several glomerular diseases, including systemic lupus (low C3 and C4) and poststreptococcal GN (low C3). The detection of C3Nef activity in plasma suggests DDD, but C3Nef can also be identified in a proportion of patients with MPGN and even in healthy individuals. Once MPGN is diagnosed, careful evaluation for secondary causes should be conducted (see Table 21-1 and Chapter 57).

NATURAL HISTORY

Idiopathic MPGN in childhood has a relatively poor prognosis, with 40% to 50% of untreated patients progressing to renal failure over

10 years. Idiopathic MPGN in adults also carries an unfavorable prognosis. Five years after biopsy, 50% of patients either die or need renal replacement therapy (dialysis or transplantation). This proportion increases to 64% after 10 years. Risk of progression increases with elevated creatinine, nephrotic proteinuria, and severe hypertension, or if a biopsy specimen shows more than 50% crescents or marked interstitial fibrosis.[18] Patients with nephritic syndrome and high C1q staining in glomerular deposits have a poor prognosis.[19]

TRANSPLANTATION

The severity of crescent formation in native kidney biopsy specimens has predictive value for recurrence of disease in subsequent renal allografts.[20,21] For further discussion of recurrent MPGN in kidney transplantation, see Chapter 108.

TREATMENT

The initial approach to the patient with MPGN seeks to identify the etiology, if possible, and initiate supportive antiproteinuric and antihypertensive measures. Treatment plans for the various types of MPGN are discussed in the following sections (Table 21-3).

Idiopathic Membranoproliferative Glomerulonephritis in Children and Adults

For patients with normal renal function and asymptomatic nonnephrotic–range proteinuria, supportive antiproteinuric and antihypertensive measures only are required (see Chapter 80). Close follow-up every 3 to 4 months is recommended.[22] In adults or children with presumed idiopathic MPGN accompanied by nephrotic syndrome and a progressive decline of kidney function, oral cyclophosphamide or mycophenolate mofetil (MMF) plus low-dose alternate-day or daily corticosteroids has been suggested, with initial therapy limited to less than 6 months.[23] These drugs in combination with high-dose pulse corticosteroids have also been administered in patients with a rapidly progressive course and crescents on renal biopsy. In an alternative approach, in patients with nephrotic syndrome and normal or impaired renal function, a 3- to 6-month course of corticosteroids (prednisone 1 mg/kg/day) may be prescribed. If there is considerable reduction of proteinuria, corticosteroids may be continued at the minimal effective dose.

Rituximab (1 g intravenously on days 1 and 15) has been administered in four adult patients with idiopathic MPGN unresponsive to previous immunosuppressive drugs, with two complete and two partial remissions.[24] Eculizumab, which inhibits C5 activation, recently was used for MPGN type I refractory to previous immunosuppressive therapy and normalized the kidney function and resolved proteinuria.[25]

Hepatitis B Virus–Associated Membranoproliferative Glomerulonephritis

In hepatitis B virus (HBV)–associated MPGN, treatment with antiviral agents aimed at eradication of HBV is the recommended initial treatment. Immunosuppressive agents are discouraged because they promote further HBV replication and occasional deterioration of hepatic function (see Chapter 57).

Hepatitis C Virus–Associated Membranoproliferative Glomerulonephritis and Cryoglobulinemia

Treatment options in mixed cryoglobulinemia with renal involvement include corticosteroids, cytotoxic drugs such as cyclophosphamide, rituximab, and antiviral therapy (see Chapter 57). Subcutaneous administration of pegylated interferon alfa-2a or alfa-2b often improves extrarenal manifestations associated with reduced levels of viremia, but relapse is common after cessation of therapy. The current treatment of choice in patients with HCV-associated MPGN or cryoglobulinemic MPGN with moderate proteinuria and nonrapid but progressive renal failure is pegylated interferon alfa-2a (180 μg every week) or alfa-2b (1.5 μg kg^{-1} every week) and ribavirin (800 to 1200 mg/day in two divided doses), adapting the dose to the stage

Suggested Management of Membranoproliferative Glomerulonephritis

Type	Treatment
All types	Supportive therapy following recommendations discussed in Chapter 80
Idiopathic MPGN in children	Non-nephrotic proteinuria, normal renal function: follow with 3-month visits Normal renal function and moderate proteinuria (>3 g/day): prednisone 40 mg/m^2 on alternate days for 3 months Nephrotic or impaired renal function: prednisone 40 mg/m^2 on alternate days (maximum 80 mg) for 2 years, tapering to 20 mg on alternate days for 3-10 years
Idiopathic MPGN in adults	Non-nephrotic, normal renal function: follow with 3-month visits Nephrotic or impaired renal function: 6-month course of corticosteroid with/without cyclophosphamide, cyclosporine, tacrolimus, or mycophenolate (MMF) Rapidly progressive renal failure with diffuse crescents: treat as for renal-limited pauci-immune crescentic GN (see Chapter 25) In the presence of heavy proteinuria: ACE inhibitors
MPGN associated with HCV or cryoglobulinemia	Non-nephrotic, normal renal function: treat with interferon alfa (see Chapter 57) based on severity of liver disease (diagnosed by biopsy) Nephrotic syndrome, reduced renal function, or signs of cryoglobulinemia: pegylated interferon alfa-2b (1 μg/kg weekly) and ribavirin (15 mg/kg/day) for 12 months, followed by short-term course of low-dose corticosteroids; if relapse occurs, consider high-dose interferon alfa (10 million U daily for 2 weeks, then every other day for 6 more weeks). Rapidly progressive renal failure or severe symptoms of vasculitis (heart failure, pulmonary disease): methylprednisolone (1 g/day) for 3 days, followed by oral prednisone (60 mg/day) with slow taper over 2-3 months Cyclophosphamide (2 mg/kg/day with adjustment for renal function) and cryofiltration may be added as adjunctive therapy; when prednisone reduced to 20 mg/day and cyclophosphamide discontinued, add interferon alfa. MPGN in renal or liver transplant recipient: consider course of oral ribavirin (0.6-1 g/day).

Table 21-3 Suggested management of membranoproliferative glomerulonephritis (MPGN).

of chronic kidney disease.[26] Patients with genotypes 1 and 4 should receive 48 weeks of interferon therapy if an early viral response is obtained at 12 weeks (>2 log fall in viral titer). The added use of protease inhibitors so far has been largely restricted to patients without renal impairment. Genotypes 2 and 3 should be treated for 24 weeks. High-dose pegylated interferon alfa may cause severe influenza-like symptoms, depression or psychosis, development of hypothyroidism, and rarely development of proteinuria (with minimal change type of lesion). The most frequent serious adverse effect of ribavirin is hematopoietic toxicity as well as hemolytic anemia and teratogenic effect.

Rituximab, a CD20 antibody selectively targeting B cells, seems to be as efficient as cyclophosphamide in blocking cryoglobulin production, is better tolerated, and does not enhance HCV replication. Rituximab should be administered at a dose of 375 mg/m^2/week for 4 weeks.[27,28] Alternatively, oral cyclophosphamide may be used (2 mg/kg/day for 2 to 4 months).

In patients with nephrotic-range proteinuria or progressive renal failure, the anti-HCV therapy is the same. Moreover, treatment may include plasma exchange (3 liters of plasma three times weekly for 2 or 3 weeks) and methylprednisolone pulses (0.5 to 1 g/day for 3 consecutive days) followed by oral prednisone (60 mg/day) with slow tapering over 2 to 3 months.[27] Imatinib (400 mg/day), corticosteroids and plasma exchange have been administered with success in a case of noninfectious type II cryoglobulinemia with MPGN[29] after the benefit observed in an experimental model of TSLP transgenic mice with established MPGN.[30]

Other Types of Membranoproliferative Glomerulonephritis

Patients with MPGN associated with other infections may respond to effective treatment of the underlying pathogenic agent. Those with MPGN caused by an autoimmune disease should receive therapy for the principal disease. MPGN associated with α_1-antitrypsin deficiency has been reported to be cured by liver transplantation, which cures the genetic defect. Patients with MPGN associated with malignant disease, such as B cell lymphoma, may respond to effective treatment of the underlying cancer.

CHAPTER 22

Glomerulonephritis Associated with Complement Disorders

H. Terence Cook and Matthew C. Pickering

DEFINITIONS

Glomerular diseases associated with abnormalities of the complement system include thrombotic microangiopathy and glomerulonephritides. Activation of complement in most cases of glomerulonephritis (GN) is secondary to other processes in the glomerulus, such as deposition of immune complexes. In a small number of cases, however, abnormalities of the complement system itself, both genetic and acquired, are the cause of GN, and these patients are the focus of this chapter. Abnormalities of the classical pathway of complement have been associated with GN. Most important, deficiencies in early components of the classical pathway of complement have been associated with autoimmunity and GN.[1] This is most clearly seen in the rare individual with C1q deficiency, who typically has a lupus-like illness. This is thought to result from failure of clearance of immunogenic apoptotic bodies and other cellular debris in the absence of normal classical pathway complement activation.

The largest group of patients with complement abnormalities and GN has an abnormality of control of the alternative pathway of complement activation, with glomerular deposition of C3 in the absence of immunoglobulin, now termed *C3 glomerulopathy* (Box 22-1).

C3 GLOMERULOPATHY

A recently introduced term, C3 glomerulopathy encompasses glomerular disease characterized by the accumulation of complement component C3 in glomeruli caused by abnormal control of complement activation, deposition, or degradation, particularly abnormal control of the alternative pathway of complement activation.[2] Characteristically, glomeruli show strong immunohistologic staining for C3 without significant staining for immunoglobulins or for components of the classical pathway of complement activation, C1q and C4. Thus defined, C3 glomerulopathy is distinct from atypical hemolytic uremic syndrome (HUS), which may also be associated with alternative pathway activation; in HUS, complement activation is on the renal endothelium and on electron microscopy (EM) is not associated with well-defined deposits (see Chapter 29). C3 glomerulopathy may show a variety of appearances on light microscopy, including mesangial proliferation, a membranoproliferative pattern, endocapillary proliferation, and crescent formation. It is now recognized that many cases previously classified morphologically as "membranoproliferative glomerulonephritis" (MPGN) are cases of C3 glomerulopathy. This includes cases that had been classified as MPGN types I, II, or III. Indeed, it appears that most cases previously called MPGN type III are examples of C3 glomerulopathy (see Chapter 21).

On EM, C3 glomerulopathy may have a variable appearance as well. However, a common presentation is of *dense deposit disease* (DDD). This condition is characterized by replacement of the basement membrane by dense bands on EM (Fig. 22-1). In some cases, the light microscopy appearance in DDD resembles membranoproliferative glomerulonephritis, which was previously designated "MPGN type II." However, most cases of DDD do not have MPGN morphology on light microscopy.

Cases of C3 glomerulopathy that do not have typical highly dense deposits of DDD show a range of appearances on EM, with deposits that may be mesangial, subendothelial, or subepithelial, and that may be more or less well defined. These cases of non-DDD C3 glomerulopathy have been given the collective name of *C3 glomerulonephritis* (C3GN).[3,4]

ETIOLOGY AND PATHOGENESIS

The pathogenesis of C3 glomerulopathy involves a dysregulation of the alternative pathway of complement (see Fig. 29-10). In health, the alternative pathway is constantly being activated, but at an extremely low rate. With constant generation of small amounts of activated C3, this low-grade activation allows the pathway to be rapidly switched on when needed. In the presence of pathogens, rapid amplification of C3b is achieved through a positive feedback loop termed the *C3b amplification loop* that can generate millions of C3b molecules within minutes. Because this amplification can progress so rapidly, efficient systems are required to prevent inappropriate activation of the pathway. The most important protein in the circulation that controls the alternative pathway is complement factor H (CFH). CFH exerts this control in three ways: (1) blocking the formation of alternative pathway C3 convertases by binding to C3b and thus inhibiting interaction between C3b and factor B, (2) promoting the spontaneous dissociation of these convertases, and (3) working with another plasma protein, factor I, to cleave C3b to iC3b. Mice that have been genetically engineered to lack factor H have undetectable circulating C3 because their C3 is constantly consumed by the uncontrolled alternative pathway.[5]

Factor H is an abundant single-chain glycoprotein predominantly made in the liver. It is composed of protein subunits, termed *short consensus repeat* (SCR) domains. The activity of CFH can be modulated by a group of closely related proteins called *factor H–related proteins* (CFHRs), five of which exist in humans. CFHRs are coded for by genes adjacent to the gene for CFH and have a similar structure to CFH. The high degree of homology of these genes has led to a number of recombination and deletion events that have resulted in both common polymorphisms and rare pathogenic mutations at this locus. The most common polymorphism is a deletion of *CFHR1* and

Definitions of Glomerulonephritic Complement Disorders

C3 Glomerulopathy

Disease process caused by abnormal control of complement activation, deposition, or degradation and characterized by predominant glomerular C3 fragment deposition with electron-dense deposits on electron microscopy.

Dense Deposit Disease (DDD)

A form of C3 glomerulopathy with a characteristic electron microscopy appearance of intensely osmiophilic transformation of the glomerular basement membrane.

C3 Glomerulonephritis (C3GN)

C3 glomerulopathy without the characteristic appearances of dense deposit disease.

Glomerulonephritis with Dominant C3

Morphologic term for cases of glomerulonephritis with dominant staining for C3c. *Dominant* is defined as C3c intensity ≥2 orders of magnitude more than any other immune reactant on a scale of 0 to 3 (including 0, trace, 1+, 2+, 3+). Many, but not all, of these will represent cases of C3 glomerulopathy.

Box 22-1 Definitions of complement disorders associated with glomerulonephritis.

CFHR3 that is present in homozygosity in 5% to 20% of healthy individuals, depending on ethnic origin. It is now clear that the CFHRs are able to compete with the binding of CFH to C3b in some circumstances.[6] CFHRs, unlike CFH, are unable to inhibit complement activation and thus are now thought to antagonize the action of CFH.

In many cases of C3 glomerulopathy, the pathogenesis is a failure of CFH to control the activation of the alternative pathway in the circulation, which is associated with low levels of circulating C3 because of uncontrolled consumption. Up to 80% of patients with DDD and up to half of patients with C3GN have low levels of serum C3.[3] Many of these patients have a C3 nephritic factor (C3NeF). C3NeFs are autoantibodies that are able to stabilize the alternative pathway C3 convertase by preventing CFH from carrying out its normal functions. It therefore seems likely that C3NeF plays an important etiologic role in these patients. However, the role of C3NeF is complicated because C3NeFs may also be found in patients with other forms of GNs and even in healthy patients. In other cases, genetic mutations lead to failure of alternative pathway control, including patients with complete CFH deficiency caused by gene deletion, mutations in CFH that interfere with its binding to C3b, and mutations in C3 that change its structure to prevent its inhibition by CFH. In some patients, failure of alternative pathway control is associated with autoantibodies directed against factor H that target its regulatory domain.

In cases of C3 glomerulopathy not associated with excessive activation of C3 in the circulation, the nephrologist can assume that there is a failure to control the alternative pathway locally within the glomerulus. This might be caused by a failure to control activation or by inappropriate handling of the fragments of C3 generated by alternative pathway activation. In most cases the pathogenesis is still not clear, but there is an example of a familial form of C3 glomerulopathy, called *CFHR5 nephropathy,* without systemic C3 activation. This is a common cause of kidney disease in the population of Cyprus, in which the mutation is a duplication of the first two exons of the *CFHR5* gene.[6] This leads to an abnormal protein that forms multimers able to deregulate the activity of CFH on surfaces.[7] Therefore, the abnormal protein interferes with the action of CFH locally within the glomerulus and enhances alternative pathway activation.

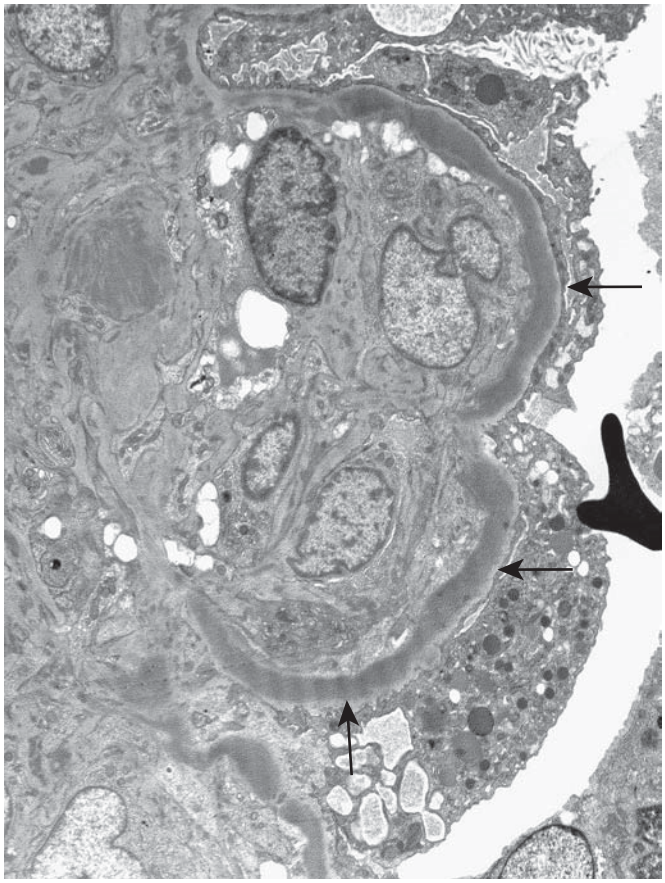

Figure 22-1 Dense deposit disease (DDD). Electron micrograph of a glomerulus with typical appearance of DDD showing very osmiophilic transformation of the basement membrane *(arrows)*.

In addition to those just described, other mutations and polymorphisms in complement genes have been associated with C3 glomerulopathy, but their role is uncertain at present. It is also notable that an association appears to exist between monoclonal gammopathy and C3 glomerulopathy.[8] In some patients, the monoclonal immunoglobulin may act as a C3NeF.

EPIDEMIOLOGY

With a reported prevalence of 2 to 3 per 1 million population, DDD is primarily a disease of children and young adults. However, in a 2009 series from New York, 39% of the adult patients were over 60 years of age.[9] DDD affects males and females equally in many cohorts, although some studies have shown a female predominance. In one large series from France, the ratio of C3GN to DDD was about 2:1, and patients with C3GN were significantly older, with a mean age at diagnosis of 30 years.[3] In the United Kingdom and Ireland, we found a C3GN-DDD ratio of about 3:1 and estimated the incidence of C3 glomerulopathy at 1 to 2 per million population per year.[10] The apparent incidence of C3GN likely will increase as the entity becomes better recognized by nephrologists and pathologists. There is no reliable information on geographic variation in incidence; the one notable exception is C3GN caused by a mutation in *CFHR5* in which almost all the cases have been found in Cyprus, where the mutation apparently occurred a few hundred years ago.[7]

CLINICAL MANIFESTATIONS

Dense Deposit Disease

At presentation, almost all patients with DDD have proteinuria, usually with hematuria. Nephrotic-range proteinuria is present in two thirds of patients,[9,11] and frank nephrotic syndrome in 12% to 65% in different series. In a series of 98 patients from North America, about one fifth did not suspect a problem, and kidney disease was detected as part of a routine annual examination.[12] A number of patients have initial signs and symptoms of acute nephritic syndrome and may have episodes of acute kidney injury that show complete clinical resolution.[13] Decreased kidney function is common at presentation and is more common in adults with DDD. Hypertension is often found either at clinical onset or during the disease course. In about half of patients, clinical onset of DDD is preceded by acute infection, often an upper respiratory tract infection, with elevated ASO titers in 20% to 40%.

Patients with DDD may develop ocular *drusen,* lipoproteinaceous deposits of complement-containing debris within the Bruch membrane beneath the retinal pigment epithelium (Fig. 22-2). This pathology is similar to age-related macular degeneration (AMD) but, in contrast to AMD, drusen in DDD may be found as early as the second decade of life. There is no correlation between disease severity in the kidney and in the eye. A small minority of patients with DDD have acquired partial lipodystrophy (APL), a condition with symmetric loss of adipose tissue from the face, arms, and upper portions of the trunk (Fig. 22-2).

The overall long-term outcome in DDD is poor. In the series cited earlier, 50% of the 98 patients progressed to end-stage renal disease (ESRD) within 10 years of diagnosis, with young women having the greatest risk for kidney failure.[12]

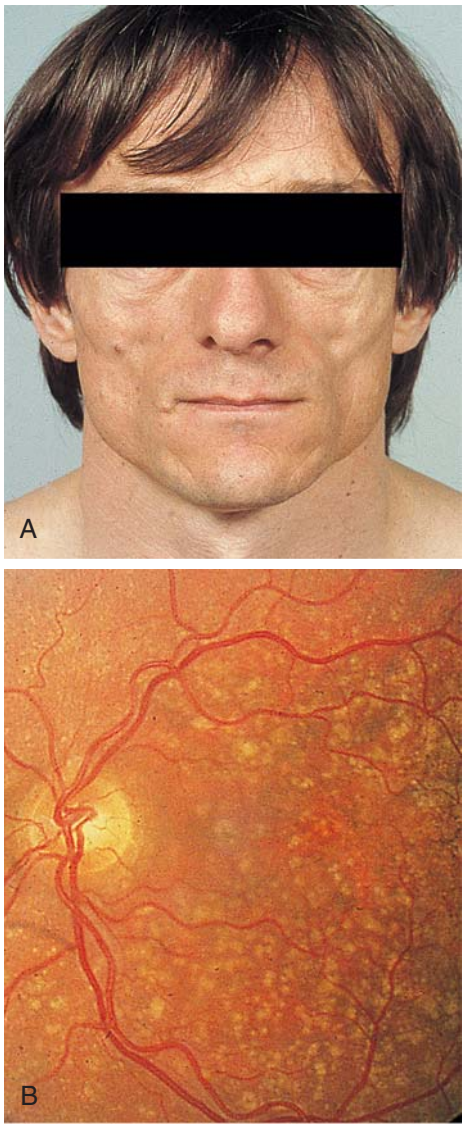

Figure 22-2 Facial and retinal features of dense deposit disease (MPGN type II). A, Partial lipodystrophy; note the absence of subcutaneous fat from the face. **B,** Drusen bodies in the retina. *(Courtesy Dr. C. D. Short, Manchester, UK.)*

C3 Glomerulonephritis

Because C3GN has only recently been recognized, clinical manifestations are less well defined. In the French series, 27% of patients with C3GN had nephrotic syndrome at presentation.[3] Approximately two thirds of patients had microhematuria at presentation, and one third had elevated blood pressure. In this series, rate of progression to ESRD in C3GN patients was similar to that in patients with DDD.

In CFHR5 nephropathy in Cyprus, the major clinical feature in young patients is hematuria. Microhematuria was present in 90% of patients, and 20% reported episodes of macrohematuria, often associated with upper respiratory tract infection.[14] Proteinuria became more common with increasing age and was seen in 80% of men and 20% of women older than 50. Impaired kidney function was more common with increasing age, particularly in men, and of 18 patients who reached ESRD, 78% were men. The reason for the striking gender difference in outcome is unclear.

LABORATORY FINDINGS

Low levels of serum C3 are found in approximately 80% of patients with DDD and up to 50% of patients with C3GN. In the case of C3GN caused by CFHR5 nephropathy, serum C3 levels are typically normal. Serum levels of the early components of the classical pathway (C1q and C4) are usually normal. Most patients with DDD are positive for serum C3NeF and in more than 50% of patients, C3NeF persists throughout the clinical course.[15] However, C3NeF is not a specific serologic marker because it also occurs with MPGN type I, lupus nephritis, and poststreptococcal glomerulonephritis, although less frequently. C3NeF is seen in fewer than half of patients with C3GN. It is important to note that methods for measuring C3NeF are not standardized.

Box 22-2 shows a list of investigations that may be helpful in C3 glomerulopathy. It is recommended that investigations in this second category be discussed with experts and performed in laboratories with experience in complement assays. Complement laboratories across the world are listed on the International Complement Society (www.complement.org) and European Complement Network (www.ecomplement.org) websites. Depending on the clinical scenario, it may be possible to prioritize some of these assays. For example, in patients with C3 glomerulopathy and low serum C3 levels in the absence of C3NeF, it would be important to screen for anti-CFH autoantibodies. In familial cases of C3 glomerulopathy, a search for genetic mutations may be important for elucidating pathogenesis and for genetic counseling.

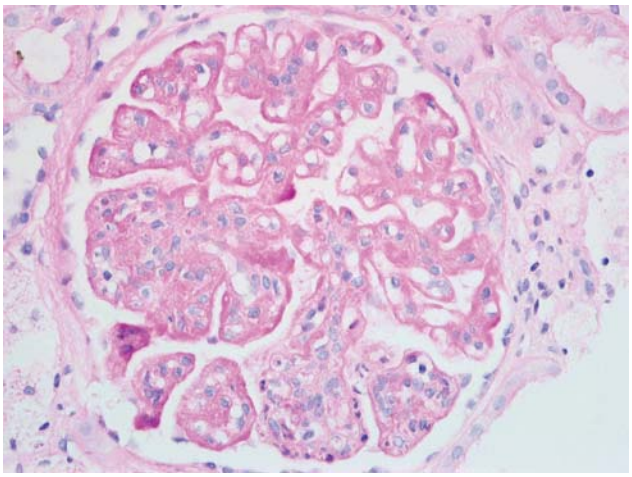

Figure 22-4 C3 glomerulonephritis. Light microscopy shows a glomerulus with a membranoproliferative pattern of injury with increased mesangium, capillary wall thickening, and segmental endocapillary hypercellularity. (Periodic acid–Schiff reaction.)

Serologic and Genetic Evaluation of C3 Glomerulopathy

Tests recommended in *all* patients with C3 glomerulopathy:

- Measurement of serum levels of C3 and C4
- Measurement of C3 nephritic factor
- Measurement of factor H
- Serum paraprotein detection

Patients with C3 glomerulonephritis (C3GN) should be screened for the genetic mutation of CFHR5 nephropathy

Tests that should be considered on a case-by-case basis:

- Measurement of serum factor B and C5
- Measurement of markers of C3 and C5 activation (e.g., C3d, soluble C5b9)
- Detection of autoantibodies to factor H and factor B
- Mutation screening of complement regulatory genes (e.g., CFH, CFI, CD46), activation protein genes (C3, CFB) and assessment of copy number variation across the CFH-CFHR locus

Box 22-2 Serologic and genetic evaluation of C3 glomerulopathy.

PATHOLOGY

The defining feature of C3 glomerulopathy is the presence of C3 (usually detected with an antibody to C3c) in glomeruli on immunohistology (Fig. 22-3). In most cases, C3 staining is seen on capillary walls and in the mesangium, but in some cases, the staining may be mainly mesangial. In some patients, particularly those with DDD, C3 may also be found on Bowman capsule or on tubular basement membranes.

The light microscopy appearances are variable. In both DDD and C3GN, the presence of membranoproliferative changes is typical, with increased glomerular lobulation, increase in mesangial matrix and cells, and capillary wall thickening with double-contour formation (Fig. 22-4). Some cases show a predominantly mesangioproliferative pattern or an endocapillary hypercellularity, partly caused by influx of macrophages or neutrophils. This hypercellularity may affect almost all the glomeruli, giving an appearance of diffuse endocapillary proliferative GN similar to that typically seen with postinfectious glomerulonephritis (PIGN). Crescent formation may be present and may be sufficiently prominent to merit the designation of *crescentic* GNs (>50% crescents). In a series of 69 patients with DDD, the incidence of different histologic patterns was membranoproliferative (25%), mesangioproliferative (45%), crescentic (18%), and acute proliferative and exudative (12%).[16] In the French series of C3GN patients, 71% showed an MPGN pattern on light microscopy.[3]

The EM appearance of C3 glomerulopathy also varies greatly, although in many cases the diagnosis can be suspected from the EM changes. By definition, DDD shows the presence of typical osmiophilic, dense transformation of the glomerular basement membrane (GBM; see Fig. 22-1), with similar features often seen in Bowman capsule and tubular basement membranes. However, these changes may be segmental within glomeruli, in some cases making it difficult to define DDD with certainty. In DDD, typically there are large electron densities in the mesangium.

In other cases of C3GN, there is electron-dense material that expands the GBM similar to the changes in DDD, but without such marked electron density; the distinction between these cases and DDD may not be clear-cut and depends on a subjective interpretation by the pathologist. Other cases have more distinct subendothelial and mesangial electron-dense deposits, reminiscent of those seen in immune complex GN. Some cases show a very complex pattern of intramembranous deposits that was previously designated as a form of MPGN type III (Fig. 22-5).

In both DDD and C3GN, subepithelial hump-shaped deposits are frequently seen. These are identical to those characteristically seen in PIGN. Their significance is not clear, although these humped deposits are more common in infectious exacerbations of disease.

Few data are available on the relationships among histology, clinical presentation, clinical course, and underlying genetic abnormalities. In several series of DDD patients, the presence of crescents was associated with a more rapid decline in renal function.

DIFFERENTIAL DIAGNOSIS

The diagnosis of C3 glomerulopathy is relatively straightforward if there is isolated C3 deposition with typical deposits on EM. However, it is now clear that some patients have an otherwise typical appearance of DDD or C3GN, but also have small amounts of immunoglobulin in glomeruli, which presents a diagnostic challenge. A recent consensus conference on C3 glomerulopathy suggests that the

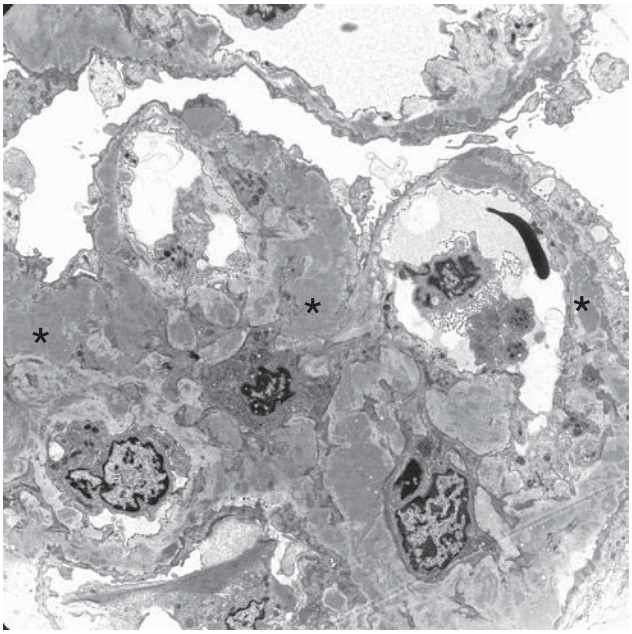

Figure 22-5 C3 glomerulonephritis. Electron micrograph of a glomerulus shows a complex pattern of thickening of the glomerular basement membrane with intramembranous electron-dense material. *Similar deposits are also seen in the mesangium.

term *glomerulonephritis with dominant C3* should be used for cases in which the staining intensity of C3 is 2 or more orders of magnitude greater than any other immune reactant on a scale of 0 to 3. Most of these cases will be C3 glomerulopathy.

Another problem is the distinction of C3 glomerulopathy from PIGN. PIGN may show greatly reduced serum C3, and glomeruli may stain for C3 without immunoglobulin. In some cases, the distinction from C3GN may only be possible by following the patient to see if resolution of the disease occurs. It has been suggested that PIGN could be considered a self-limiting form of C3 glomerulopathy. Some patients who have been labeled as "atypical" postinfectious glomerulonephritis have C3 glomerulopathy.[17] In addition, HCV-associated MPGN may be associated with C3 and minimal or absent IgG (although IgM is usually present). Thus, testing for HCV should be part of the differential.

TREATMENT

The optimal treatment for C3 glomerulopathy remains undefined. Most information relates to DDD because C3GN was not previously recognized as a specific diagnostic category. In many studies, however, DDD was grouped together with forms of MPGN, which makes it difficult to develop specific recommendations for DDD. Attempted treatments include renin-angiotensin system blockade, corticosteroids and other immunosuppressants, anticoagulants, and plasma exchange.[18] Recent KDIGO (Kidney Disease: Improving Global Outcomes) clinical guidelines (www.kdigo.org) suggest, on the basis of low-quality evidence, that "adults and children with presumed idiopathic MPGN accompanied by the nephritic syndrome and progressive decline in kidney function" receive oral cyclophosphamide or mycophenolate mofetil (MMF) plus low-dose daily or alternate-day corticosteroids, with initial therapy of less than 6 months. However, whether these recommendations also apply to C3 glomerulopathy with an MPGN-like pattern remains doubtful, and effective therapy for this group of diseases is still largely undefined.

In many cases of C3 glomerulopathy, the deposition of C3 in glomeruli leads to subsequent activation of C5, and there is considerable interest in the possibility of using the anti-C5 antibody eculizumab for treatment. There are a number of case reports and a small, open-label nonblinded clinical trial of eculizumab for C3 glomerulopathy.[19] Some patients have shown clinical improvement, and some showed decreased glomerular inflammation on repeat biopsy. In the rebiopsied patients, IgG-κ was found, consistent with binding of the monoclonal eculizumab to C5 in the biopsy, giving a histologic pattern similar to monoclonal immunoglobulin deposition disease[20] (see Chapter 27). However, the exact role of eculizumab remains to be defined. Rational treatment of C3 glomerulopathy would involve inhibition of C3 activation, and several drugs are in preclinical development that may achieve this and allow more targeted therapy in the future.

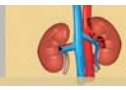
CHAPTER 23



IgA Nephropathy and Henoch-Schönlein Nephritis

John Feehally and Jürgen Floege

DEFINITIONS

IgA nephropathy (IgAN) is a mesangial proliferative glomerulonephritis characterized by diffuse mesangial deposition of IgA. Also called Berger disease, IgAN was first recognized in 1968 by Jean Berger when immunofluorescence techniques were introduced for the study of renal biopsy specimens. IgAN is unique among glomerular diseases in being defined by the presence of an *immune reactant* rather than by any other morphologic feature on renal biopsy, and the light microscopy changes are variable. IgAN is the most prevalent pattern of glomerular disease seen in most Western and Asian countries where renal biopsy is widely practiced. The term *benign recurrent hematuria* was previously used for IgAN, but it is now known that IgAN is an important cause of end-stage renal disease (ESRD). It is likely that IgAN is not a single entity but rather a common response to various injurious mechanisms.

Henoch-Schönlein purpura (HSP) is a small-vessel vasculitis affecting the skin, joints, gut, and kidneys that predominantly affects children. It is defined by tissue deposition of IgA. HSP was described separately by Schönlein in 1837 and Henoch in 1874. Typically, there is clinical involvement in the skin, gut, and kidneys. The nephritis associated with HSP is also characterized by mesangial IgA deposition; indeed, the renal histologic features of Henoch-Schönlein (HS) nephritis are indistinguishable from those of IgAN. HS nephritis is differentiated from IgAN by the extrarenal manifestations.

ETIOLOGY AND PATHOGENESIS

Although infective episodes precede HSP in up to 50% of cases and usually precipitate macrohematuria episodes in young IgAN patients, no evidence indicates a role for any specific antigen. The clinical association of visible hematuria with upper respiratory tract infection in IgAN indicates that the mucosa may be a site of entry for foreign antigens. An infectious source has long been suspected, and there have been occasional reports of IgAN in association with microbial infection, both bacterial (e.g., *Campylobacter, Yersinia, Mycoplasma, Haemophilus*) and viral (e.g., cytomegalovirus, adenovirus, coxsackievirus, Epstein-Barr virus). A severe form of IgAN, which may be crescentic, has been reported in association with severe staphylococcal infection. No organism, however, has been consistently implicated by the finding of microbial antigen in glomerular deposits in typical cases of IgAN. In addition there is evidence for a mucosal hyperresponsiveness to a variety of food antigens in IgAN patients.[1] The mesangial IgA may thus represent a common immune response to a variety of foreign antigens. Another common feature of this immune response is that the deposited IgA is undergalactosylated, and that the occurrence of this type of IgA in the circulation may elicit an autoimmune IgA- and IgG-response (see later discussion).

The regular recurrence of IgAN and HS nephritis after renal transplantation strongly implies an abnormality in the host IgA immune system (see Chapter 108).

IgA Immune System

IgA is the most abundant immunoglobulin in the body and is chiefly concerned with mucosal defense. It has two subclasses, IgA1 and IgA2. Mucosal antigen challenge provokes *polymeric* IgA (pIgA) production by plasma cells of the mucosa-associated lymphoid tissue; the pIgA is then transported across epithelium into mucosal fluids, where it is released after coupling to secretory component as *secretory* IgA (sIgA). The function of circulating IgA is less clear; it is bone marrow derived and mostly *monomeric* IgA1 (mIgA1). Circulating IgA1 is cleared by the liver through hepatocyte asialoglycoprotein receptors and Kupffer cell Fcα receptors.

The mesangial IgA in IgAN is predominantly pIgA1. The clinical association with mucosal infection or superantigens from *Staphylococcus aureus* originally suggested that the mesangial pIgA1 comes from the mucosal immune system. In IgAN, however, pIgA1 production is downregulated in the mucosa and upregulated in the bone marrow. Moreover, the pIgA response to systemic immunization with common antigens is increased, whereas the response to mucosal immunization is impaired. Impaired mucosal IgA responses allowing enhanced antigen challenge to the marrow could be the primary abnormality in IgAN, although this remains unproven. Similarly attractive, yet still unproven, is the hypothesis that some mucosal IgA-producing plasma cells translocate to the bone marrow in IgAN; this could also explain the particular glycosylation of serum IgA in IgAN. Tonsillar pIgA1 production is also increased, although IgAN can occur after tonsillectomy, and the tonsil is a very minor source of IgA production compared with the mucosa or marrow. There are reports of sIgA in the mesangium, but this finding is not easily explained by current pathogenic concepts of IgAN. Hepatic clearance of IgA is reduced, possibly because of the altered molecular characteristics of IgA in IgAN (see later discussion).

Serum IgA levels are increased in one third of patients with IgAN and HSP. There are elevations in both mIgA and pIgA. However, high serum IgA itself is not sufficient to cause IgAN. High circulating levels of monoclonal IgA in myeloma or polyclonal IgA, in acquired immunodeficiency syndrome (AIDS), only infrequently provoke mesangial IgA deposition.

Circulating macromolecular IgA is characteristic of IgAN. It is often described as IgA immune complexes, although the antigen is only rarely identified. There are circulating IgA rheumatoid factors (IgA against constant domain of IgG) in 30% of patients with

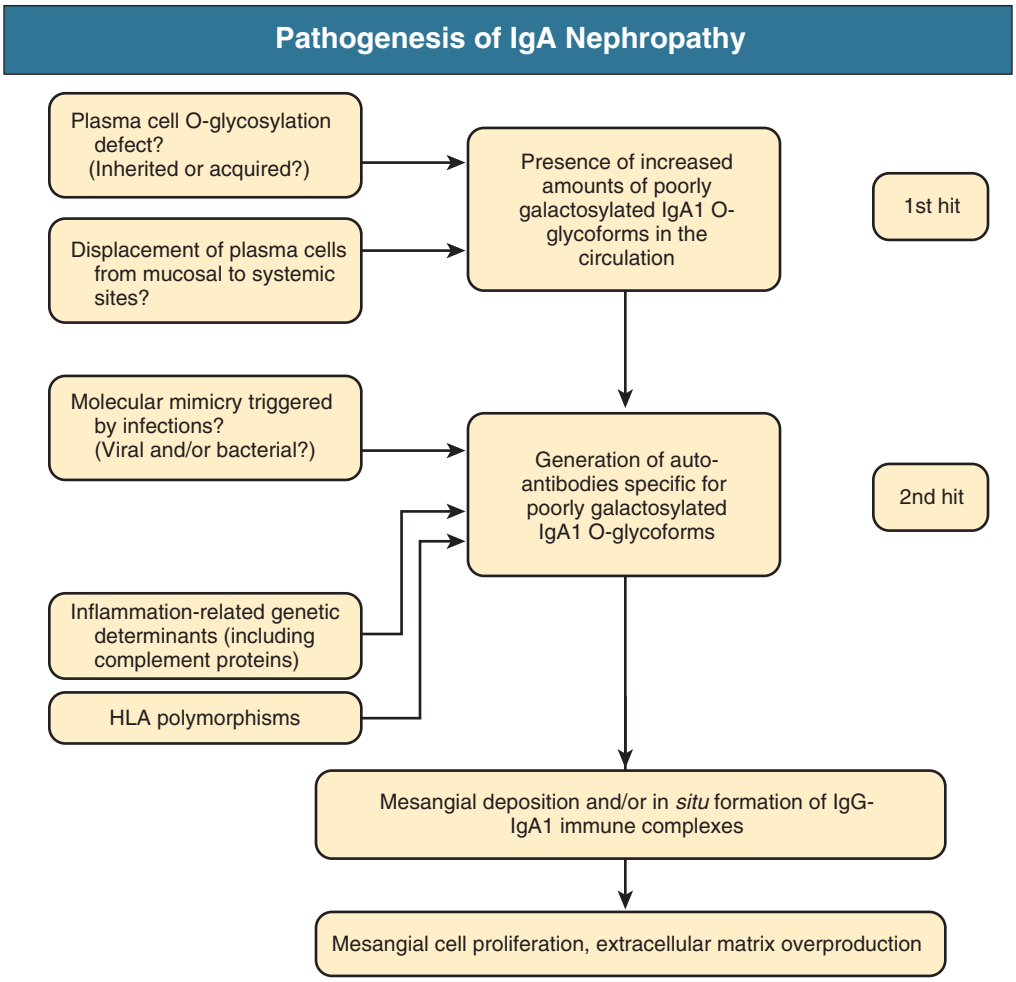


Figure 23-1 Pathogenesis of IgA nephropathy. Proposed mechanisms leading to mesangial deposition of abnormally glycosylated IgA1 and mesangial injury. Not shown in this scheme is the role of generic progression factors (e.g., primary hypertension, smoking, obesity).

IgAN and 55% of those with HSP. Studies *in vitro* indicate that IgA production by mononuclear cells is exaggerated in IgAN, and that these cells show abnormal patterns of cytokine production. However, the direct relevance of these observations to events *in vivo* is uncertain.

IgA Glycosylation

IgA1 carries distinctive *O*-linked sugars at its hinge region; IgA2 has no hinge and carries no such sugars. There is good evidence that circulating IgA1 in IgAN and HS nephritis has abnormal *O*-linked hinge-region sugars with reduced galactosylation because of altered IgA production in lymphocytes of patients with IgAN.[1] Some data indicate defective function of the relevant glycosyltransferases that *O*-glycosylate IgA1, possibly with a genetic basis. Other findings suggest that the primary abnormality may be that IgA of mucosal type, which has glycosylation patterns different from serum IgA1, reaches the circulation, for example, by translocation of mucosal lymphocytes to the bone marrow. The latter is consistent with experiments, where immortalized lymphocytes from IgAN patients continue to produce dimeric and polymeric IgA with altered galactosylation *in vitro*.[2]

Mesangial IgA1 in IgAN has the same abnormalities of *O*-glycosylation.[3,4] The altered glycosylation may lead to IgG anti-IgA autoantibodies and promote mesangial IgA1 deposition by predisposing to the formation of circulating IgA1 immune complexes or by directly modifying IgA1 interactions with matrix proteins and mesangial cell or monocyte Fc receptors.[5] It may also impair IgA1 clearance by inhibiting IgA1 interactions with hepatic and circulating myeloid cell IgA receptors. Figure 23-1 summarizes some key elements involved in the pathogenesis of IgAN.

Glomerular Injury After IgA Deposition

Polymeric IgA deposition in the mesangium is typically followed by mesangial proliferative glomerulonephritis (GN). In animal models, co-deposition of IgG and complement is necessary for inflammation, but this is not mandatory in human disease. Complement deposits are usually C3 and properdin without C1q and C4. There may be complement activation via the mannose-binding lectin pathway. The extent to which IgA engages inflammatory cells in the circulation and especially in the kidney will determine the intensity of inflammation. Fc receptors for IgA (Fcα receptors) on myeloid and mesangial cells may play a key role.[6]

The mechanisms of mesangial proliferative GN have been studied in detail in animal models, particularly anti–Thy 1 nephritis in the rat. These studies have shown the key role of cytokines and growth factors in mesangial cell proliferation, particularly the B and D isoforms of platelet-derived growth factor[7] (PDGF) and in the subsequent matrix production and sclerosis, particularly transforming growth factor-β (TGF-β). Studies of renal biopsy specimens in human IgAN also support a role for PDGF and TGF-β. These

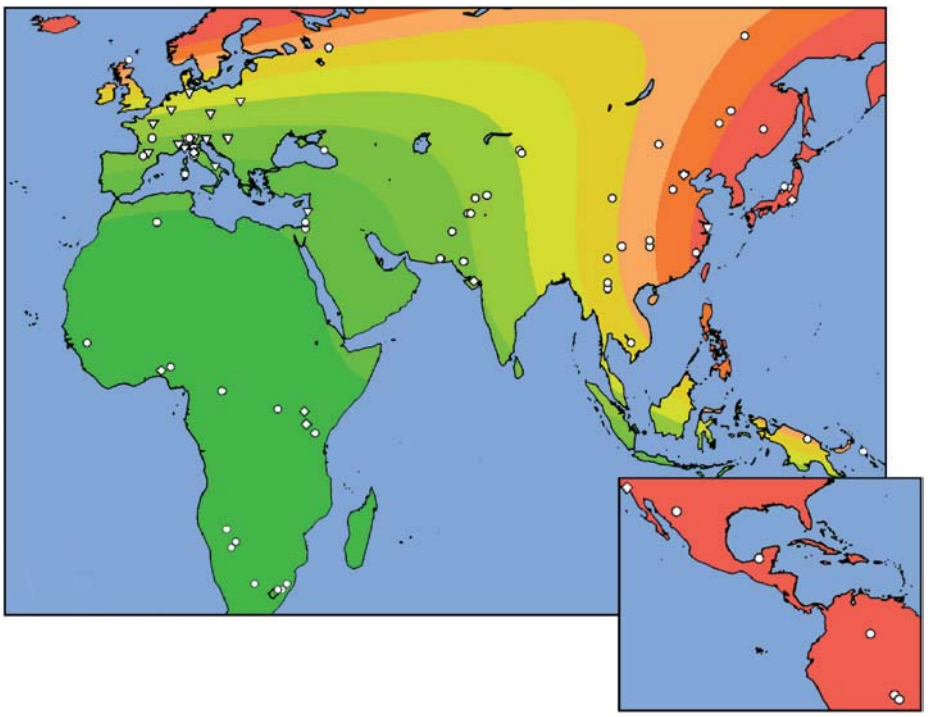

Figure 23-2 Geographical variation in genetic risk for IgA nephropathy. Genome-wide association studies indicate a geographical gradient of risk from green (low risk) to red (high risk). *(From reference 11.)*

mechanisms are not unique to IgAN but are likely involved in all forms of mesangial proliferative GN, including those without IgA deposition.

Animal Models of IgA Nephropathy

Animal IgA does not have the same characteristics as human IgA1, and some animals also have IgA clearance mechanisms distinct from those in humans. Therefore, animal models, even if they provoke mesangial IgA deposits, are not particularly informative about the mechanisms that underlie human mesangial pIgA1 deposition, although they have provided many insights into events after IgA deposits have developed. There is no animal model in existence for HSP.

Relationship Between IgA Nephropathy and Henoch-Schönlein Purpura

Despite some differences in age at onset and natural history of IgAN and HS nephritis,[8] there is much evidence to support a close pathogenetic link between the two conditions, and the outcome of the two diseases may be similar.[9] Monozygotic twins who developed IgAN and HSP, respectively, at the same time have been described. The evolution of IgAN into HSP in the same patient is described in both adults and children, and HSP patients with ESRD receiving a renal transplant may experience recurrent disease in the form of IgAN. Many of the abnormalities of IgA production and handling reported in IgAN are also detected in HSP.

EPIDEMIOLOGY

IgA nephropathy is the most prevalent pattern of glomerular disease in most countries where renal biopsy is widely used as an investigative tool. Its estimated frequency is at least 2.5 cases per year per 100,000 adults.[10] However, the striking geographic variation has been associated with the presence of particular gene alleles that protect from IgAN[11] (Fig. 23-2). This racial predisposition is maintained in other locations; in the United States, for example, IgAN is less common in Blacks than in Caucasians of European origin. Perceived prevalence of IgAN may also be influenced by attitudes to the investigation of microhematuria. A country with an active program of routine urine testing will inevitably identify more individuals with urine abnormalities, but IgAN will be identified only if renal biopsy is performed. Even then, the prevalence of IgAN will be underestimated; a study of kidney donors suggests that the prevalence of IgAN with mesangial proliferative changes and glomerular C3 deposits in the general population in Japan may be 1.6%.[12] This suggests that the vast majority of IgAN patients never come to medical attention and spontaneously remit.

In children, HSP is usually diagnosed on clinical grounds without biopsy confirmation of tissue IgA deposition. Transient urine abnormalities are common in the acute phase. However, only those with persistent urine abnormalities or with more overt renal disease will come to renal biopsy. Therefore, the incidence of HS nephritis is almost certainly underestimated, with many unidentified mild and transient cases. There is no information on geographic variations in HSP.

Genetic Basis of IgA Nephropathy

Urine abnormalities increase in frequency among the relatives of IgAN patients, although only in a few pedigrees is IgAN found in multiple generations. One large pedigree has been described in Kentucky, and other large families have been found in Italy and Canada. However, more than 90% of all cases of IgAN appear to be sporadic.

Large worldwide genome-wide association studies have identified genetic modulators that seem to affect the prevalence of sporadic IgAN and modulate its course.[11-13] Variations in major histocompatibility gene loci (HLA-DR, -DQ, -DP and HLA-B) have consistently been identified. Other gene loci are less consistent and include

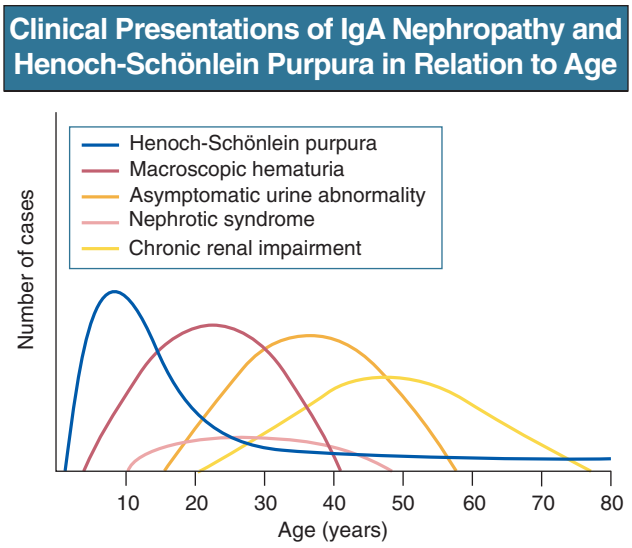

Figure 23-3 Age in clinical presentation of IgA nephropathy and Henoch-Schönlein purpura. HSP is most common in childhood but may occur at any age. Macrohematuria is very uncommon after age 40. The importance of asymptomatic urine abnormality as the presentation of IgAN will depend on attitudes to routine urine testing and renal biopsy. It is uncertain whether patients presenting late with chronic renal impairment have a disease distinct from that of those presenting younger with macrohematuria. *(Data from patients presenting in Leicester, UK, 1980-1995.)*

inflammatory mediators (tumor necrosis factor and α-defensin) and gene loci affecting complement factor H.[14]

CLINICAL MANIFESTATIONS

IgA Nephropathy

The wide range of clinical presentations of IgAN varies in frequency with age (Fig. 23-3). No clinical pattern is pathognomonic of IgAN. In populations of Caucasian descent, IgAN is more common in males than females by a ratio of 3:1, whereas the ratio approaches 1:1 in most Asian populations.

Macroscopic Hematuria

In 40% to 50% of patients with IgAN, the clinical presentation is episodic macroscopic hematuria, most frequently in the second decade of life. The urine is usually brown rather than red, and clots are unusual. There may be loin pain caused by renal capsular swelling. Hematuria usually follows intercurrent mucosal infection, typically in the upper respiratory tract (the term *synpharyngitic hematuria* has been used) or occasionally in the gastrointestinal tract. Hematuria is usually visible within 24 hours of the onset of the symptoms of infection, differentiating it from the 2- to 3-week delay between infection and subsequent hematuria in postinfectious (e.g., poststreptococcal) GN. The macroscopic hematuria resolves spontaneously over a few days. Microscopic hematuria persists between attacks. Most patients have only a few episodes of frank hematuria, which become less frequent and resolve over a few years or sooner. Such episodes may be associated with acute kidney injury (AKI).

Asymptomatic Hematuria and Proteinuria

Asymptomatic urine testing identifies 30% to 40% of patients with IgAN in most reported series. Microhematuria with or without proteinuria (usually <2 g/24 h) is noted. The number of patients identified in this way will depend on local attitudes to urine screening as well as on the use of renal biopsy in patients with isolated microscopic hematuria. Most patients with IgAN are asymptomatic and would be identified only when the urine is tested.

Proteinuria and Nephrotic Syndrome

It is rare for proteinuria to occur without microscopic hematuria. Whereas nephrotic-range proteinuria may occur, in particular in the presence of uncontrolled hypertension, full-blown nephrotic syndrome is uncommon, occurring in only 5% of all patients with IgAN. Nephrotic syndrome may occur early in the course of the disease, with minimal glomerular change or with active mesangial proliferative GN. Alternatively, it may occur as a late manifestation of advanced chronic glomerular scarring.

Acute Kidney Injury

Although uncommon in IgAN (<5% of all cases), one study reports that AKI may be the presentation in up to 27% of patients older than 65 years.[15] AKI develops by three distinct mechanisms. There may be acute severe immune and inflammatory injury with necrotizing GN and crescent formation (crescentic IgAN); this may be the first presentation of IgAN, or it may be superimposed on established, less aggressive disease. Rapid deterioration in IgAN in pregnancy may be caused by crescentic transformation. Alternatively, AKI can occur with mild glomerular injury when heavy glomerular hematuria leads to tubule occlusion by red blood cells (RBCs). Third, especially in elderly patients, chronic IgAN will predispose to AKI from a variety of incidental renal insults (see Chapter 69).

Chronic Kidney Disease

Some patients already have renal impairment and hypertension when they are first diagnosed with IgAN. These patients tend to be older, and they probably have longstanding disease that previously remained undiagnosed because the patient neither had frank hematuria nor underwent routine urinalysis. Hypertension is common, as in other chronic glomerular disease; accelerated hypertension occurs in 5% of patients.

Clinical Associations with IgA Nephropathy

Mesangial IgA deposition is a frequent finding in autopsy studies in chronic liver disease. Although particularly associated with alcoholic cirrhosis, IgA deposition can occur in other chronic liver disease, including that caused by hepatitis B and schistosomiasis. It is thought to result from impaired clearance of IgA by the Kupffer cells, which express Fcα receptors, and hepatocytes, which express the asialoglycoprotein receptor. Clinical evidence of renal disease is more common than previously appreciated, and patients occasionally develop ESRD.

A number of case reports have associated IgAN with human immunodeficiency virus and AIDS. It is not clear whether the polyclonal increase in serum IgA, which is a feature of AIDS, is the predisposing factor.

There are case reports associating IgAN with many other conditions, particularly with a number of immune and inflammatory diseases (Table 23-1). Their relationship to abnormalities of the IgA immune system is not always clear, and some may represent the coincidental development of unrelated but relatively common conditions.

Henoch-Schönlein Purpura

Although most prevalent in the first decade of life, HSP may occur at any age. A palpable purpuric rash, which may be recurrent, occurs

Diseases Reported in Association with IgA Nephropathy			
Disease	**Common**	**Reported**	**Rare**
Rheumatic and autoimmune disease	Ankylosing spondylitis Rheumatoid arthritis Reiter syndrome Uveitis	Behçet syndrome* Takayasu arteritis† Myasthenia gravis	Sicca syndrome

Infection	HIV, hepatitis B (in endemic areas)	Brucellosis	Leprosy
Miscellaneous		Wiskott-Aldrich syndrome‡	

Table 23-1 Diseases reported in association with IgA nephropathy: common, reported, and rare. Rare associations have been made in one or two reported cases only. In a disease as common as IgA nephropathy, it is therefore uncertain whether these are truly related. *HIV,* Human immunodeficiency virus. *Behçet syndrome: systemic vasculitis typified by orogenital ulceration and chronic uveitis. †Takayasu arteritis: systemic vasculitis involving the aorta and its major branches, most often found in young women. ‡Wiskott-Aldrich syndrome: X-linked disorder in which increased serum IgA is associated with the triad of recurrent pyogenic infection, eczema, and thrombocytopenia.

Figure 23-4 Henoch-Schönlein purpura. The rash is a palpable purpuric vasculitis on the lower limbs spreading on extensor surfaces to the buttocks and occasionally to the upper limbs. Histology shows leukocytoclastic vasculitis with IgA deposits in blood vessel walls.

on extensor surfaces (Fig. 23-4). There may be polyarthralgia (usually without joint swelling) and abdominal pain caused by gut vasculitis. This may be severe, with bloody diarrhea if intussusception develops. In practice, the diagnosis is made by clinical criteria in the great majority of children, in whom HSP is a self-limiting illness. In adults, clinical features include purpura, arthritis, and gastrointestinal symptoms in 95%, 60%, and 50% of patients, respectively.[16] Renal involvement in adults with HSP does not differ from isolated IgAN. Tissue confirmation of IgA deposition by renal or skin biopsy is necessary to establish the diagnosis.

Much renal involvement in HSP is transient. Urine abnormalities are noted during the acute presentation but may disappear. Of those referred to a nephrologist, asymptomatic urine abnormality is still the most frequent clinical manifestation. Nephrotic syndrome occurs in 20% to 30% of patients. AKI may develop as a result of crescentic GN.

PATHOLOGY

The renal histopathologic findings in IgAN and HSP nephritis may be indistinguishable (Fig. 23-5).

Immune Deposits

Diffuse mesangial IgA is the defining hallmark of IgAN (Fig. 23-5, *A*). C3 is co-deposited in up to 90% of cases. IgG in 40% and IgM in 40% of cases may also be found in the same distribution. IgA may also deposit along capillary loops, a pattern more common in HS nephritis; in IgAN, this pattern is associated with a worse prognosis. C5b-9 is found with properdin but not C4, indicating alternative complement pathway activation. Disappearance of IgA deposits after prolonged clinical remission has been documented in both children and adults. About one third of the patients also have deposits of sIgA in the mesangium and are characterized by more severe disease.[17]

Light Microscopy

Light microscopy changes are remarkably variable and do not correlate topographically with the IgA deposits. There can be almost normal glomerular architecture, mesangial hypercellularity that may be diffuse (Fig. 23-5, *B*), or segmental, or in rare cases, focal segmental necrotizing GN with extracapillary proliferation. Typical cases are characterized by an increase in mesangial cells and mesangial matrix with normal-appearing capillary loops, although endocapillary hypercellularity can occur (Fig. 23-5, *C*). Focal segmental or global glomerular sclerosis indicates that the disease has been ongoing for some time (Fig. 23-5, *D*). In addition to glomerular changes, the

(***B, C,*** *and* ***D*** *courtesy Prof. I. Roberts.)*

preglomerular arterial vessels often exhibit wall hyalinosis and subintimal fibrosis even in patients with only mild arterial hypertension. In longstanding disease, tubulointerstitial inflammation leads to interstitial fibrosis and tubular atrophy in a pattern no different from other progressive glomerular disease. On occasion, IgAN and minimal change nephrotic syndrome coincide (see under Differential Diagnosis), in which case light microscopy is normal, but there are mesangial IgA deposits.

Morphology is of value in predicting prognosis in patients with slowly progressive disease. The Oxford classification of IgAN is now being widely accepted, although it still requires further validation.[18] This classification identifies four features of prognostic value and can be easily scored on light microscopy: mesangial hypercellularity (M1 when present, M0 when absent), endocapillary hypercellularity (E1), segmental sclerosis (S1), and three degrees of tubular atrophy and interstitial fibrosis (T0, T1, T2). Examples of the glomerular features are shown in Figure 23-5.

Two distinct patterns of injury are seen in AKI. There may be tubular occlusion by RBCs with acute tubular epithelial injury in AKI associated with macroscopic hematuria (Fig. 23-6). Alternatively, glomerular injury may be the cause of AKI, with necrotizing GN and cellular crescent formation. Such crescentic IgAN may develop on a histologic background of established chronic renal injury caused by IgAN or may be the first presentation of IgAN. Small numbers of crescents may be seen in hypertensive patients with stable renal function and no other pathologic evidence of severe glomerular inflammation; the term *crescentic IgAN* should not be used for such patients, in whom the prognosis is often favorable.

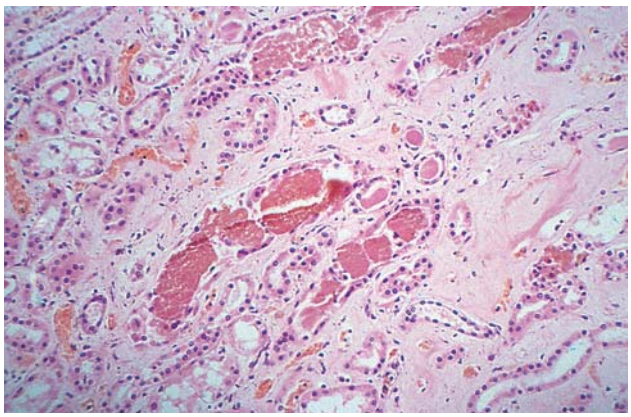

Figure 23-6 Acute kidney injury in IgA nephropathy. Tubular occlusion by red blood cells. This appearance may be associated with only minor glomerular changes. (Hematoxylin-eosin stain; ×300.)

Electron Microscopy

Electron-dense deposits correspond to the mesangial (or capillary loop) IgA (Fig. 23-5, *E*). Typically, electron-dense deposits are confined to mesangial and paramesangial areas, although subepithelial and subendothelial deposits can also be seen. Up to one third of patients will have some focal thinning of the glomerular basement membrane (GBM). On occasion, there will be extensive GBM thinning, suggesting a coincident diagnosis of thin membrane nephropathy (see Chapter 48).

DIFFERENTIAL DIAGNOSIS

The diagnosis of IgAN or HSP nephritis requires identification of mesangial IgA in the glomeruli. Therefore, it cannot be made without a renal biopsy, no matter how suggestive the clinical presentation. Serum IgA is often increased, and there may be IgA in cutaneous

Differential Diagnosis of IgA Nephropathy: Conditions Associated with Mesangial IgA Deposition

- IgA nephropathy
- Henoch-Schönlein nephritis
- Lupus nephritis*
- Alcoholic liver disease
- IgA monoclonal gammopathy
- Schistosomal nephropathy
- IgA-dominant postinfectious glomerulonephritis (usually induced by *Staphylococcus aureus*)

Box 23-1 Differential diagnosis of IgA nephropathy: conditions associated with mesangial IgA deposition. *Distinguishing lupus nephritis (especially International Society of Nephrology/Renal Pathology Society classes II and III) may cause difficulty. The finding of C1q deposition is useful. It indicates classical pathway involvement found in lupus nephritis but not in IgAN.

blood vessels in IgAN and in both affected and unaffected skin in HSP. Neither finding, however, is reliable enough to support the diagnosis without a renal biopsy. Serum complement components are normal.

Mesangial IgA occurs in other conditions and can usually be differentiated by clinical, serologic, and histologic criteria (Box 23-1). None of the light microscopic features alone is diagnostic of IgAN.

An important differential diagnosis is IgA-dominant acute postinfectious glomerulonephritis (APIGN), in which IgA is the dominant immunoglobulin in glomerular deposits. It usually occurs in association with staphylococcal infections. Risk factors particularly include diabetes. Compared with IgAN, patients with IgA-dominant APIGN are more likely to be older and have AKI, documented staphylococcal infection, hypocomplementemia, diffuse glomerular endocapillary hypercellularity with prominent neutrophil infiltration on light microscopy, stronger immunofluorescence staining for C3 than IgA, and the presence of subepithelial humps on electron microscopy.[19]

Hematuria

Nonglomerular causes of hematuria, particularly stones and neoplasia, must be excluded by appropriate investigations (see Chapter 61). In its most characteristic clinical setting—recurrent macroscopic hematuria coinciding with mucosal infection in a man in the second or third decade of life—the diagnosis can be strongly suspected. Such a diagnosis, however, cannot be made without a biopsy because recurrent macroscopic hematuria also occurs in other glomerular diseases, particularly in children and young adults. In young adults, thin basement membrane nephropathy is the most important differential diagnosis for isolated microhematuria.

Nephrotic Syndrome

Patients with IgAN occasionally develop nephrotic syndrome, which is indistinguishable from that in minimal change disease (MCD). There is a sudden onset of nephrosis, with biopsy evidence of glomerular epithelial cell foot process effacement and a prompt complete remission of proteinuria in response to corticosteroids. Only hematuria and mesangial IgA deposits persist after treatment. This pattern occurs particularly in children. These patients are usually regarded as having two separate common glomerular diseases, IgAN and MCD.[20]

Other patients with IgAN may develop nephrotic syndrome with more structural glomerular damage and lack the response to corticosteroids. The clinical differential diagnosis includes common causes of nephrotic syndrome appropriate for the age of the patient (see Chapter 15).

Chronic Kidney Disease: Hypertension, Proteinuria, Renal Impairment

In this context, IgAN will be clinically indistinguishable from many forms of chronic kidney disease (CKD). The renal biopsy may be diagnostic by identifying mesangial IgA, even when structural damage is so advanced on light microscopy that it has the nonspecific features of ESRD.

Acute Kidney Injury

When AKI occurs in a patient known to have IgAN, renal biopsy should be performed unless there is rapid improvement in renal function, after at least 5 days from the onset of kidney function worsening, in response to supportive care and vigorous hydration.[21] Renal biopsy may be required to differentiate the tubular occlusion and acute tubular necrosis that occasionally follow heavy glomerular hematuria from crescentic IgAN or other coincidental causes of AKI (see Fig. 23-6).

Differential Diagnosis of Henoch-Schönlein Purpura

In children, the diagnosis of HSP is usually made on the basis of clinical criteria. Confirmatory evidence of tissue IgA deposition will not be obtained unless persistence of renal disease results in a renal biopsy. In adults, the differential diagnosis is much wider and includes other forms of systemic vasculitis, requiring diagnosis by clinical, serologic, and histologic characteristics (see Chapter 25).

NATURAL HISTORY

IgA Nephropathy

The overall prognosis of IgAN has been reevaluated in recent long-term natural history studies.[22,23] By age 20 years, one fourth of patients will have ESRD, and a further 20% will have progressive impairment of renal function.

Although an active approach to the investigation of microhematuria will increase the size of the cohort of patients found to have IgAN, it will include more with a good prognosis, thus altering the perceived risk of disease progression. Episodes of macrohematuria do not confer a worse prognosis. This may indicate that such episodes occur only early in the natural history of the disease, and that patients doing less well from the point of diagnosis in fact were identified at a later stage in their disease. This is also suggested by the adverse influence on outcome of advancing age at diagnosis.

The risk of ESRD is not uniform. As in any chronic glomerular disease, the presence of hypertension, proteinuria, and reduced glomerular filtration rate (GFR) at presentation, as well as histologic evidence of glomerular and interstitial fibrosis, identifies at the time of diagnosis those with a poor prognosis (Table 23-2). Hyperuricemia, smoking, and increased body mass index are also independent risk factors for progression. However, during follow-up, only hypertension and proteinuria are reliable predictors of risk of progression. Canadian and French studies indicate that risk of progression is

Prognostic Markers at Presentation in IgA Nephropathy	
Clinical	**Histopathologic**
Poor Prognosis	
Hypertension Renal impairment Severity of proteinuria Smoking Hyperuricemia Gross obesity Long duration of preceding symptoms Increasing age	Mesangial hypercellularity Endocapillary proliferation Segmental glomerulosclerosis Tubular atrophy Interstitial fibrosis Capillary loop IgA deposits Crescents (controversial)
Good Prognosis	
Recurrent macroscopic hematuria	
No Impact on Prognosis	
Gender Serum IgA level	Intensity of IgA deposits

Table 23-2 Prognostic markers at presentation in IgA nephropathy. None of the clinical or histopathologic adverse features, except capillary loop IgA deposits, is specific to IgA nephropathy.

negligible when proteinuria remains below 0.2 g/24 h with normal blood pressure.[22,23]

If a renal biopsy documents IgAN in patients with mild disease (i.e., those manifesting with isolated microhematuria, little or no proteinuria, normotension, and normal GFR), the 7- to 10-year prognosis is mostly good.[24,25] However, up to 40% of the patients will develop increasing proteinuria, and up to 5% will lose GFR over this period, implying the need for regular follow-up in such patients. Large studies with long-term follow-up indicate a slow attrition.

Pathologic findings and clinical findings together inform prognosis. The Oxford classification of IgAN has shown that mesangial hypercellularity, endocapillary proliferation, and segmental sclerosis, as well as tubular atrophy and interstitial fibrosis, each add prognostic information even when clinical features (proteinuria, hypertension, GFR) are known at presentation and during follow-up.[18]

Henoch-Schönlein Nephritis

The natural history for HSP is less well defined than for IgAN. Observations are restricted to patients referred for renal biopsy, which excludes the majority of patients with minor transient renal involvement who have an excellent prognosis. The renal prognosis is worse in adults than in children with HSP. In adults, up to 40% will have CKD or ESRD 15 years after biopsy. One series reports an increased mortality from lung and gastrointestinal malignant disease.[16]

TRANSPLANTATION

Recurrent IgA Nephropathy

Transplant registry data show that transplant outcome is not affected for the first 10 years if IgAN is the patient's primary renal disease; thereafter, however, recurrent disease may lead to accelerated graft loss (see also Chapter 108). Mesangial IgA deposits recur in the donor transplant kidney in up to 60% of patients with IgAN.[26] They may occur within days or weeks, but the risk increases with the duration of the transplant. The deposits seem benign in the short term and are not often associated initially with light microscopy changes. In pooled series, recurrent IgAN is 30% in living related transplants versus 23% in cadaveric grafts,[26] but this does not affect graft survival, and living related donation should not be discouraged. However, any urinary abnormality in a potential related donor requires thorough evaluation, including, if necessary, a renal biopsy. Recurrence of crescentic IgAN with rapid graft failure occurs infrequently and is generally resistant to treatment.

In a few unwitting experiments, cadaver kidneys with IgA deposits have been transplanted into recipients without IgAN. In all cases, the IgA rapidly disappeared, supporting the concept that abnormalities in IgAN lie in the IgA immune system and not in the kidney.

Recurrent Henoch-Schönlein Nephritis

Henoch-Schönlein purpura can recur as isolated IgA deposits in the graft (~50% of transplants), as full-blown yet isolated IgAN, or rarely as a full recurrence of systemic involvement including a rash. The characteristics of renal recurrence are apparently similar to those of recurrent primary IgAN.[26] Delay of transplantation once ESRD is reached does not reduce the risk of HSP recurrence.

TREATMENT OVERVIEW

Although specific early treatment intervention might influence the IgA immune system abnormalities that underlie IgAN, the mechanisms of chronic disease progression are unlikely to be unique. Therefore, studies of such IgAN patients likely will provide information applicable to many forms of chronic GN for which IgAN is the paradigm.

The balance of risk against benefit for immunosuppressive therapy is often unfavorable in patients with IgAN, except in the unusual circumstance of crescentic IgAN.

The need for randomized controlled trials (RCTs) of adequate power to answer questions about the prevention of ESRD in IgAN is pressing. It is disappointing, despite the prevalence of IgAN and consensus about its definition and natural history, that there are so few such studies.[27] Patients with HSP have been excluded from almost all treatment studies, so it is uncertain whether any strategies developed for IgAN are applicable to HS nephritis.

TREATMENT OF IgA NEPHROPATHY

Figure 23-7 provides a treatment algorithm for IgAN that is based on the current Kidney Disease: Improving Global Outcomes (KDIGO) guidelines.[21] The approach distinguishes among the following[27]:

- The "good prognosis" patient, with minor urinary abnormalities, normal GFR, and normotension, who only needs sporadic follow-up for a prolonged period (>10 years)
- The "intermediate prognosis" patient, with significant proteinuria, hypertension, and slow reduction of GFR, who particularly benefits from comprehensive supportive care
- The "poor prognosis" patient, with a rapid loss of GFR, who may require more aggressive immunosuppression

Slowly Progressive IgA Nephropathy ("Intermediate Prognosis")

Minimal evidence exists to suggest the events of progressive glomerular injury are unique to IgAN. Comprehensive supportive therapy following the strategies outlined in Chapter 80 therefore

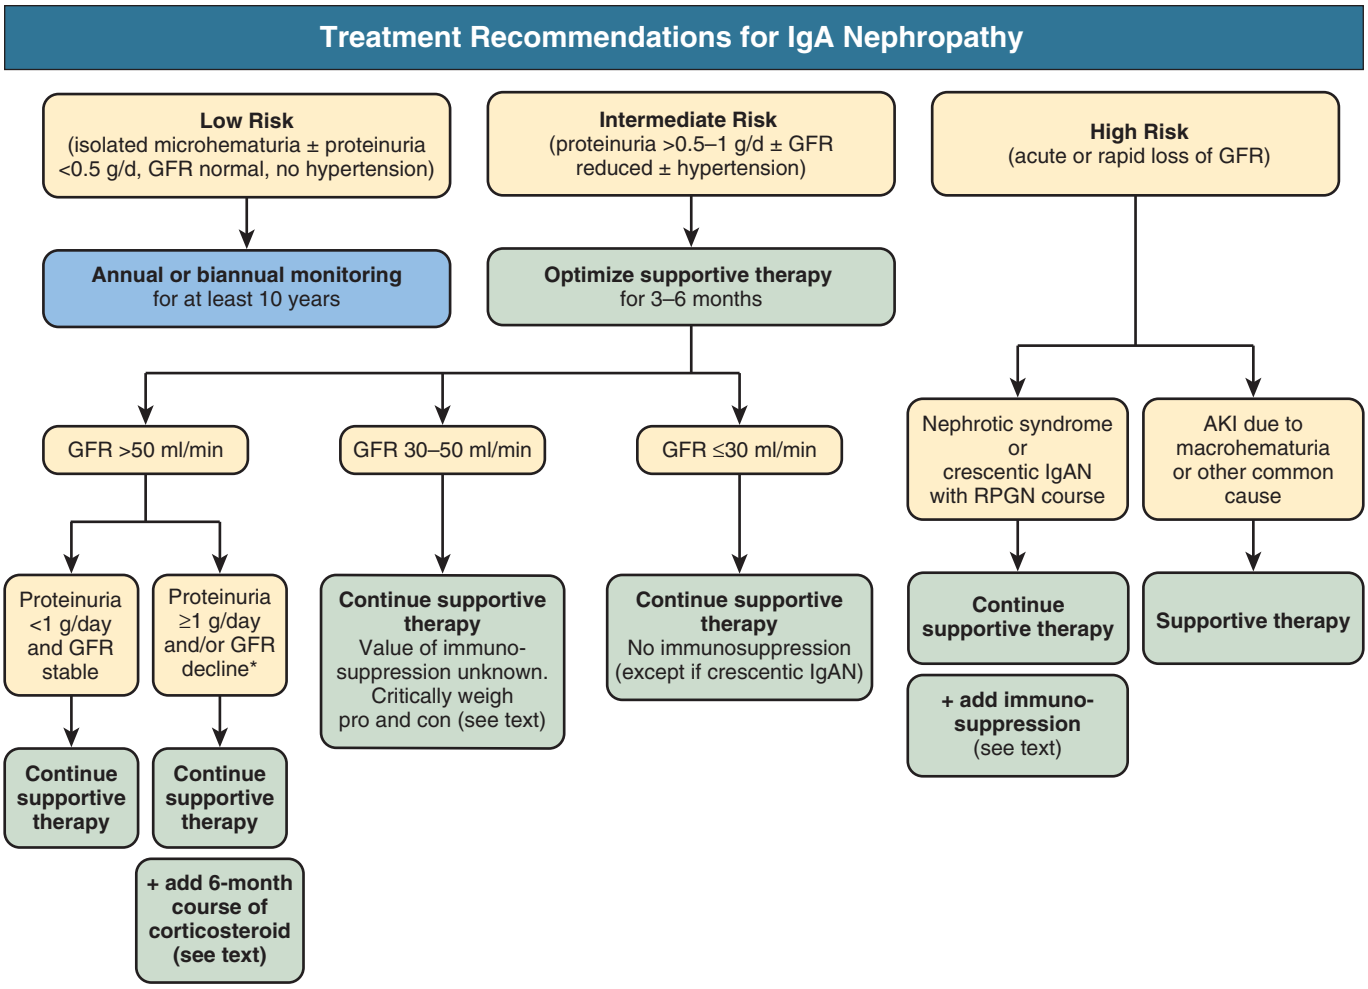

Figure 23-7 Treatment recommendations for IgA nephropathy. *AKI,* Acute kidney injury; *GFR,* glomerular filtration rate; *RPGN,* rapidly progressive glomerulonephritis. *(Modified from reference 27.)*

remains central in the therapeutic approach to patients at risk for progressive IgAN (Fig. 23-7).

Antihypertensives and Proteinuria-Lowering Drugs

There is compelling evidence for the benefit of lowering blood pressure (BP) in the treatment of chronic progressive glomerular disease such as IgAN. In patients with IgAN, there is also evidence that casual clinic BP readings underestimate BP load, as judged by ambulatory BP monitoring and echocardiographic evidence of increased left ventricular mass.[28] Two prospective, controlled trials strongly support the use of angiotensin-converting enzyme (ACE) inhibitors in IgAN patients as first-choice hypotensive agents to lower BP.[29,30] In a randomized study of IgAN, achieving a mean BP of 129/70 mm Hg prevented the decrease in renal function over 3 years seen in patients achieving mean BP of 136/76 mm Hg.[31]

Observational studies indicate that the risk of progression in IgAN decreases significantly if proteinuria can be reduced to less than 1 g/day by any therapeutic maneuver.[23] Another compelling indication for the role of lowering proteinuria in IgAN is based on the superior effectiveness of ACE inhibitors over other antihypertensive agents.[29,30]

Fish Oil

The favorable effects of supplementing the diet with omega-3 fatty acids in the form of fish oil include reductions in eicosanoid and cytokine production, changes in membrane fluidity and rheology, and reduced platelet aggregability. These features should significantly reduce the adverse influence of many mechanisms thought to affect progression of chronic glomerular disease.

The evidence for a beneficial action of fish oil in IgAN is weak; its suggested use in patients at risk in the 2012 KDIGO guidelines is only supported by low-level evidence.[21] However, fish oil treatment does not have the drawbacks associated with immunosuppressive treatment. Fish oil is safe except for a decrease in blood coagulability, which is not usually a practical problem, and an unpleasant taste, with flatulence, which may make compliance difficult. Some fish oil preparations contain significant amounts of cholesterol, necessitating close surveillance if such treatment is initiated. A further confirmatory study of fish oil would be of great value.

Immunosuppressive or Anti-Inflammatory Regimens

Corticosteroids Corticosteroids were given in a short-term RCT in nephrotic adults.[32] Although the trial overall showed no benefit, a small group with minor histologic changes responded rapidly to treatment. Nephrotic syndrome may occur in this setting when MCD and IgAN coincide, in which case the nephrotic syndrome will be fully and promptly corticosteroid responsive. A trial of high-dose corticosteroid therapy is therefore justified in IgAN patients who have nephrotic syndrome associated with minimal glomerular injury.

Five prospective clinical trials have used corticosteroids in nonnephrotic IgAN. Two failed to show any benefit, whereas three found reduced progression of IgAN.[27] Corticosteroid dosage was somewhat lower in the negative versus the positive trials, and several trials did not optimize supportive therapy, in particular ACE inhibitors, or required that such drugs be temporarily halted before the trial. In clinical practice and consistent with the KDIGO guidelines, corticosteroids should only be initiated in high-risk patients if proteinuria remains above 1 g/day after supportive care has been optimized for 3 to 6 months, and only if GFR remains above 50 ml/min. At present, no evidence supports a more intense or complex regimen of intravenous as well as oral corticosteroid therapy over a purely oral prednisolone regimen, starting with 1 mg/kg/day for 2 months, then reduced by 0.2 mg/kg/day/month.[27] At least two large prospective trials of oral corticosterods in IgAN added to optimized supportive care (STOP-IgAN and TESTING) are underway.

Cyclophosphamide and Azathioprine Cyclophosphamide has been used in combination with warfarin and dipyridamole in two RCTs, with inconsistent results. Both showed modest reduction in proteinuria, but only one preserved renal function. Cyclophosphamide followed by azathioprine combined with prednisolone preserved renal function in patients with a poor prognosis, although BP control was suboptimal.[33] Many physicians regard the toxicity of cyclophosphamide as unacceptable in young adults with IgAN.[27] In another recent study, adding azathioprine to corticosteroids in proteinuric IgAN patients with a GFR greater than 50 ml/min had no added benefit and only increased side effects.[34] Neither agent is therefore recommended in "intermediate risk" IgAN patients by the 2012 KDIGO guidelines.[21]

Mycophenolate Mofetil Mycophenolate mofetil (MMF) has been used in several controlled trials in high-risk patients. Two trials in Caucasian patients failed to demonstrate a benefit, whereas a study in Chinese patients noted reduced proteinuria and preservation of GFR.[27] Whether racial effects underlie these discrepant results remains to be clarified. In another Chinese trial, four of 32 IgAN patients receiving MMF plus corticosteroids died of *Pneumocystis* pneumonia.[35] MMF is therefore not recommended in "intermediate risk" IgAN patients by the 2012 KDIGO guidelines.[21]

Dipyridamole and Warfarin Two RCTS with dipyridamole and warfarin showed mutually inconsistent results. There was no benefit in one and preserved renal function in the other. Neither drug is currently recommended in IgAN patients.[21]

Cyclosporine Cyclosporine has been used in one controlled trial in IgAN.[35a] Patients showed a reversible decrease in proteinuria along with a decrease in creatinine clearance, suggesting the changes were a hemodynamic effect of cyclosporine rather than an immunomodulating effect.

Pooled Human Immunoglobulin Pooled human immunoglobulin has given encouraging preliminary results in patients with IgAN who have an aggressive clinical course. Proteinuria was reduced, deterioration of GFR slowed, and histologic activity lessened on repeated renal biopsies.[36] No RCT is available for this approach.

Rapidly Progressive IgA Nephropathy ("Poor Prognosis")

In this uncommon situation of rapidly progressive renal failure associated with crescentic IgAN, the risk-benefit ratio most strongly favors intensive immunosuppressive therapy, because untreated the patient will rapidly progress to ESRD. Treatment has often combined plasma exchange with prednisolone and cyclophosphamide.[37] Early clinical response is favorable, as in other crescentic nephritis. Medium-term results, however, are disappointing; in one half of the reported cases, patients have reached ESRD within 12 months. A subset of patients with circulating IgG-ANCA (antineutrophil cytoplasmic antibody) may have a more favorable response to immunosuppressive therapy similar to that seen in other ANCA-positive crescentic nephritis.[38] With no RCTs of treatment, it is not possible to be certain which elements of the regimen (corticosteroids, cyclophosphamide, or plasma exchange) are mandatory.

Other Therapeutic Approaches to Progressive IgA Nephropathy

Reduction of IgA Production

Tonsillectomy reduces the frequency of episodic hematuria when tonsillitis is the provoking infection. A long-term retrospective study from Japan suggests that tonsillectomy may reduce the risk of renal failure, but this is not supported by studies from Germany, Italy, or China. The lack of controlled trials is particularly important because the natural history is that macrohematuria becomes frequent with time, independent of a specific treatment. Tonsillectomy may be indicated in the occasional patient with recurrent AKI with macroscopic hematuria induced by tonsillitis, but is not routinely recommended[21]; there is no role for prophylactic antibiotics. Dietary gluten restriction, used to reduce mucosal antigen challenge, has not been shown to preserve renal function. A trial evaluating the role of an enteric corticosteroid preparation in "intermediate prognosis" IgAN patients (NEFIGAN) is underway.

Prevention and Removal of IgA Deposits

The ideal treatment of IgAN patients would remove IgA from the glomerulus and prevent further IgA deposition. This remains a remote prospect while the pathogenesis remains incompletely understood.

Transplant Recurrence

There is no evidence that newer immunosuppressive agents have modified the frequency of recurrent IgA deposits or are of value in recurrent disease. There is, however, registry evidence that transplant outcome is improved if corticosteroids are continued long term.[38a] Most clinicians therefore merely optimize supportive care in such patients. When crescentic IgAN recurs with rapidly deteriorating graft function, treatment as for primary crescentic IgAN has been used, although evidence of its success is sparse.

TREATMENT OF HENOCH-SCHÖNLEIN NEPHRITIS

Many patients have transient nephritis during the early phase of HSP, which spontaneously remits and requires no treatment. There are no prospective RCTs to guide the treatment of HS nephritis. Most therapeutic studies of IgAN exclude those with HSP, so it is uncertain whether a number of potential treatments have a role in HS nephritis[21] (Box 23-2).

Rapidly Progressive Chronic Kidney Disease Caused by Crescentic Nephritis

Crescentic nephritis is more common in HS nephritis than in IgAN, particularly early in the course of HSP. There is little specific information on treatment in adults or children, but regimens based on those for other forms of systemic vasculitis are widely used. These have included corticosteroids and cyclophosphamide, with the

addition of plasma exchange or pulse methylprednisolone in some cases. However, a recent randomized French study in adults with severe HS nephritis failed to detect a benefit of cyclophosphamide plus steroids over steroids alone.[39]

Active Henoch-Schönlein Nephritis Without Renal Failure

There is little information about less aggressive HS nephritis. Corticosteroids alone have never been shown to be beneficial. There is no evidence that early use of corticosteroids in HSP may prevent nephritis.[21] Promising findings with combination therapy of corticosteroids, cyclophosphamide, and antiplatelet agents have been reported in only small, nonrandomized studies.[21] A nonrandomized study reported that prednisolone and azathioprine preserved renal function and improved histologic appearances, but relied on historical controls.[40]

Slowly Progressive Chronic Kidney Disease

Whereas the renal histology and clinical course of slowly progressive HS nephritis and IgAN may be indistinguishable, patients with HS nephritis have not been included in studies of fish oil. Tight BP control with ACE inhibitors or angiotensin receptor blockers (ARBs) is recommended for proteinuric HS nephritis as for IgAN. The 2012 KDIGO guidelines recommend a similar indication for corticosteroids in slowly progressive HS nephritis as in intermediate-risk IgAN patients.[21]

Transplant Recurrence

No treatment is known to reduce the risk of recurrence. There is some evidence that recurrence is more common and more likely to lead to graft loss in children receiving kidneys from living rather than deceased donors, although this is not confirmed in adults.[41,42] If crescentic HS nephritis recurs, intensive immunosuppression may be justified as for primary disease. This, however, has not been thoroughly evaluated.

CHAPTER 24

Anti–Glomerular Basement Membrane Disease and Goodpasture Disease

Richard G. Phelps and A. Neil Turner

The syndrome of renal failure and lung hemorrhage was associated with the name of Ernest Goodpasture by Stanton and Tange in their description of nine cases in 1958.[1,2] All nine patients presented with lung hemorrhage and acute renal failure and died within hours or days. These features had been prominent in the case of a young man who died during the influenza pandemic of 1919, whose postmortem findings were memorably reported by Goodpasture[1]: "The lungs gave the impression of having been injected with blood through the bronchi so that all the air spaces were filled" (Fig. 24-1).

Several diseases are now recognized as being associated with alveolar hemorrhage and rapidly progressive glomerulonephritis (RPGN). Nevertheless, this remains a striking clinical entity with relatively few causes and few pathogenetic mechanisms.

Because the first recognized mechanism was anti–glomerular basement membrane (anti-GBM) antibody formation and deposition, Goodpasture's name is firmly associated with anti-GBM disease (Goodpasture disease), even though this is responsible for only a proportion of patients with Goodpasture syndrome of lung hemorrhage and RPGN. The terminology used in this chapter is defined in Table 24-1.

ETIOLOGY AND PATHOGENESIS

Autoimmunity to a Component of Glomerular Basement Membrane

Goodpasture disease is caused by autoimmunity to the carboxyl terminal, noncollagenous (NC1) domain of a type IV collagen chain, α3(IV)NC1, also known as the Goodpasture antigen[3,4] (Fig. 24-2). Type IV collagen is an essential constituent of all basement membranes. In most tissues, it is composed of trimers comprising two α1 chains and one α2 chain, but there are also four tissue-specific chains, α3 through α6.[5,6] Three of these, α3 through α5, are found in GBM as well as in the basement membranes of the alveolus, the cochlea, parts of the eye (including corneal basement membrane and Bruch membrane), the choroid plexus of the brain, and some endocrine organs.

All patients with RPGN, lung hemorrhage, and anti-GBM antibodies have antibodies to α3(IV)NC1, usually binding predominantly to a single or a very restricted set of epitopes. Some patients also have antibodies to other basement membrane constituents, including other collagen IV chains, usually in low titer.

Predisposing Factors

Both environmental and genetic factors appear to be important in etiology. There are strong associations between Goodpasture disease and HLA class II alleles, including DRB1*1501 and DR4 alleles, whereas DR1 and DR7 confer strong and dominant protection.[7] Of likely increasing importance, it is now clear that treatment of multiple sclerosis (MS) with alemtuzumab, a monoclonal antibody targeting CD52 on B and T cells, is associated with the development of new autoimmunity, including anti-GBM disease, sometimes as late as 4 years after treatment. Only a handful of cases have been reported during development of the drug for MS, but with wider use, this could become a numerically very significant predisposing factor. It remains to be established whether carriage of DRB1*1501, which is overrepresented in MS, influences the risk of developing anti-GBM disease after alemtuzumab therapy.

Precipitating Factors

The onset of acute disease has long been linked to various precipitating factors. Theories of pathogenesis include factors that alter antigen processing to generate peptides that are usually destroyed or hidden, and to which tolerance is therefore deficient[8,9] and molecular mimicry.[10] None of these is proved. Reports of temporal and geographic clustering of cases suggest an environmental trigger,[11] but no specific infectious agent has been consistently identified. Hydrocarbon exposure has been linked to disease onset in several striking case reports; but in some cases, such exposure may simply trigger lung hemorrhage in patients who already have the disease. Furthermore, exposures of this kind are very common in the modern world. Similarly, cigarette smoking may precipitate lung hemorrhage in patients who already have circulating autoantibodies, but there is no evidence for a role in causation.

In several cases, renal trauma or inflammation has preceded the development of the disease (Box 24-1). These may alter α3(IV)NC1 turnover and metabolism qualitatively or quantitatively, providing an opportunity for self-tolerance to be broken. Qualitative changes in the basement membrane epitopes presented to T cells could be a result of overloading of the usual or recruitment of alternative processing pathways, such as extracellular processing by proteases released into inflamed glomeruli. The quantity of α3(IV)NC1 presented to T cells may be greater where there has been damage to the basement membrane, as occurs in systemic small-vessel vasculitis (see Chapter 25). Some features suggest that an anti-GBM response may be a secondary phenomenon in some patients with vasculitis.[12,13] The association with membranous nephropathy is interesting because the thickened GBM in that disease contains increased amounts of the tissue-specific type IV collagen chains, including the Goodpasture antigen. The same could apply to a recently suggested possible association with longstanding type 1 diabetes mellitus.[14]

Mechanisms of Renal Injury

The α3(IV)NC1 autoantibodies are central in the pathogenesis of Goodpasture disease[15,16] (Fig. 24-3). Antibodies eluted from the kidneys of patients who had died of Goodpasture disease rapidly bind to the GBM and cause glomerulonephritis (GN) when they are

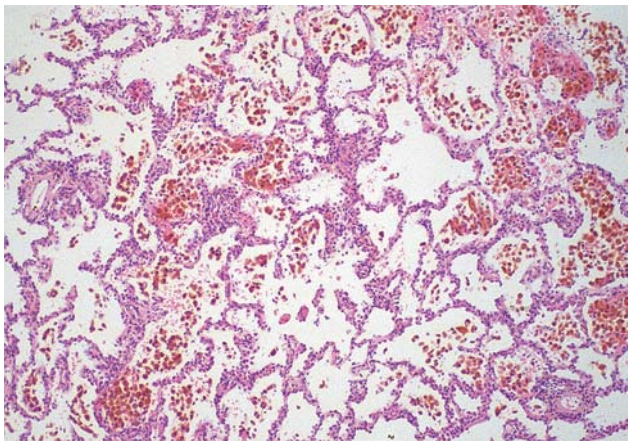

Figure 24-1 Alveolar hemorrhage. Open lung biopsy in a patient with Goodpasture disease shows alveolar hemorrhage. *(Courtesy Dr. E. Mary Thompson, St Mary's Hospital, London.)*

Predisposing Events Associated with Presentation of Goodpasture Disease

Possibly Induce Autoimmune Response and Disease

Systemic small-vessel vasculitis affecting glomeruli
Membranous nephropathy (MN)
Lithotripsy of renal stones
Urinary obstruction
Alemtuzumab therapy for multiple sclerosis

Precipitate Pulmonary Hemorrhage

Cigarette smoke
Hydrocarbon exposure
Pulmonary infection
Fluid overload

Box 24-1 Predisposing events associated with the presentation of Goodpasture disease.

Type IV Collagen Structure

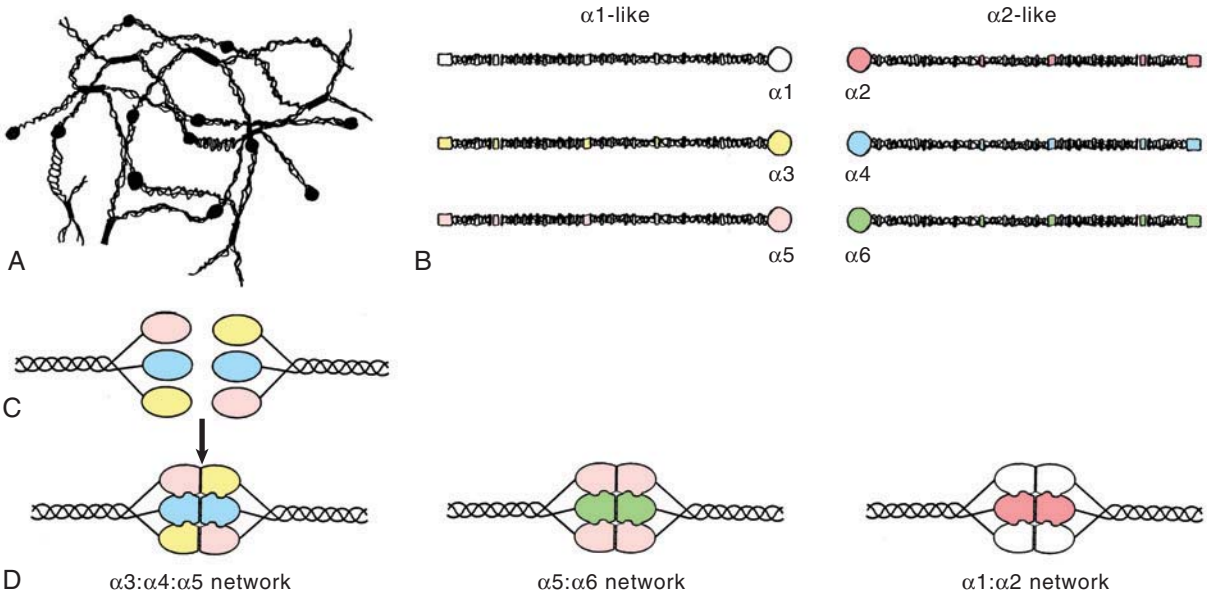

Figure 24-2 Type IV collagen structure. A, The type IV collagen network makes a "chicken wire" structure in the GBM. **B,** Six paired type IV collagen genes, *COL4A1* to *COL4A6,* encode type IV collagen monomers α1 to α6. These associate in two or three defined monomer types per protomer (carboxyl terminal domains of α3:α4:α5 shown in **C,** to form three recognized networks shown in **D,** α1:α2 is present in almost all basement membranes; α3:α4:α5 is the major constituent of GBM and is a significant component of alveolar basement membrane and other locations; and α5:α6 is found in Bowman capsule, skin, esophagus, and other locations.

Anti–Glomerular Basement Membrane (GBM) Terminology

Term	Definition	Pathogenesis
Pulmonary renal syndrome	Renal and respiratory failure	Many causes (see Fig. 24-7)
Goodpasture syndrome	RPGN and alveolar hemorrhage	Several causes (see Box 24-2)
Anti-GBM disease	Disease associated with antibodies specific for (any) components of GBM	Most important are Goodpasture disease and Alport syndrome post-transplant anti-GBM disease
Goodpasture disease	Disease associated with autoantibodies specific for α3(IV)NC1 May include RPGN, lung hemorrhage, or both	Autoimmunity to α3(IV)NC1
Alport syndrome post-transplant anti-GBM disease	Glomerulonephritis associated with anti-GBM antibodies developing after renal transplantation in Alport syndrome patients	Immunity to foreign collagen IV chains not expressed in Alport syndrome patients usually α3 or α5 (IV)NC1

Table 24-1 Definition of terms associated with anti-GBM disease and Goodpasture syndrome. *RPGN,* Rapidly progressive glomerulonephritis.

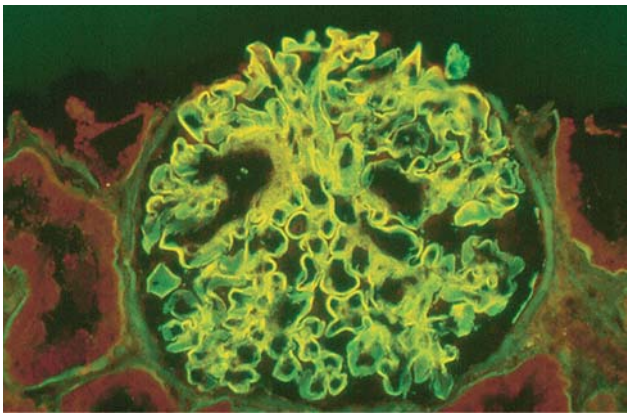

Figure 24-3 Autoantibodies to Goodpasture antigen bound to a normal glomerulus. Direct immunofluorescence of normal kidney with sera from a patient with Goodpasture disease shows the antigen in a patient with lung hemorrhage and hematuria. *(Courtesy Dr. Richard Herriot, Aberdeen Royal Infirmary, UK.)*

injected into monkeys.[17] Furthermore, the deposited antibodies are predominantly IgG1 and are complement fixing. Contributions to renal injury mediated by such antibodies come from complement and from neutrophil and macrophage infiltration. T cells are essential for driving autoantibody production by T cell–dependent B cells, and in experimental renal disease, they are critical in producing glomerular crescents,[15,18] which are a usual feature of Goodpasture disease. Moreover, in mice engineered to express the human susceptibility HLA allele, DRB1*1501, α3(IV)NC1-specific CD4 T cells are sufficient to transfer disease between animals.[19]

Agents that downregulate inflammation by inhibiting interleukin-1 or tumor necrosis factor, or that inhibit recruitment of inflammatory cells by blockade of adhesion molecules or chemoattractants, suppress injury in experimental models of anti-GBM disease. Evidence in humans and in experimental animals supports the severity of renal injury being increased by proinflammatory cytokines or by stimuli likely to elicit them, such as bacteremia.[18] Crescent formation is seen in aggressive inflammatory GN, as described in Chapter 16 (see Fig. 16-8).

Lung Hemorrhage

Lung hemorrhage in Goodpasture disease (but not in small-vessel vasculitis, the other major cause of Goodpasture syndrome) occurs only if there is an additional insult to the lung, which is usually cigarette smoke. However, infection, fluid overload, toxicity from inhaled vapors or other irritants, and the systemic effects of some cytokines are also possibilities. This is probably because the alveolar capillary endothelial cell provides a better barrier between circulating immunoglobulin and the underlying basement membrane than the diaphragm-free fenestrations of the glomerular capillary endothelial cell. In the glomerulus, antibodies have direct access to the GBM because of the fenestrations of glomerular endothelium. Other sites at which the Goodpasture antigen is found are not involved in Goodpasture disease, except possibly the choroid plexus, where the endothelium is again fenestrated, and more rarely the eye.

EPIDEMIOLOGY

Goodpasture disease is rare, with a possibly increasing incidence in Caucasian populations approaching 1 case per 1 million population per year.[14] The incidence in black and South Asian populations appears to be lower. The incidence in other racial groups is uncertain. There is a slight male predominance. Lung hemorrhage is more common in younger patients.

CLINICAL MANIFESTATIONS

Between 50% and 75% of patients present with acute symptoms of lung hemorrhage and are found to be in a state of advanced renal failure. Symptoms are usually confined to the preceding few weeks or months, but rapid progression (during days) or much slower progression (during many months) may occur. A lack of systemic symptoms, other than those related to anemia, is typical, although an apparently minor infection often triggers the clinical presentation.

Lung Hemorrhage

Lung hemorrhage may occur with renal disease or in isolation. Presenting symptoms may include cough and hemoptysis, but hemorrhage into alveolar spaces may result in marked iron deficiency anemia and exertional dyspnea, even in the absence of hemoptysis. Depending on the degree and chronicity of lung hemorrhage, examination findings may include pallor, dry inspiratory crackles, signs of consolidation, or respiratory distress. Recent lung hemorrhage typically is shown on the radiograph as central shadowing that may traverse fissures and give rise to the appearance of an air bronchogram (Fig. 24-4). However, even lung hemorrhage sufficient to reduce the hemoglobin concentration may cause only minor or transient radiographic changes, and these cannot be confidently distinguished radiologically from other causes of alveolar shadowing, notably edema or infection. The most sensitive indicator of recent lung hemorrhage is an increased uptake of inhaled carbon monoxide (DLCO). Patients with lung hemorrhage are usually current cigarette smokers.

In isolated lung disease, progressive alveolar or fibrotic disease or pulmonary hemosiderosis may be suspected, although at least hematuria is usually present. This may continue for months or in rare cases recurrently for years before significant renal disease occurs.

Glomerulonephritis

Patients with GN may notice dark or red urine, but progression to oliguria is sometimes so rapid that this phase, if it occurs, is missed. In one third to half of patients, GN occurs in the absence of lung hemorrhage. In this subgroup, because systemic symptoms are generally not prominent, presentation is often late with renal failure.

Whatever the early pattern of disease, once significant renal impairment has occurred, further deterioration in renal function is usually rapid. Presentation at or shortly after acceleration of the disease process is common, and patients may demonstrate very rapid loss of renal function and life-threatening lung hemorrhage. Urinalysis always reveals hematuria (even in apparently isolated pulmonary disease), usually modest proteinuria, and dysmorphic red blood cells and RBC casts on microscopy. The kidneys are generally of normal size but may be enlarged. Hematuria may be substantial or associated with loin pain in acute disease.

PATHOLOGY

Renal biopsy is essential as it provides diagnostic and prognostic information. Typical appearances are of diffuse proliferative GN with

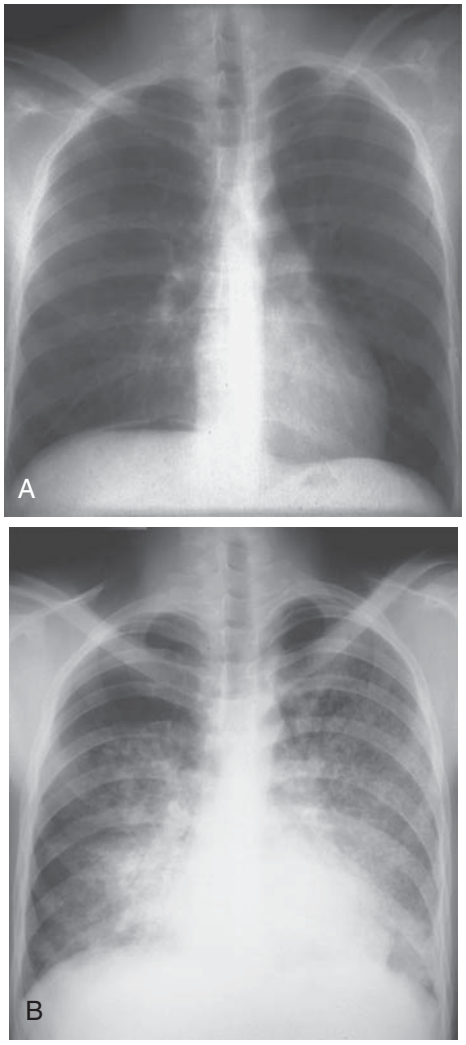

Figure 24-4 Lung hemorrhage. A, Patient with early pulmonary hemorrhage. The chest radiograph still appears normal. **B,** Radiograph taken 4 days later shows the evolution of alveolar shadowing caused by lung hemorrhage.

variable degrees of necrosis, crescent formation, glomerulosclerosis, and tubular loss (Fig. 24-5). The degree of crescent formation and tubular loss correlates with renal prognosis. Characteristically, the crescents all appear to be of similar age and cellularity. When biopsy is performed earlier in the disease, changes may be limited to focal and segmental mesangial expansion, with or without necrosis. This progresses to hypercellularity and then to more general changes, including fractures of the GBM and Bowman capsule, neutrophils in the glomeruli, and glomerular capillary thrombosis.[20]

Immunohistology

In the presence of severe glomerular inflammation, linear deposition of immunoglobulin along the GBM is pathognomonic. The immunoglobulin is usually IgG, sometimes (10% to 15%) with IgA or IgM, but rarely, IgA alone is detected. Linear deposition of C3 is detectable in about 75% of biopsies. Linear immunofluorescence with anti-immunoglobulin reagents is occasionally seen in other conditions, usually without glomerular inflammation (Box 24-2). In most cases, the deposited immunoglobulin is less abundant than in Goodpasture disease and is either nonspecifically deposited or bound to GBM components other than type IV collagen chains.

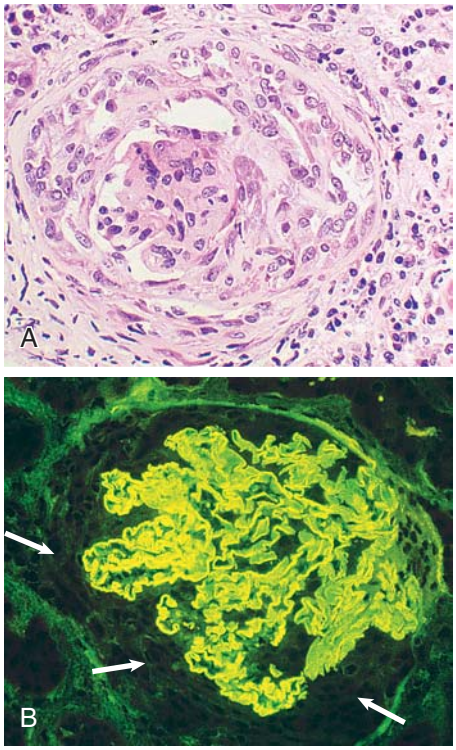

Figure 24-5 Renal biopsy in Goodpasture disease. A, Glomerulus from a patient with Goodpasture disease showing a recent, mostly cellular crescent. **B,** Direct immunofluorescence study showing ribbon-like linear deposition of IgG along the glomerular basement membrane. The glomerular tuft is slightly compressed by cellular proliferation (exhibiting no immunofluorescence), forming a crescent *(arrows). (Courtesy Dr. Richard Herriot, Aberdeen Royal Infirmary, UK.)*

Conditions Associated with Linear Binding of Immunoglobulin to GBM

Specific Binding to GBM
Goodpasture syndrome
Alport syndrome after renal transplantation

Nonspecific Binding to GBM
Diabetes
Cadaver kidneys
Light-chain disease
Fibrillary glomerulopathy
Systemic lupus erythematosus (possibly specific but not considered directly pathogenic)

Box 24-2 Conditions associated with linear binding of immunoglobulin to the glomerular basement membrane (GBM).

Circulating IgG anti-GBM antibodies are almost invariably present, even in the rare instances in which only IgM or IgA is demonstrated on the GBM. Antibodies may be detected and quantified by use of immobilized Goodpasture antigen in an immunoassay. The titer of anti-GBM antibody at presentation correlates with the severity of nephritis. Treatment and relapse are often mirrored by changes in titer.

Pathology in Other Tissues

Pathologic changes in lung tissue can be difficult to interpret because the changes, including immunoglobulin deposition, are often patchy

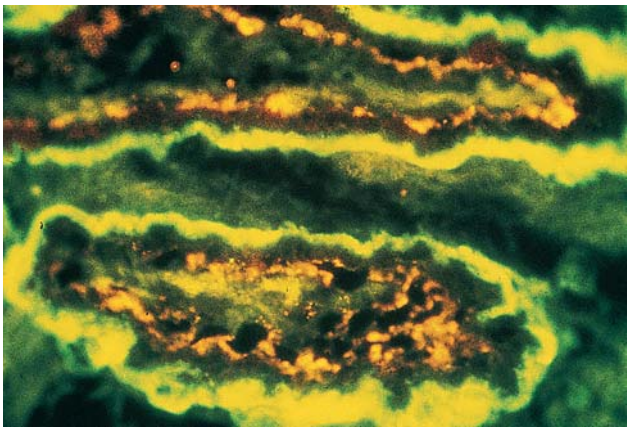

Figure 24-6 IgG binding to choroid plexus. Direct immunofluorescence study showing binding of IgG to the choroid plexus of a patient who died of Goodpasture disease. *(Courtesy Dr. Stephen Cashman, Imperial College, London.)*

and may be missed. Frequently, the only findings are mild, chronic inflammation and hemosiderin-laden macrophages, which are consistent with other more common pathologic diagnoses. This makes negative bronchoscopic or open lung biopsy findings unhelpful in excluding the diagnosis.

Other tissues in which α3(IV)NC1 is expressed are rarely available for pathologic analysis, but even if antibody is deposited in these other sites, it is rarely associated with clinical disease. A number of case reports describe neurologic syndromes, particularly convulsions, that may be related to antibody deposition in the choroid plexus, but may have other explanations in patients with acute kidney injury (Fig. 24-6). Other reports have described retinal detachment, in one case with antibody deposition, but again, this is rare. Placental tissue also contains the Goodpasture antigen and has been reported in a single case to act as a "sink" that binds anti-GBM antibody during pregnancy, resulting in exacerbation of glomerulonephritis following delivery.

DIFFERENTIAL DIAGNOSIS

Diagnosis of Goodpasture disease in patients who present with Goodpasture syndrome does not usually present difficulties once the possibility has been raised, although the urgency is often not appreciated. Direct immunofluorescence on renal tissue and assay for circulating anti-GBM antibodies are the most rapid techniques, and renal biopsy is always indicated. Diagnosis is often delayed when patients present with subacute disease affecting the lung or the kidney in isolation. Patients with subacute lung hemorrhage may never report hemoptysis and may present with diffuse lung disease, which has many causes. Testing for hematuria is important.

Detection of Anti–Glomerular Basement Membrane Antibodies

Direct immunohistology using antibodies that are specific for different Ig classes is very sensitive for detection of anti-GBM antibody production, because the GBM selectively adsorbs and concentrates low levels of circulating antibody. However, in some circumstances, GBM may also adsorb antibody nonspecifically (see Box 24-2). Detection of anti-GBM antibodies in serum requires solid-phase immunoassays based on preparations of human or animal GBM or recombinant antigen. The quality of these assays is variable. Confirmation of the specificity of anti-GBM antibodies may be obtained by Western blotting of serum onto solubilized human GBM or recombinant α3(IV)NC1, usually at a reference laboratory. Indirect immunohistology (putting patient serum onto normal kidney sections) is too insensitive for reliable diagnostic use.

False-positive results may be encountered in sera from patients with inflammatory diseases that often exhibit increased nonspecific binding. This places greater emphasis on the purity of antigen used for anti-GBM assays. False-negative results are usually encountered in patients with low titers of antibodies in association with isolated lung disease or with very early or subacute renal disease. Low titers may also be associated with anti-GBM disease that occurs after renal transplantation in patients with Alport syndrome (see later discussion).

In very advanced disease, linear antibody deposition may not be seen because of extensive destruction of GBM structure. Otherwise, deposited immunoglobulin remains detectable for some months after immunoassays have become negative.

Patients with Anti-GBM Antibodies and Other Diseases

Antineutrophil Cytoplasmic Antibody and Systemic Small-Vessel Vasculitis

Anti-GBM antibodies are sometimes detected in patients with antineutrophil cytoplasmic antibody (ANCA), especially ANCA with specificity for myeloperoxidase (see Chapter 25). Such "double-positive" patients may have a clinical course and response to treatment more typical of vasculitis than of Goodpasture disease and have possibly developed anti-GBM antibodies secondary to vasculitic glomerular damage.[8-11] Anti-GBM titers tend to be lower in ANCA-positive anti-GBM antibody–positive patients than in patients with anti-GBM antibodies alone. Recovery of renal function may be more likely if ANCAs are present, even if patients are dialysis dependent when treatment is started, although newer series have failed to detect the differences described in early reports.

Membranous Nephropathy

Anti-GBM antibodies are occasionally identified in patients with membranous nephropathy (MN), usually coincident with an accelerated decline in renal function and the formation of glomerular crescents.[5,14,21] About two thirds of studies report evidence of evolution from preexisting nephrotic syndrome, and about half report a previous kidney biopsy showed typical MN. Progression to end-stage renal disease (ESRD) has usually been rapid, but the diagnosis has rarely been made at an early enough stage to expect intensive treatment to be successful. Three patients with Goodpasture disease later developed typical MN.

Goodpasture Syndrome

A wide variety of conditions may cause simultaneous pulmonary and renal disease. The term *pulmonary-renal syndrome* implies failure of both organs, the most common cause being fluid overload in a patient with renal failure of any cause. This may resemble Goodpasture syndrome, particularly if there is hematuria and preexisting cardiac dysfunction. However, a number of diseases may mimic Goodpasture syndrome (lung hemorrhage with RPGN) to varying degrees by causing acute kidney injury with acute lung disease (Box 24-3). Diseases associated with the syndrome fall into two pathogenetic classes: those characterized by systemic vasculitis and those associated with anti-GBM antibodies (Goodpasture disease; Box 24-4).

Nonimmune Causes of Pulmonary-Renal Syndrome

With Pulmonary Edema
Acute kidney injury with hypervolemia
Severe cardiac failure

Infective
Severe bacterial pneumonia (e.g., *Legionella*) with renal failure
Hantavirus infection
Opportunistic infections in the immunocompromised patient

Other
Acute respiratory distress syndrome with renal failure in multiorgan failure
Paraquat poisoning
Renal vein/inferior vena cava thrombosis with pulmonary emboli

Box 24-3 Nonimmune causes of pulmonary-renal syndrome.

Causes of Lung Hemorrhage and Rapidly Progressive Glomerulonephritis

Diseases Associated with Antibodies to the GBM (20%-40% of cases)
Goodpasture disease (spontaneous anti-GBM disease)

Diseases Associated with Systemic Vasculitis (60%-80% of cases)
Granulomatosis with polyangiitis (Wegener) (common)
Microscopic polyangiitis
Systemic lupus erythematosus
Eosinophilic granulomatosis with polyangiitis (Churg-Strauss)
Henoch-Schönlein purpura
Behçet syndrome
Essential mixed cryoglobulinemia
Rheumatoid vasculitis
Drugs: penicillamine, hydralazine, propylthiouracil

Box 24-4 Causes of lung hemorrhage and rapidly progressive glomerulonephritis. *GBM,* Glomerular basement membrane.

These diseases can sometimes be differentiated clinically, but serology and renal biopsy are usually required. Renal biopsy also provides valuable prognostic information.

NATURAL HISTORY

There is some variability in the pattern of early disease. Most patients present acutely with lung hemorrhage or advanced renal failure and report that the illness developed during only weeks or a few months. However, there are several reports of patients presenting with mild respiratory symptoms or incidental microscopic hematuria with disease progressing much more slowly during months or years; some have abruptly developed the full acute syndrome.

Once RPGN has developed, renal function is rapidly and often irretrievably lost. Progression is often much more rapid than in RPGN occurring in other contexts, such as microscopic polyangiitis, perhaps because more glomeruli are simultaneously affected. Consequently, there is a much narrower window of opportunity for effective treatment.

Response to Immunosuppressive Treatment in a Patient with Goodpasture Disease

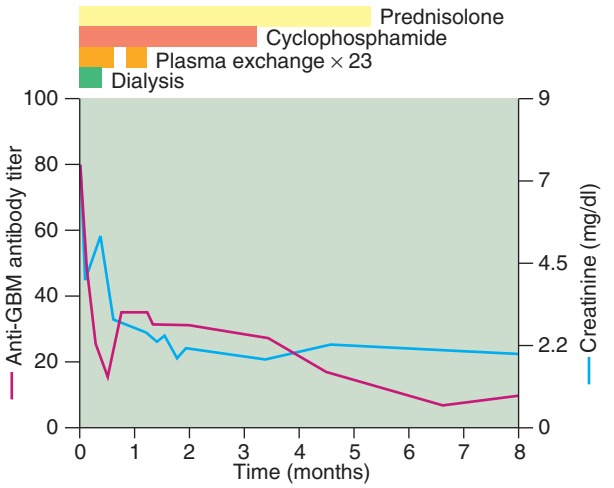

Figure 24-7 Response to immunosuppressive treatment in Goodpasture disease. The patient required dialysis for renal disease but had no lung hemorrhage. The good response to treatment was unusual but not unique. The renal biopsy showed that 85% of glomeruli contained recent (mostly cellular) crescents, suggesting very acute disease, which may be indicative of a more favorable response to treatment.

Although a severe exacerbation of lung disease usually coincides with deterioration of renal function, the natural history of isolated lung disease critically depends on continued exposure to irritants.

TREATMENT

Immunosuppressive Regimens

Before the introduction of immunosuppressive treatment, most patients died shortly after the development of renal impairment or lung hemorrhage.[18] Lung hemorrhage can usually be arrested now within 24 to 48 hours. Renal function can be protected if impairment is mild, and even severe renal impairment can be reversed in some patients. However, dialysis-dependent patients rarely recover kidney function despite immunosuppression and should probably be immunosuppressed only if lung hemorrhage occurs.

Figure 24-7 shows a chart recording the treatment of a patient with Goodpasture disease. Treatment recommendations for acute severe disease were devised to reduce levels of circulating pathogenic antibodies as rapidly as possible, as well as lessen their contribution to rapid glomerular destruction (Table 24-2). However, this regimen is almost certainly effective through a much broader range of mechanisms, including T cell depletion. Once the disease is controlled, immunosuppression can usually be tapered off during 3 months, and subsequent relapse is uncommon. The immune response is self-limited in the absence of immunosuppression, with antibodies disappearing over 1 to 2 years. Spontaneous remissions and effectiveness of relatively brief periods of immunosuppression are in striking contrast to the more prolonged immunosuppression generally required to prevent relapse of vasculitis and suggest a greater capacity for restoration of usual tolerance to α3(IV)NC1[22] than to targets in vasculitis.

In RPGN with no evidence of an infective cause, immunosuppressive therapy should be started immediately, sometimes before the renal biopsy findings are available. If therapy is stopped after a

Treatment Regimen for Acute Goodpasture Disease	
Therapy	**Recommendation**
Prednisolone	1 mg/kg/24 h orally. Reduce at weekly intervals to achieve one sixth of this dose by 8 weeks. For a starting daily dose of 60 mg, use weekly reductions to 45, 30, 25, 20, and 15 mg; then 2 weekly to 12.5 and 10 mg. Maintain this dose to 3 months; then taper to stop by 4 months.
Cyclophosphamide	3 mg/kg/24 h orally, rounded down to the nearest 50 mg. Patients older than 55 years receive a reduced dose of 2.5 mg/kg.
Plasma exchange	Daily exchange of 1 volume of plasma for 5% human albumin for 14 days or until the circulating antibody is suppressed. In the presence of pulmonary hemorrhage or within 48 hours of invasive procedure, 300 to 400 ml of fresh-frozen plasma is given at end of each treatment or according to coagulation tests.
Monitoring	Daily blood count during plasma exchange and while antibody titer remains elevated. At least twice weekly during first month, weekly thereafter. If white blood cell count decreases to $<3.5 \times 10^9$/l, stop cyclophosphamide until the count recovers. Resume at lower dose if cessation has been necessary. Baseline D_{LCO}, with further measurements as indicated. Daily coagulation tests during plasma exchange to monitor for significant depletion of clotting factors. Initially, daily checks of renal and hepatic function, glucose.
Prophylaxis against complications of treatment	Oral antifungal lozenges or rinse; proton pump inhibitor. Cotrimoxazole prophylaxis against *Pneumocystis carinii.* Avoid nonessential lines and catheters.

Table 24-2 Treatment regimen for acute Goodpasture disease.

few days, the patient will have incurred minimal risk (as long as pulse high-dose corticosteroids are avoided) but may have much to gain from earlier treatment.

Plasma Exchange and Immunosuppression

The regimen described in Table 24-2 dramatically improved the outlook for patients when it was introduced in the 1970s. An early randomized trial suggested some additional benefit of plasma exchange, but the interpretation was complicated by the recipient group's less severe disease at presentation.[23] It showed that milder disease can be effectively treated with corticosteroids and cyclophosphamide alone, although the overall outcomes for all patients were not as good as described with more intensive regimens.[23] Historical evidence suggests that treatment with corticosteroids alone, or corticosteroids with azathioprine, is less effective. Plasma exchange is of value only if it is accompanied by adjunctive immunosuppressive therapy. Immunoadsorption to protein A also lowers anti-GBM antibodies rapidly and does not deplete complement components or clotting factors, and a few reports suggest that it is as effective as plasma exchange. Information on the effectiveness of newer immunosuppressive agents such as mycophenolate mofetil (MMF) or anti–B cell antibodies, which tend to have only a slow effect on antibody production but may affect antigen presentation, is lacking. Their use over proven therapy is rarely justifiable in this often rapidly progressive disease. In contrast to advanced renal failure, in which treatment is unlikely to lead to recovery of renal function, even severe lung hemorrhage is likely to respond to treatment with full or almost full recovery of lung function.

Lung hemorrhage occurring alone tends to be relapsing and remitting, so there have been many reports of treatments (e.g., bilateral nephrectomy) that may help. Pulse methylprednisolone has been advocated, but high doses of corticosteroids fail to alter the underlying pathogenetic immune response and put the patient at increased risk of infectious and other complications. We recommend treating seriously ill patients with moderate doses of corticosteroids plus plasma exchange and cyclophosphamide.

In other acute severe diseases, daily administration of cyclophosphamide has often been superseded by pulse administration. We still prefer to use daily oral administration because it is known to work and requires only 3 months of therapy. Patients unable to take the drug orally can be given daily intravenous therapy at the usual oral dose. Dose does not need to be reduced in severe renal failure provided the white blood cell count is monitored closely, but reductions for older patients are important (see Table 24-2), and close monitoring of leukocyte counts is imperative in all patients. If pulsed therapy were chosen, the CYCLOPS regimen would be a reasonable if untested option (see Chapter 25).

Results from all series show that recovery of renal function is unlikely if, at initiation of treatment, the patient is oliguric, has a very high proportion of glomeruli with circumferential crescents, or has a serum creatinine level above 5.5 to 6.5 mg/dl (~500 to 600 µmol/l).[24] This is a notably different experience from that encountered in systemic vasculitis or idiopathic RPGN (see Chapter 25), in which renal disease of apparently similar severity (using histology and serum creatinine) can be salvaged by similar treatment protocols.[25] This has led to the suggestion that immunosuppressive treatment should be withheld from patients with only slight chance of recovery (Table 24-3; also see later).

Supportive Treatment

The most likely cause of death in the first few days is respiratory failure caused by lung hemorrhage. Lung hemorrhage may be precipitated or exacerbated by the following:

- Fluid overload
- Smoking and other pulmonary irritants, possibly including high Fio_2
- Local or distant infection
- Anticoagulation used during dialysis or plasma exchange
- Thrombocytopenia, defibrination, and depletion of clotting factors as a consequence of plasma exchange

It is therefore advisable to ensure correct fluid balance, to prohibit smoking, to use the lowest fractional inspired oxygen concentration (Fio_2) that gives adequate oxygenation, and to minimize the use of heparin.

Plasma exchange should be monitored by daily blood counts, calcium concentration (if regional citrate anticoagulation is used), and coagulation tests. Diminished clotting factor levels should be replenished by administration of fresh-frozen plasma or clotting factor preparations at the end of each plasma exchange session, as required.

After the first few days, the major cause of morbidity and mortality is infection. Infection carries the added risk of potentiating glomerular and lung inflammation and injury, so precautions to reduce

Factors in Decision to Treat Goodpasture Disease Aggressively		
	Factors Favoring Aggressive Treatment	**Factors Against Aggressive Treatment**
Pulmonary hemorrhage	Present	Absent
Oliguria	Absent	Present
Creatinine	<5.5 mg/dl (approximately 500 μmol/l)	>5.5-6.5 mg/dl (approximately 500-600 μmol/l) and ANCA negative Severe damage on kidney biopsy No desire for early kidney transplantation
Other factors	Creatinine >5.5-6.5 mg/dl (~500-600 μmol/l) *but* Rapid and recent progression ANCA positive Glomerular damage less severe than expected Crescents recent, nonfibrous Early renal transplantation desired	
Associated disease	Absent	Unusually high risk from immunosuppression

Table 24-3 Factors influencing decision to treat aggressively or not to treat aggressively in Goodpasture disease. *ANCA,* Antineutrophil cytoplasmic antibody.

risk, such as minimizing indwelling cannulas, are important. If leukopenia below 3.5×10^9/l or neutropenia develops, cyclophosphamide should be discontinued and resumed at a lower dose when the neutrophil count recovers, if necessary with the assistance of granulocyte colony-stimulating factor.

Monitoring Effect of Treatment on Disease Activity

The effect of treatment on the renal disease is monitored by following serum creatinine values. Indicators of recent lung hemorrhage include hemoptysis, decreases in hemoglobin concentration, chest radiograph changes, and increases in the DLCO, the last being the most sensitive. Any worsening of symptoms during treatment may indicate inadequate immunosuppression, but it is frequently a consequence of intercurrent infection exaggerating immunologic injury or fluid overload or other factors precipitating lung hemorrhage.

Monitoring of anti-GBM titers during, and particularly 24 hours after, the last planned plasma exchange treatment is useful for confirming effective suppression of autoantibodies. They should be undetectable within 8 weeks, but even without treatment, autoantibodies generally become undetectable by an average of 14 months.

Duration of Treatment and Relapses

Corticosteroid treatment may be gradually reduced and cyclophosphamide discontinued at 3 months. In contrast to treatment of small-vessel vasculitis, immunosuppression longer than this is usually not necessary. Longer treatment is appropriate for patients who are both anti-GBM antibody positive and ANCA positive (see later discussion). Late increases in anti-GBM level may predict clinical relapse, although antibodies are generally permanently suppressed in patients who have completed the immunosuppressive regimen. If there is recurrence, success has been achieved by treating as at first presentation.

Electing Not to Treat

Advanced renal failure, frequently already established at presentation, is generally not salvaged by any current treatment.[24,26,27] Furthermore, the immunosuppressive regimen outlined carries significant risks, and careful monitoring is required. For these reasons, it may be reasonable not to initiate immunosuppression in patients who present with advanced renal failure without lung hemorrhage. The decision not to treat is strengthened if the renal biopsy specimen shows widespread glomerulosclerosis and tubular loss and the patient is dialysis dependent at presentation (see Table 24-3). The risk for development of late lung hemorrhage in these patients seems to be low but warrants particular care to avoid the major precipitating factors, smoking and pulmonary edema, in at least the first few months. However, patients who are dialysis dependent should usually be treated if the renal histopathologic changes are unexpectedly mild or very recent (highly cellular crescents, even if 100% of glomeruli are involved, or acute tubular necrosis). Several reports describe good outcomes in these patients even after prolonged oliguria.

Treatment of Double-Positive Patients

Patients with both ANCA and anti-GBM antibodies may have other extrarenal disease requiring treatment (see Table 24-3). There is conflicting evidence as to whether their renal prognosis is the same as or better than that of other patients with anti-GBM antibodies. Earlier series suggested a better prognosis, but this was not confirmed in two later reports.[12,13] Because of the risk of serious disease in other organs, double-positive patients should usually receive an immunosuppressive regimen similar to that given for small-vessel vasculitis, with continuing immunosuppression with azathioprine after 3 months of cyclophosphamide (see Chapter 25).

TRANSPLANTATION

Renal transplantation in patients who have had Goodpasture disease carries the additional risk of disease recurrence. Recurrence with consequent loss of the graft has been reported and appears more likely when circulating anti-GBM antibodies are still detectable at transplantation. Therefore, it is reasonable to delay transplantation until circulating anti-GBM antibodies have been undetectable for 6 months, and to monitor graft function, urinary sediment, and circulating anti-GBM antibody levels to detect recurrent disease (see Chapter 108). Biopsies of well-functioning grafts sometimes show linear deposition of immunoglobulin on the GBM without clinical or histologic disease or apparently an adverse prognosis.

ALPORT SYNDROME POST-TRANSPLANT ANTI–GLOMERULAR BASEMENT MEMBRANE DISEASE

Patients with Alport syndrome have mutations in a gene encoding one of the tissue-specific type IV collagen chains, usually α5. Because these chains assemble with each other during biosynthesis, the resulting phenotype in the case of most mutations often has all the tissue-specific chains (α3 through α5) missing from the basement membranes, where they are normally coexpressed. Altered expression may lead to absent or inadequate immunologic tolerance to these proteins and to the preservation of the capacity to mount a powerful (allo)immune response to the type IV collagen chains expressed in a normal donor kidney after renal transplantation. Most Alport syndrome patients accommodate renal transplants with conventional immunosuppression without development of anti-GBM nephritis. However, development of low titers of anti-GBM antibodies is shown by many such patients having linear deposition of IgG on the GBM of the transplanted kidney on direct immunofluorescence, without disease. This alone does not justify treatment.

Up to 5% of Alport patients develop RPGN in the transplanted kidney. It is clinically indistinguishable from Goodpasture syndrome but without lung hemorrhage. This is more likely if the patient has a large gene deletion causing the disease rather than a point mutation, with the inference that the immune system has never been exposed to the mature protein. Typically, graft function is lost despite treatment for presumed acute rejection. Disease is usually encountered some months or longer after a first renal transplant, after weeks in a second, and after days in a third.[26] However, regrafting has been successful in two cases known to us and in two further cases in the literature. If the disease is recognized early, there are sound theoretical reasons for treating with the regimen recommended for Goodpasture syndrome, but there are few data on its effectiveness.[28]

In contrast to spontaneous Goodpasture disease, the specificity of anti-GBM antibodies in Alport post-transplant anti-GBM disease is not always to α3(IV)NC1. In many patients, possibly in most, the autoantibodies are specific for α5(IV)NC1, encoded by the *COL4A5* gene usually implicated in causation of the disease.[29] This is important because immunoassays for anti-GBM antibodies are optimized for detection of the anti-α3(IV)NC1 antibodies of spontaneous Goodpasture disease, and they may have low sensitivity for anti-α5(IV)NC1 antibodies. In the absence of widely available assays for these uncommon antibodies, renal biopsy with immunohistology is the only reliable method of diagnosis.

CHAPTER 25

Renal and Systemic Vasculitis

J. Charles Jennette, Ronald J. Falk, and JulieAnne G. McGregor

DEFINITION

The kidneys are targets for a variety of systemic vasculitides, especially those that affect small vessels.[1-5] This is not surprising given the large number and variety of renal vessels. Vasculitis involving the kidneys can produce a wide variety of clinical manifestations, depending mainly on the type of renal vessel affected. Vasculitides can be categorized as large-vessel vasculitis, medium-vessel vasculitis, and small-vessel vasculitis (Figs. 25-1 and 25-2). For the purposes of the discussion in this chapter, the 2012 Chapel Hill Consensus Conference definitions are used (Table 25-1).[4]

A number of the vasculitides listed in Figure 25-2 are covered in other chapters and are not reviewed in detail here except in the context of differential diagnosis, for example, cryoglobulinemic vasculitis (Chapter 21), IgA vasculitis (Henoch-Schönlein purpura; Chapter 23), and anti–glomerular basement membrane (anti-GBM) disease (Chapter 24). Nephrologists most often encounter patients with small-vessel vasculitides because these often cause glomerulonephritis (GN). Therefore, small-vessel vasculitis is the primary focus of this chapter.

Small-Vessel Vasculitis

Small-vessel vasculitis is necrotizing polyangiitis that affects predominantly vessels smaller than arteries, including capillaries, venules, and arterioles; however, arteries also may be involved.[4] The most common renal target for small-vessel vasculitis are glomerular capillaries, and therefore the most common renal clinical manifestations are those of GN.

Medium-Vessel Vasculitis

Medium-vessel vasculitis is necrotizing arteritis that affects predominantly major visceral arteries.[4] The interlobar arteries and arcuate arteries are affected most often in the kidneys, although any arteries from the main renal artery to the smallest interlobular arteries may be affected. Inflammation and necrosis of arteries may result in thrombosis or rupture, which causes renal infarction and hemorrhage, respectively.

Large-Vessel Vasculitis

Large-vessel vasculitis is chronic granulomatous arteritis that affects the aorta and its major branches more often than other forms of vasculitis.[4] When there is renal involvement, the ostia of the renal arteries and the main renal arteries are most often affected. The most common clinical renal manifestation is renovascular hypertension.

SMALL-VESSEL PAUCI-IMMUNE VASCULITIS

Small-vessel vasculitis can be divided into *immune complex* small vessel vasculitis with moderate to marked vessel wall deposits of immunoglobulin and *pauci-immune* small-vessel vasculitis with few or no immune deposits in vessel walls.[4] Pauci-immune small-vessel vasculitis often is associated with circulating antineutrophil cytoplasmic autoantibodies (ANCAs).[5] The ANCA-associated vasculitides share an indistinguishable form of necrotizing small-vessel vasculitis that affects capillaries, venules, arterioles, and small arteries.[1-5] Some patients with *ANCA-associated vasculitis* (AAV) have no evidence of involvement of arteries, even though they have involvement of glomerular capillaries, causing GN; pulmonary alveolar capillaries, causing pulmonary hemorrhage; or dermal venules, causing purpura. The clinicopathologic variants of pauci-immune small-vessel vasculitis are categorized on the basis of clinical, laboratory, and pathologic findings, as follows[4]:

- *Microscopic polyangiitis* (MPA) is pauci-immune small-vessel vasculitis occurring in the absence of evidence of necrotizing granulomatous inflammation.
- *Granulomatosis with polyangiitis* (Wegener) (GPA) is pauci-immune vasculitis associated with necrotizing granulomatous inflammation, most often affecting the respiratory tract.
- *Eosinophilic granulomatosis with polyangiitis* (Churg-Strauss) (EGPA) is pauci-immune vasculitis associated with asthma, eosinophilia, and necrotizing granulomatous inflammation.

MPA, GPA, and less frequently EGPA share an indistinguishable pattern of GN that is the expression of the vasculitis in glomerular capillaries.[1,2] In the acute phase, the GN usually has necrosis and crescent formation and an absence or paucity of immunoglobulin deposition and is often designated *pauci-immune crescentic glomerulonephritis*. When occurring in the apparent absence of systemic vasculitis, pauci-immune crescentic GN is sometimes referred to as *renal-limited vasculitis*.

Pathogenesis

Microscopic polyangiitis, GPA, EGPA, and renal-limited pauci-immune crescentic GN are all associated with ANCA.[5-9] The most common antigen specificities of ANCA in patients with vasculitis and GN are for proteinase 3 (PR3) and myeloperoxidase (MPO). Recently, autoantibodies to lysosome-associated membrane protein 2 (LAMP-2) were reported in the circulation of most patients with either MPO-ANCA or PR3-ANCA.[10] LAMP-2 has homology to the bacterial adhesin FimH, and thus autoantibodies to LAMP-2 may arise by molecular mimicry secondary to infection with fimbriated gram-negative bacteria. Further, rats injected with anti–LAMP-2 or immunized with FimH develop pauci-immune focal necrotizing and

crescentic GN. At least one research group was not able to reproduce these results.[11] These observations are intriguing but need additional confirmation.

The strong association of ANCA with this distinctive form of small-vessel vasculitis suggests that ANCAs are involved in the pathogenesis.[5-9] The report of a neonate who developed GN and pulmonary hemorrhage possibly caused by transplacental passage of MPO-ANCA IgG is intriguing but has not been substantiated by additional reports.[12] The observation that ANCA titers correlate with disease activity also suggests a pathogenic role; however, this correlation is not strong, and some patients with clinically and pathologically typical MPA, GPA, or renal-limited pauci-immune crescentic GN are negative using conventional serologic testing for ANCA. A recent report explains both these discrepancies, at least in patients with MPO-ANCA, based on a multiplicity of ANCA epitope specificities.[13] The MPO-ANCA epitope specificity determines not only the pathogenicity but also the detectability and clinical predictive value of circulating MPO-ANCA. For example, ANCAs with certain epitope specificities only occur in patients with active disease, whereas other MPO-ANCA epitope specificities occur not only in patients with active disease, but also in patients in remission and even in healthy controls (natural ANCA), although at very low titers. Some AAV patients who are negative by conventional serologic testing have MPO-ANCA with very restricted epitope specificity that can be detected with special unmasking techniques.[13]

The pathogenic potential of ANCA is supported by the observation that administration of certain drugs, such as propylthiouracil, hydralazine, and penicillamine, can induce AAV.[14] Cocaine adulterated with levamisole also can induce AAV associated with high titers of MPO-ANCA, PR3-ANCA, and ANCA specific for another neutrophil granule protein elastase.[15] Levamisole-induced vasculitis has frequent cutaneous leukocytoclastic angiitis and upper respiratory tract involvement, but rarely renal or lung involvement.

A number of *in vitro* observations suggest mechanisms by which ANCA can cause vascular injury.[6,7] Priming of neutrophils by cytokines, as would occur with a viral infection, causes neutrophils to increase expression of ANCA antigens on their surfaces, where they are accessible to interact with ANCA. Cytokine-primed neutrophils that are exposed to ANCA release IgG from granules, release toxic oxygen metabolites, and kill cultured endothelial cells.[6,7,16-18]

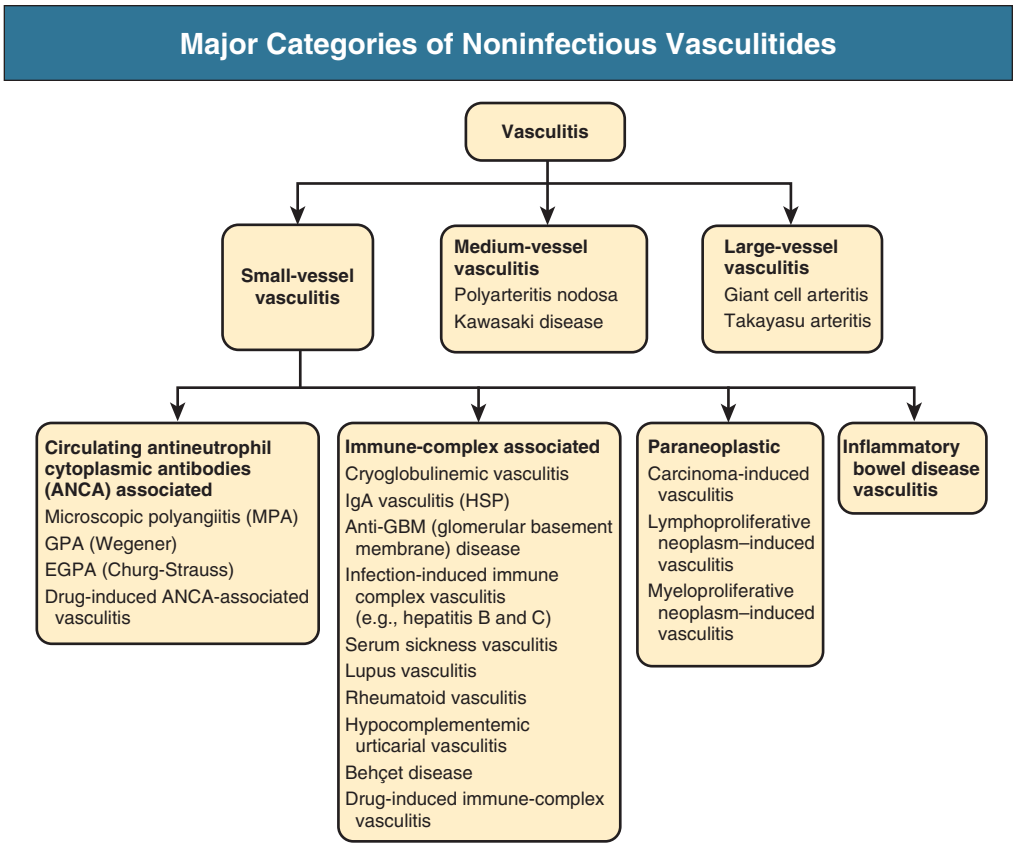

Figure 25-2 Major categories of noninfectious vasculitis. Not included are vasculitides that are known to be caused by direct invasion of vessel walls by infectious pathogens, such as rickettsial vasculitis and neisserial vasculitis. *EGPA,* Eosinophilic granulomatous polyangiitis; *GPA,* granulomatous polyangiitis; *HSP,* Henoch-Schönlein purpura.

ANCA-antigen complexes adsorb onto endothelial cells, where they could participate in *in situ* immune complex formation.[19] ANCA activation of neutrophils is mediated by both $F(ab)'_2$ binding to neutrophils and Fc receptor engagement.[20,21] Neutrophils that have been activated by ANCA adhere to endothelial cells and release mediators of inflammation and cell injury.[17,18] If occurring *in vivo,* these events would lead to vasculitis as a result of neutrophils adhering to, penetrating, and destroying vessel walls (Fig. 25-3).[22]

The ability of ANCA IgG to cause pauci-immune necrotizing and crescentic GN and vasculitis has been demonstrated in multiple animal models induced with MPO-ANCA, although no widely accepted model of PR3-ANCA disease has been developed. Wild-type or immunodeficient mice that receive anti-MPO antibodies intravenously develop pauci-immune focal necrotizing GN with crescents.[23]A rat model of pauci-immune necrotizing and crescentic GN has been developed by immunizing rats with human MPO, resulting in the development of antibodies that cross-react with rat MPO and are able to induce pauci-immune glomerular necrosis and crescents.[24] MPO-ANCA GN in mice is mediated by neutrophil activation, modulated by Fc gamma receptor repertoire, and can be prevented by neutrophil depletion.[6,7,25] Activation of the alternative complement pathway plays a role in amplifying ANCA-induced inflammation.[26] ANCA-activated neutrophils release factors that activate the alternative complement pathway, resulting in the generation of C5a that is strongly chemotactic for neutrophils and primes neutrophils to facilitate further activation by ANCA.[27,28] The relevance of these experimental observations in patients is supported by a report that AAV patients have increased plasma levels of alternative pathway activation markers C3a, C5a, soluble C5b-9, and Bb during active disease but no remission, and that the plasma level of Bb correlated with percentage of cellular crescents in the renal biopsies and with Birmingham Vasculitis Activity Scores.[29]

Thus, the clinical and experimental data indicate that ANCA can activate neutrophils and cause vasculitis, especially if there are concurrent synergistic proinflammatory stimuli. The requirement for a synergistic inflammatory process may be reflected in the frequent association of the onset of ANCA small-vessel vasculitis with an influenza-like syndrome.[30] An influenza-like syndrome is a manifestation of high levels of circulating cytokines that could serve as priming factors for neutrophils, making them more receptive to activation by ANCA.

Epidemiology

Wegener granulomatosis (GPA), MPA, and EGPA usually begin during the fifth, sixth, and seventh decades of life but may occur at any age. There is a slight male predominance. The incidence is disproportionately greater in Caucasians than in African Americans. In Europe, MPA has a prevalence of approximately 2.5 in 100,000; GPA, 2.5 in 100,000; and EGPA, 1 in 100,000 population.[31] GPA is more common in colder than in warmer climates, whereas MPA has the opposite trend. AAV in Asia is much more often associated with MPO-ANCA than PR3-ANCA.[32]

Clinical Manifestations

Generalized nonspecific manifestations of systemic inflammatory disease, such as fever, malaise, anorexia, weight loss, myalgias, and arthralgias, often are present. Many patients with vasculitis trace the onset of their disease to a flu-like illness.[30]

The clinical manifestations of GPA, MPA, and EGPA are extremely varied because they are influenced by the sites of involvement and the activity versus the chronicity of involvement. All three categories of vasculitis share features caused by the small-vessel vasculitis, and

Vasculitis Categories and Definitions	
Category/Name	**Definition**
Large-Vessel Vasculitis	
Takayasu arteritis	Arteritis, often granulomatous, predominantly affecting aorta and/or its major branches. Onset usually in patients younger than 50.
Giant cell arteritis	Arteritis, often granulomatous, usually affecting aorta and/or its major branches, with predilection for branches of carotid and vertebral arteries; often involves temporal artery. Onset usually in patients older than 50 and often associated with polymyalgia rheumatica.
Medium-Vessel Vasculitis	
Polyarteritis nodosa	Necrotizing arteritis of medium or small arteries without glomerulonephritis (GN) or vasculitis in arterioles, capillaries, or venules; and not associated with ANCA.
Kawasaki disease	Arteritis associated with mucocutaneous lymph node syndrome and predominantly affecting medium and small arteries; coronary arteries are often involved; aorta and large arteries may be involved. Usually occurs in infants and young children.
Small-Vessel Vasculitis	
ANCA-Associated Small-Vessel Vasculitis	
	Necrotizing vasculitis, with few or no immune deposits, predominantly affecting small vessels (capillaries, venules, arterioles, small arteries), associated with MPO-ANCA or PR3-ANCA. Not all patients have ANCA. Add prefix indicating ANCA reactivity, e.g., PR3-ANCA, MPO-ANCA, ANCA-negative.
Microscopic polyangiitis (MPA)	Necrotizing vasculitis, with few or no immune deposits, predominantly affecting small vessels (capillaries, venules, arterioles). Necrotizing arteritis involving small and medium arteries may be present. Necrotizing GN is common. Pulmonary capillaritis often occurs. Granulomatous inflammation is absent.
Granulomatosis with polyangiitis (Wegener) (GPA)	Necrotizing granulomatous inflammation usually involving upper and lower respiratory tract, and necrotizing vasculitis affecting predominantly small to medium vessels (capillaries, venules, arterioles, arteries, veins). Necrotizing GN is common.
Eosinophilic granulomatosis with polyangiitis (Churg-Strauss) (EGPA)	Eosinophil-rich and necrotizing granulomatous inflammation often involving the respiratory tract, and necrotizing vasculitis predominantly affecting small to medium vessels, and associated with asthma and eosinophilia. ANCA is more common when GN is present.
Immune Complex Small-Vessel Vasculitis	
	Vasculitis with moderate to marked vessel wall deposits of immunoglobulin and/or complement components predominantly affecting small vessels (capillaries, venules, arterioles, small arteries). GN is common.
Anti–glomerular basement membrane (anti-GBM) disease	Vasculitis affecting glomerular capillaries, pulmonary capillaries, or both, with basement membrane deposition of anti–basement membrane autoantibodies. Lung involvement causes pulmonary hemorrhage, and renal involvement causes GN with necrosis and crescents.
Cryoglobulinemic vasculitis	Vasculitis with cryoglobulin immune deposits affecting small vessels (predominantly capillaries, venules, or arterioles) and associated with cryoglobulins in serum. Skin, glomeruli, and peripheral nerves are often involved.
IgA vasculitis (IgAV) (Henoch-Schönlein purpura)	Vasculitis, with IgA1-dominant immune deposits, affecting small vessels (predominantly capillaries, venules, or arterioles). Often involves skin and gastrointestinal tract and frequently causes arthritis. GN indistinguishable from IgA nephropathy may occur.
Hypocomplementemic urticarial vasculitis (anti-C1q vasculitis)	Vasculitis accompanied by urticaria and hypocomplementemia affecting small vessels (capillaries, venules, arterioles), and associated with anti-C1q antibodies. GN, arthritis, obstructive pulmonary disease, and ocular inflammation are common.

Table 25-1 Names and definitions of vasculitis. Adopted by the Chapel Hill Consensus Conference on the nomenclature of systemic vasculitis. Note that all three categories affect arteries, but only small-vessel vasculitis has a predilection for vessels smaller than arteries. *ANCA,* Antineutrophil cytoplasmic antibody. *(Modified from reference 22.)*

patients with GPA and EGPA have the additional features that define each of these syndromes.[3,4,30,33,34]

Renal involvement occurs often in GPA and MPA and less frequently in EGPA (Table 25-2). The most common renal manifestations are caused by glomerular involvement and include hematuria, proteinuria, and renal failure. The renal failure often has the characteristics of rapidly progressive glomerulonephritis (RPGN) in GPA and MPA but usually is less severe in EGPA. Patients with GPA and MPA also can present with a subacute or chronic nephritis. A cohort of more than 300 pauci-immune crescentic GN patients evaluated at renal biopsy had a mean age of 56 ± 20 years (range 2 to 92 years), male-to-female ratio of 1.0:0.9, mean serum creatinine concentration of 6.5 ± 4.0 mg/dl (range 0.8 to 22.1 mg/dl), and proteinuria of 1.9 ± 3.0 g/day (range 0.1 to 18 g/day).[35]

Cutaneous involvement occurs frequently in vasculitis. Purpura is a common manifestation of GPA, MPA, and EGPA (Fig. 25-4). The purpura is most common on the lower extremities and tends to occur as recurrent crops. The purpura may be accompanied by small areas of ulceration. Nodular cutaneous lesions are much more frequent in GPA and EGPA than MPA. Nodules can be caused by dermal or subcutaneous arteritis and the necrotizing granulomatous inflammation.

Upper respiratory tract involvement is most common in GPA and EGPA but also occurs in MPA.[36] In all three categories, patients can have pulmonary hemorrhage caused by hemorrhagic alveolar capillaritis. Patients with GPA and EGPA also can have pulmonary injury caused by necrotizing granulomatous inflammation, which may be detected radiographically as nodular or cavitating lesions. By

definition, patients with MPA do not have granulomatous respiratory tract lesions.[4]

Manifestations of upper respiratory tract disease include subglottic stenosis, sinusitis, rhinitis, nasal septal collapse, otitis media, and ocular inflammation. These features are most common in GPA but may occur in EGPA and MPA. The upper respiratory inflammation in MPA is caused by angiitis alone, without granulomatous inflammation. Destruction of bone, for example, resulting in septal perforation and saddle nose, appears to require necrotizing granulomatous inflammation and therefore does not occur in MPA. When patients with saddle nose have ANCA, it is almost always PR3-ANCA.[36]

Cardiac disease is identified in approximately 50% of patients with EGPA but in less than 20% of patients with GPA or MPA. Manifestations range from transient heart block and ventricular hypokinesis that respond to immunosuppressive treatment to infarction and severe life-threatening myocarditis. Pericarditis and endocarditis also may occur.

Peripheral neuropathy, usually with a mononeuritis multiplex pattern, is the most common neurologic manifestation and is most frequent in EGPA. Central nervous system involvement is less common and most often is manifested as vasculitis within the meninges. Gastrointestinal involvement typically causes abdominal

Figure 25-4 Cutaneous vasculitis. Ankle of a patient with small-vessel vasculitis, showing purpura and a few small ulcers.

pain and blood in the stool, with mesenteric ischemia and rarely intestinal perforation. Vasculitis in the pancreas and liver can mimic pancreatitis and hepatitis symptomatically and cause elevated serum pancreatic and liver enzymes.

Antineutrophil Cytoplasmic Autoantibody

Serologic testing for ANCA is a useful diagnostic procedure for pauci-immune small-vessel vasculitis and pauci-immune crescentic GN but should be interpreted in the context of other characteristics of the patient.[37-41] Laboratory testing for ANCA should include both indirect immunofluorescence microscopy assay (IFA) and enzyme immunoassay (EIA).[38] IFA using normal human neutrophils as substrate produces two major staining patterns (Fig. 25-5): cytoplasmic (c-ANCA), in which staining occurs diffusely throughout the cytoplasm, and perinuclear (p-ANCA). By EIA, most c-ANCA have specificity for protease 3 (PR3-ANCA), and most p-ANCA have specificity for myeloperoxidase (MPO-ANCA). For adequate diagnostic accuracy, all serologic testing for ANCA should include an immunochemical analysis for antigen specificity, such as an EIA.[38] Although positive results are rare in completely healthy individuals, approximately one fourth of patients with other inflammatory renal diseases (especially lupus) will have a false-positive IFA result (usually with a p-ANCA pattern), and approximately 5% will have a false-positive EIA result (usually at low titer).[39]

ANCA testing has good sensitivity for AAV (80% to 90%). The specificity and predictive value depend on the population of patients and the quality of the assay.[37,41] Although ANCAs are most frequent in patients with pauci-immune crescentic GN, one fourth to one third of patients with anti-GBM crescentic GN and one fourth of those with idiopathic immune complex crescentic GN with 50% or more crescents are ANCA positive.[35,42] Some of these patients have well-recognized types of immune complex GN complicated by ANCA, such as membranous glomerulopathy and IgA nephropathy, whereas others have nonlupus IgG-dominant immune complex disease that cannot be categorized further. Patients with concurrent ANCA and anti–glomerular basement membrane (anti-GBM) antibodies have a worse prognosis than patients with ANCA alone.

(Original magnification ×250.)

Table 25-3 provides an estimate of the relative frequencies of PR3-ANCA/c-ANCA and MPO-ANCA/p-ANCA in the different clinical phenotypes of AAV. PR3-ANCA/c-ANCA are most prevalent in GPA, and MPO-ANCA/p-ANCA are most prevalent in renal-limited pauci-immune crescentic GN and EGPA. Patients with MPA have a more even distribution of PR3-ANCA/c-ANCA and MPO-ANCA/p-ANCA, although this varies among geographic regions as stated earlier. Patients with EGPA have the lowest overall frequency of ANCA, but the frequency of ANCA is much higher in patients with GN (75%) than in those with no GN (26%).[43] The ANCA specificity correlates with clinical symptoms, with PR3-ANCA having the highest frequency (~90% when ANCA present) in patients who have destructive upper respiratory disease, especially saddle nose.[36]

Changes in ANCA titers over time correlate to a degree with disease activity but are not infallible markers and thus must be interpreted with caution.[39,44] In general, titers decrease with treatment and increase before or at disease recurrence. An increase in ANCA titer should prompt careful evaluation of the patient for corroborating evidence of exacerbation, but most physicians do not modify treatment on the basis of an increase in titer without accompanying clinical signs. A recent report suggests that epitope-specific assays may provide much better correlation with and prediction of disease outcome.[13] MPO-ANCAs with certain epitope specificities occur only in patients with active disease, disappear with remission, and reappear during relapse, whereas MPO-ANCAs with other specificities remain during disease remission.

ANCA in Small-Vessel Vasculitis			
	Frequency (%)		
Disorder	***Proteinase 3 (PR3, usually c-ANCA)***	***Myeloperoxidase (MPO, usually p-ANCA)***	***Negative***
Granulomatosis with polyangiitis (Wegener)	70	25	5
Microscopic polyangiitis	40	50	10
Eosinophilic granulomatosis with polyangiitis (Churg-Strauss)	5	40	55
Renal-limited pauci-immune crescentic GN	20	70	10

Table 25-3 Antineutrophil cytoplasmic antibody (ANCA) in small-vessel vasculitis. Figure 25-7 Necrotizing arteritis of interlobular artery in patient with ANCA-associated small-vessel vasculitis. The fibrinoid necrosis is indicated by the *red* staining. (Masson trichrome; ×100.)

From 10% to 20% of patients with pauci-immune necrotizing and crescentic GN and pauci-immune small-vessel vasculitis will be ANCA negative. The clinicopathologic and outcome characteristics of these patients are no different from those of ANCA-positive patients.[45] In the same epitope-specific assays previously mentioned, some AAV patients who are negative by current clinical assays have MPO-ANCA with restricted epitope specificity that can be detected with sensitive assays that remove a masking factor.[13]

ANCA may be positive in inflammatory conditions other than vasculitis, including inflammatory bowel disease (IBD), rheumatoid disease, chronic inflammatory liver disease, bacterial endocarditis, and cystic fibrosis. In IBD, specificity of the ANCA may not be against PR3 or MPO but against other neutrophil antigens, including lactoferrin, cathepsin G, and anti–bactericidal/permeability-increasing protein (BPI).

Pathology

The acute vascular lesion of the pauci-immune small-vessel vasculitides is segmental fibrinoid necrosis, often accompanied by leukocyte infiltration and leukocytoclasia[1,2,46-49] (leukocyte fragmentation; Figs. 25-6 and 25-7). The earliest vasculitic lesions have infiltrating neutrophils that are quickly replaced by predominantly mononuclear leukocytes. The acute necrotizing lesions evolve into sclerotic lesions and may be complicated by thrombosis.

These focal necrotizing lesions can affect many different vessels, thus causing many different signs and symptoms. For example, involvement of glomerular capillaries causes nephritis; of alveolar capillaries, pulmonary hemorrhage; of dermal venules, purpura; of upper respiratory mucosal venules, rhinitis and sinusitis; of abdominal visceral arteries, abdominal pain; and of epineural arteries, mononeuritis multiplex.

The shared glomerular lesion of the pauci-immune small-vessel vasculitides is a necrotizing GN, usually with resultant crescent formation.[1,2,46-49] Early mild lesions have segmental fibrinoid necrosis with or without an adjacent small crescent (Fig. 25-8). Severe acute lesions may have essentially global necrosis with large circumferential crescents (Fig. 25-9). In a cohort of 181 renal biopsy specimens from patients with ANCA-associated GN, 90% had glomerular crescents that on average affected 50% of glomeruli, with half having crescents in more than 50% of glomeruli.[27] Non-necrotic segments within segmentally injured glomeruli (see Fig. 25-8) and glomeruli without necrosis typically have slight or no histologic abnormalities.

As mentioned previously, approximately one fourth of patients with anti-GBM crescentic GN and one fourth of patients with immune complex–mediated crescentic GN will be ANCA positive.[35] By contrast, less than 5% of patients with immune complex GN who do not have crescents will be ANCA positive. Therefore, even in patients with immune complex GN, the presence of ANCA is

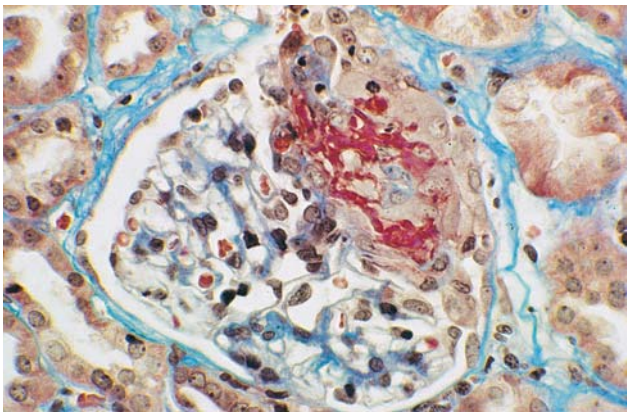

Figure 25-8 Segmental glomerular necrosis and crescent formation in patient with ANCA-associated small-vessel vasculitis. The fibrinoid material is *red*. The uninvolved segments appear normal. (Masson trichrome; ×150.)

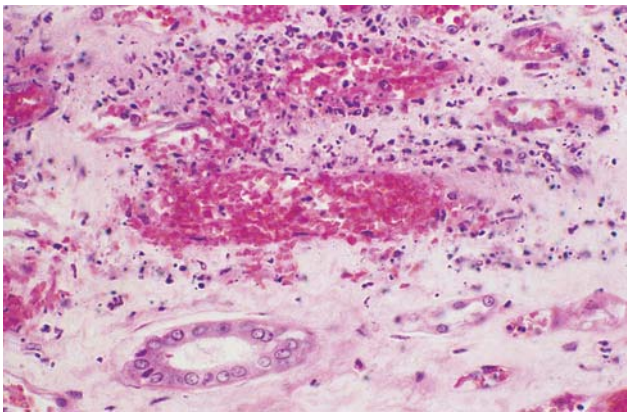

Figure 25-10 Medullary leukocytoclastic angiitis involving vasa recta in patient with granulomatosis with polyangiitis. (HE stain; ×150.)

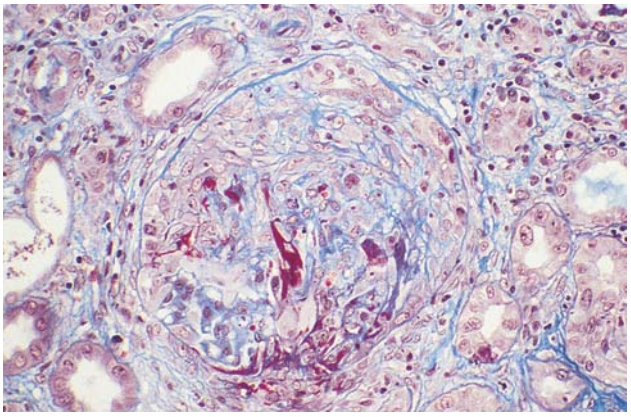

Figure 25-9 Global glomerular necrosis and circumferential crescent formation in a glomerulus from patient with ANCA-associated small-vessel vasculitis. (Masson trichrome; ×150.)

associated with an increased incidence of crescents (and also inflammation in vessels other than glomerular capillaries). A histopathologic classification has been proposed for AAV GN: sclerotic class (≥50% globally sclerotic glomeruli), focal class (≥50% normal glomeruli), crescentic class (≥50% of glomeruli with cellular crescents), or mixed class if none of these features predominated.[49] Renal survival at 5 years was 93% for the focal class, 76% for crescentic class, 61% for mixed class, and 50% for sclerotic class. Validation studies are underway to better understand the utility of this classification.

In addition to GN, patients with AAV also may have renal arteritis, most often affecting interlobular arteries (see Figs. 25-6 and 25-7), and medullary angiitis affecting the vasa recta (Fig. 25-10). The medullary angiitis may be severe enough to cause papillary necrosis, although this is a rare complication.

Patients with GPA and EGPA have pathologic lesions in addition to the necrotizing small-vessel vasculitis.[1-4] The necrotizing granulomatous inflammation of GPA occurs most often in the respiratory tract and is characterized by zones of necrosis surrounded by mixed infiltrates of neutrophils, lymphocytes, monocytes, and macrophages, often including scattered multinucleated giant cells. Varying numbers of eosinophils may be present in the lesions of GPA, but these are more conspicuous in the necrotizing granulomatous inflammation of EGPA. Eosinophils also are typically conspicuous in the vasculitic lesions of EGPA, but this is not a pathognomonic observation because numerous eosinophils may be present in the vasculitic lesions of GPA, MPA, polyarteritis nodosa, and other vasculitides.

Differential Diagnosis

ANCA-associated small-vessel vasculitis must be differentiated from other forms of small-vessel vasculitis that can produce the same signs and symptoms.[2] In addition, an attempt should be made to distinguish MPA, GPA, and EGPA, although in some patients this cannot be accomplished conclusively and is not required for initiation of therapy. Pathologic confirmation of the granulomatous inflammation that is seen in ANCA disease is particularly difficult because small biopsy specimens often show only nonspecific acute and chronic inflammation and necrosis. Thus, findings other than histologic lesions, such as nodular or cavitating lung lesions observed radiographically or destructive bone lesions in the nasal septum, often must be used as markers of necrotizing granulomatous inflammation to categorize patients. Because of the toxicity of the treatment, even in a patient with substantial clinical and serologic evidence of ANCA disease, pathologic confirmation of vasculitis is warranted. This can be accomplished with biopsy of many different involved sites, including skin, muscle, nerve, gut, and kidney. When the patient has substantial renal involvement, renal biopsy findings also can be useful for predicting response to treatment and clinical outcome.[46-49]

All forms of small-vessel vasculitis listed in Figure 25-2 are capable of producing clinically indistinguishable overlapping features of disease, such as nephritis, purpura, peripheral neuropathy, myalgias, arthralgias, and abdominal pain. Table 25-4 lists a number of features that help distinguish several important categories of small-vessel vasculitis.[2] Accurate differentiation is very important for proper patient management because the natural histories and appropriate treatments vary greatly. For example, a patient presenting with nephritis, arthralgias, and abdominal pain could have IgA vasculitis (IgAV, formerly Henoch-Schönlein purpura), MPA, cryoglobulinemic vasculitis, or a number of other small-vessel vasculitides. A number of serologic and pathologic observations are useful for reaching the correct diagnosis (Table 25-4). A positive ANCA assay (confirmed by EIA to be MPO-ANCA or PR3-ANCA) supports a diagnosis of MPA or one of the other pauci-immune small-vessel vasculitides. A negative ANCA assay and positive cryoglobulin assay (especially accompanied by hypocomplementemia and positive hepatitis C serology) support a diagnosis of cryoglobulinemic vasculitis. A negative ANCA assay, negative cryoglobulin assay, and normal

Differential Diagnostic Features of Small-Vessel Vasculitis

Table 25-4 Differential diagnostic features of select forms of small-vessel vasculitis. *All these vessel vasculitides can manifest any of the shared features of small-vessel vasculitides, such as nephritis, purpura, abdominal pain, peripheral neuropathy, myalgias, and arthralgias. Each is distinguished by the presence and, just as important, by the absence of certain specific features. *ANCAs,* Antineutrophil cytoplasmic antibodies; *GPA,* granulomatosis with polyangiitis; *EGPA,* eosinophilic granulomatosis with polyangiitis; *HSP,* Henoch-Schönlein purpura. *(Modified from reference 2.)*

complement levels support a diagnosis of IgAV, especially in a patient younger than 21 years. The age of a patient influences the likelihood of a specific diagnosis. For example, approximately 80% of children younger than 10 years who have purpura, nephritis, and arthralgias will have IgAV, whereas approximately 80% of adults older than 60 years with the same symptoms will have an AAV. However, each disease can occur at any age.

Exposure to drugs that may provoke AAV must be considered, including penicillamine, hydralazine, and propylthiouracil,[14] as well as cocaine adulterated with levamisole.[15] Cholesterol embolization can also mimic the clinical features of small-vessel vasculitis with lower extremity rash, but ANCA assay is negative. The differential diagnosis of lung hemorrhage and nephritis includes anti-GBM disease, alone or with ANCA disease.

Natural History

Before the advent of immunosuppressive therapy, the survival of patients with MPA and GPA was poor, with most patients dying in less than 1 year. With adequate immunosuppressive therapy, 5-year renal and patient survival is 65% to 75%.[50-52] The likelihood of success of long-term maintenance of renal function is inversely correlated with the serum creatinine concentration when therapy begins, which indicates the importance of early diagnosis and prompt initiation of appropriate treatment. The likelihood of patient survival increases with early treatment of pulmonary hemorrhage and sepsis and avoidance of overimmunosuppression leading to life-threatening infections. Adverse events from therapy, including infections, are the leading cause of death in the year following diagnosis.[50] Older age, higher serum creatinine concentration at presentation, pulmonary hemorrhage, and especially dialysis-dependent renal failure correlate with an overall poor outcome. However, even dialysis-dependent renal failure may resolve with aggressive early therapy. Respiratory tract disease and PR3-ANCA are predictors of higher relapse rates.[52] Pathologic features that correlate with renal outcome include histologically normal glomeruli, glomerular sclerosis, interstitial leukocyte infiltration, tubular necrosis, and tubular atrophy.[48,49] Increased numbers of histologically normal glomeruli or glomeruli with cellular crescents correlated with a better prognosis than higher proportions of globally sclerotic glomeruli, suggesting that active inflammatory lesions may be suppressed if not reversed by treatment, whereas chronic injury at initiation of treatment may be irreversible.

When severe GN is present, the renal prognosis is similar for patients with MPA, GPA, or EGPA, and renal-limited pauci-immune crescentic GN. Renal involvement, however, is less common and usually less severe in patients with EGPA. Cardiac involvement is the most frequent cause of death in patients with EGPA, but only rarely causes mortality in MPA or GPA. GPA has a broad spectrum of clinical manifestations, from localized indolent disease to fulminant multisystem disease. For example, some patients have disease limited to the upper respiratory tract or to the upper and lower respiratory tract. Such limited disease may have a more benign natural history than systemic disease with substantial renal involvement and may warrant less aggressive treatment.

Patients with MPO-ANCA have a slightly better renal outcome than those with PR3-ANCA, even though they have more renal impairment and more chronic renal pathologic changes at presentation. Patients with PR3-ANCA have more extrarenal organ manifestations (especially respiratory tract disease), higher chance for relapse, and higher mortality than MPO-ANCA patients. Regardless of the category of ANCA disease, the best clinical predictor of renal outcome is the glomerular filtration rate (GFR) at diagnosis.

Treatment

This section focuses on patients with ANCA-associated small-vessel vasculitis affecting the kidneys. The goal should be not to overtreat mild disease and not to undertreat severe disease. Glomerulonephritis that is severe enough to cause renal impairment is an indication for immunosuppressive treatment in patients with GPA, MPA, EGPA, and renal-limited pauci-immune crescentic GN. Patients with AAV who have concurrent anti-GBM disease or concurrent immune complex disease should be treated similarly to patients with AAV alone. Treatment involves three phases: induction of remission, maintenance of remission, and treatment of relapse[53] (Fig. 25-11).

Induction Therapy

The consensus is that corticosteroids alone are not as effective for induction therapy as corticosteroids combined with a cytotoxic agent such as cyclophosphamide.[54-61] Combined treatment with corticosteroid and cyclophosphamide induces remission in approximately 75% of patients at 3 months and 90% at 6 months. The specifics of combined induction regimens vary with respect to agents, doses, route of administration, and duration. One induction approach is to begin with 7 mg/kg/day intravenous (IV) methylprednisolone for 3 days followed by oral prednisone 1 mg/kg/day, tapering to an alternate-day regimen and discontinuing within 3 to 4 months.[54] Alternatively, the corticosteroids can be administered as 1 mg/kg/day prednisolone tapered to 0.25 mg/kg/day by 3 months.[58] The corticosteroid treatment is combined with 2 mg/kg/day oral cyclophosphamide or IV cyclophosphamide at 0.5 g/m^2 per month adjusted upward to

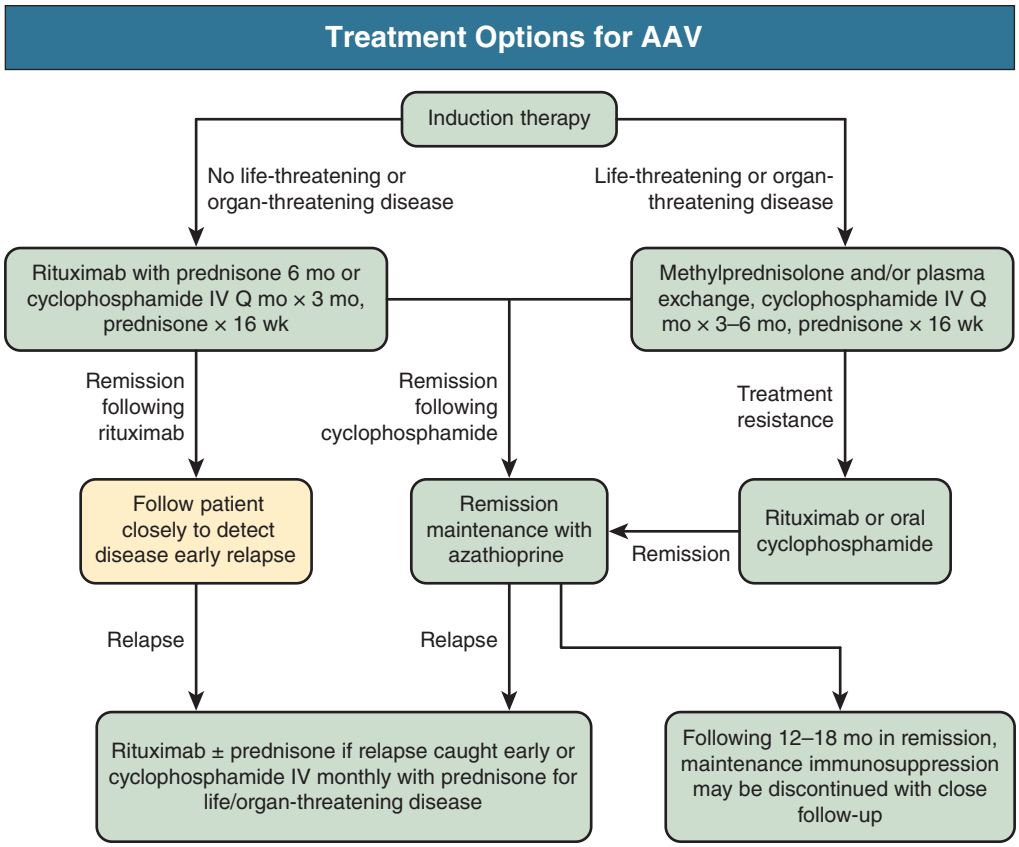

Figure 25-11 **Algorithm of recommended treatment for ANCA-associated vasculitis.**

1 g/m^2 on the basis of the leukocyte count after 2 weeks with a target nadir of 3000 cells/mm^3. The dose of oral cyclophosphamide can be reduced by 25 mg for patients older than 60.[58] A comparison by the European Vasculitis Study Group (CYCLOPS trial) indicated that IV cyclophosphamide results in the same remission rates as oral cyclophosphamide while reducing the total dose of cyclophosphamide.[62]

The U.S. Food and Drug Administration (FDA) has approved rituximab for use as induction therapy for AAV based on the results of two randomized controlled trials (RCTs) noting that rituximab-based cyclophosphamide-sparing strategies were comparable to traditional cyclophosphamide induction protocols.[60,61] The Rituximab for ANCA-associated Vasculitis (RAVE) trial noted no difference in remission off all therapy in 6 months between patients treated with four infusions of 375 mg/m^2 rituximab plus prednisone and those receiving oral cyclophosphamide with prednisone (64% in rituximab arm, 55% in cyclophosphamide arm). The RITUXVAS trial compared 6 to 10 infusions of cyclophosphamide followed by maintenance therapy with azathioprine to four infusions of 375 mg/m^2 rituximab in combination with two infusions of cyclophosphamide without maintenance therapy. There was no difference in remission rates at 12 months between the groups. In both RAVE and RITUXVAS, enthusiasm is tempered by higher adverse event rates, which may signify no improvement in safety over cyclophosphamide. This is somewhat disappointing because there was hope that targeted B cell therapy would have less adverse events than broader-spectrum immunosuppression.

Plasma exchange may be of benefit in patients with life-threatening pulmonary hemorrhage[63] and patients who have dialysis-dependent renal failure at presentation.[64] With pulmonary hemorrhage, 20 of 20 patients treated with early plasma exchange had resolution of pulmonary bleeding compared with a 50% mortality in historical controls.[63] A trial by the European Vasculitis Study Group (MEPEX) evaluated the efficacy of IV methylprednisolone as induction therapy or plasma exchange in patients who had a serum creatinine of more than 500 µmol/l.[64] Results from this study suggest that plasma exchange compared with pulse methylprednisolone in this population increases the rate of recovery from renal failure. Patient survival and adverse events were similar in patients who did or did not receive plasma exchange. Plasma exchange was associated with a 24% reduced risk of progression to end-stage renal disease (ESRD), from 43% to 19% at 1 year.

Maintenance Therapy

The duration of induction therapy and the intensity of maintenance therapy should be decreased as much as possible to reduce toxic side effects. This is a difficult challenge because of the tendency of AAV to recur. A number of approaches have been used to reduce the cyclophosphamide dose, such as giving less cyclophosphamide through IV rather than oral schedules,[54] substituting a less toxic maintenance drug after 3 to 6 months,[58] and discontinuing therapy earlier in patients with lower risk of relapse. IV cyclophosphamide regimens afford one-third to one-half the total dose of cyclophosphamide given in oral regimens. Long-term follow up, however, notes longer time to relapse in the oral cyclophosphamide treated group, at the cost of increased leukopenia.[65] Another approach to reducing cyclophosphamide dose is to substitute azathioprine after 3 to 6 months of therapy.[49,58] In the European Vasculitis Study Group CYCAZAREM trial, cyclophosphamide was replaced with 2 mg/kg/day azathioprine after 3 to 6 months with no change in the relapse rate at the end of the study.[58] Azathioprine (2 mg/kg/day) has been compared to mycophenolate mofetil (MMF 2 g/day) in a randomized control fashion, noting that relapses were more common in the

MMF group compared to the azathioprine group (unadjusted HR for MMF 1.69; 95% CI 1.06 to 2.70). Adverse events, disease activity score, GFR, and proteinuria did not differ between the groups.[66]

Cyclophosphamide dose also could be reduced by alternative induction therapies. The French Vasculitis Study Group examined methotrexate compared with azathioprine as maintenance therapy in patients with GPA and MPA.[67] In this study, methotrexate was as effective as azathioprine for maintenance of remission, but methotrexate did not have fewer side effects. Of special note to nephrologists, methotrexate should not be used in patients with low GFR. An attractive alternative is to stop induction therapy at 6 to 12 months if the patient is in full remission, especially if the patient is at lower risk of relapse.[52]

Although there are proponents of reinfusion strategies every 4 to 6 months with rituximab,[68,69] enthusiasm is substantially diminished for repetitive use of rituximab for remission maintenance for at least four reasons. First, the 18-month data from the RAVE trial suggest equal efficacy and also equal numbers of adverse events when compared with 6 months of oral cyclophosphamide and 12 months of azathioprine. Thus, the rituximab approach is not without significant adverse events. Second, a number of patients, especially those with MPO-ANCA, may not need remission maintenance therapy. Rather, they need careful supportive care. Third, rituximab has a significant amount of immunogenic mouse protein as part of its structure, so a growing number of patients have become sensitized to this biologic agent, and some have developed serum sickness–like disease. Thus, when these patients need rituximab for clinical disease activity, it may not be an option. Fourth, the expense of rituximab may become prohibitive for some patients.

The role of antimicrobial agents such as trimethoprim-sulfamethoxazole in maintenance of remission is controversial. Some studies have suggested a benefit, but others have not because of an increased likelihood of relapse.[70,71] TMP-SMX may be useful adjunct therapy, especially in patients with upper respiratory disease, but should not be used in the absence of immunosuppressive drugs with more proven efficacy (e.g., cyclophosphamide, azathioprine) for induction or maintenance therapy for systemic vasculitis or GN.

Relapse Therapy

Approximately one fourth to one half of patients with AAV will experience a relapse within several years. Relapses are diagnosed on the basis of clinical and pathologic evidence of recurrent disease, not by an increase in ANCA titer alone.[44] However, an increase in ANCA titer increases the likelihood of a relapse, and some advocate preemptive immunosuppressive therapy if the ANCA titer increases by at least fourfold.[44] We prefer to identify clear-cut clinical or pathologic evidence of relapse before increasing immunosuppressive therapy.[54]

Observational data suggest that the best treatment for relapses may be rituximab. There is mounting evidence that use of rituximab for relapse is superior to cyclophosphamide.[60] Reinstitution of treatment similar to an induction regimen is used most often, but less intensive or less toxic therapy may be adequate.[46,54,55] In addition to rituximab or cyclophosphamide, a number of therapies can be used in the treatment of relapse, including azathioprine, MMF, methotrexate, or combinations of these drugs tailored to the individual patient with recalcitrant disease.

In some individuals, long-term therapy may not be required, especially if there is a very low risk of relapse. In prospective observational studies from the Glomerular Disease Collaborative Network, the relative risk of relapse was increased in those individuals who had PR3-ANCA and respiratory tract disease.[52] Patients had more than a threefold risk of relapse compared with those individuals with MPO-ANCA and without lung or ear, nose, and throat disease. In a follow-up study, this model of relapsing disease was investigated in a separate registry in France, in which PR3-ANCA and lung disease was the most important predictive marker.[72] Thus, in those who have a much smaller risk of relapse, all therapy may be stopped, provided the patient and physician pursue a monitoring course in which the risk of early relapse is detected (e.g., home urinary dipstick testing to monitor for recurrence of hematuria). The risk of relapse is about 10% to 15% even with remission maintenance therapy.

Transplantation

Renal transplantation is not contraindicated in patients with ESRD caused by AAV. In a multicenter experience, the vasculitis relapse rate was 0.02 per patient-year[73] (see Chapter 108). A positive ANCA titer at the time of transplantation does not increase the risk of recurrent disease in the transplant.[74,75] Recurrent ANCA GN in a renal transplant responds similarly to recurrent disease in native kidneys.[64] As with native kidney disease, an increase in ANCA titer and an active urine sediment should suggest recurrent GN, but the diagnosis requires pathologic confirmation.

POLYARTERITIS NODOSA

Polyarteritis nodosa is a systemic necrotizing arteritis that affects predominantly main visceral arteries and their intraparenchymal branches.[1,4,5,76] The Chapel Hill nomenclature system limits the diagnosis of polyarteritis nodosa to patients who have only arteritis.[4] The presence of vasculitis in vessels other than arteries, such as capillaries, venules, or arterioles, excludes a diagnosis of polyarteritis nodosa and indicates some form of small-vessel vasculitis. Thus, GN excludes a diagnosis of polyarteritis nodosa. When polyarteritis nodosa is distinguished from MPA by this approach, the two categories of vasculitis have not only different pathologic characteristics but also different clinical features and natural histories, which justifies the nosologic distinction between polyarteritis nodosa and MPA.[76-80]

Pathogenesis

The etiology and pathogenesis of polyarteritis nodosa are unknown. When polyarteritis nodosa is separated from MPA, the latter but not the former is associated with ANCA. An immune complex trigger for polyarteritis nodosa has been proposed but has not been confirmed as the major pathogenetic process. A minority of patients have hepatitis B virus (HBV) infection, suggesting that the HBV infection is producing immune complexes that are localizing in arterial walls and inducing inflammation.[80] However, the evidence that HBV infection is causing vascular immune complex deposition is stronger in certain forms of GN and small-vessel vasculitis than in polyarteritis nodosa.

Epidemiology

When defined by the Chapel Hill nomenclature system, polyarteritis nodosa had a prevalence of approximately 3 in 100,000 population in a study of an urban area in France.[31] This is a higher prevalence for polyarteritis nodosa than for the ANCA-associated vasculitides than has been reported in other studies, perhaps influenced by environmental factors. Polyarteritis nodosa affects males and females equally and is found in all races. Onset occurs most frequently between ages 40 and 60 years.

Clinical Manifestations

The usual clinical presentation of polyarteritis nodosa includes nonspecific constitutional symptoms, such as fever, malaise, arthralgias, myalgias, and weight loss, as well as manifestations of arteritis.[76-80] Peripheral neuropathy, typically in the form of a mononeuritis multiplex, is a common manifestation. This is caused by inflammation of small epineural arteries and is clinically indistinguishable from the peripheral neuropathy caused by other forms of vasculitis that can affect epineural arteries, such as MPA, GPA, and EGPA. Gastrointestinal involvement occurs in about half of patients, usually manifesting as abdominal pain and blood in the stool. Bowel infarction is uncommon and perforation rare. Renal involvement produces infarction and hemorrhage, as indicated by flank pain and hematuria. Rupture of an arterial aneurysm with retroperitoneal or peritoneal hemorrhage is an uncommon but potentially lethal renal complication. Approximately one third of patients develop hypertension, which rarely reaches the malignant range. Red, tender inflammatory nodules are the most common cutaneous manifestation. Infarction, ulceration, and livedo reticularis may be present.

Arterial aneurysms may be detected by angiography in patients with polyarteritis nodosa (Fig. 25-12). This is not a completely specific determination because any necrotizing arteritis that affects arteries large enough to be seen by angiography can produce this finding.

Pathology

Any artery in the kidney can be affected by polyarteritis nodosa, from the main renal artery to the interlobular arteries, although the interlobar and arcuate arteries are affected most often.[1] Nodular inflammatory lesions and aneurysms (pseudoaneurysms) can be observed grossly when medium-sized arteries are involved. Inflammation in small arteries can be observed only by microscopy.

The characteristic acute lesion is segmental transmural fibrinoid necrosis of arteries, usually accompanied by infiltrating leukocytes with leukocytoclasia[3] (Fig. 25-13). The earliest lesions have numerous neutrophils, and later lesions have predominantly mononuclear leukocytes. Acute lesions may be complicated by thrombosis or hemorrhage. Older lesions develop fibrosis and endarterial remodeling. The aneurysms of necrotizing arteritis are not true aneurysms but rather inflammatory pseudoaneurysms. That is, the walls of the arteries are not dilated but rather have been eaten away by the necrotizing inflammation, which then erodes into the surrounding perivascular tissue to create an enlarged lumen at the site of inflammation. This explains the propensity for such lesions to induce thrombosis or to undergo rupture.

The necrotizing arteritis of polyarteritis nodosa cannot be distinguished by light microscopy from arteritis caused by other necrotizing vasculitides affecting arteries.[1,2] For example, necrotizing arteritis in a skeletal muscle biopsy specimen or a peripheral nerve biopsy specimen is histologically identical whether caused by polyarteritis nodosa, MPA, GPA, or EGPA. For these vasculitides to be distinguished, additional clinical and serologic information is required.

Differential Diagnosis

Clinical features may assist in distinguishing polyarteritis nodosa from other forms of vasculitis, especially other forms of necrotizing vasculitis that can affect arteries, such as MPA[79] (Table 25-5). A

Polyarteritis Nodosa and Microscopic Polyangiitis: Distinguishing Features

Clinical Feature	Polyarteritis Nodosa	Microscopic Polyangiitis
Microaneurysms by angiography	Yes	No (rare)
Rapidly progressive nephritis	No	Yes (very common)
Pulmonary hemorrhage	No	Yes
Renovascular hypertension	Yes (10%-33%)	No
Peripheral neuropathy	Yes (50%-80%)	Yes (10%-20%)
Positive hepatitis B serology	Uncommon	No
Positive ANCA	Rare	Frequent
Relapses	Rare	Frequent

Table 25-5 Clinical differences between polyarteritis nodosa and microscopic polyangiitis. *(Modified from reference 34.)*

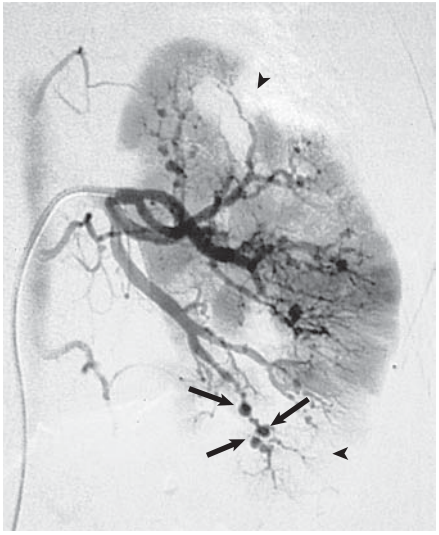

Figure 25-12 Renal angiogram in polyarteritis nodosa. Angiogram shows patchy renal perfusion defects *(arrowheads)* and aneurysms *(arrows)*.

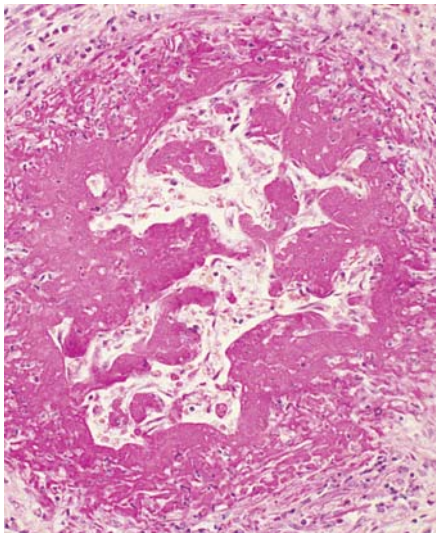

Figure 25-13 Necrotizing arteritis in arcuate artery of patient with polyarteritis nodosa. The lumen is partially occluded by thrombotic material that is continuous with the fibrinoid material that has replaced the entire wall of the artery. (HE stain; ×50.)

positive ANCA test result supports the diagnosis of one of the ANCA-associated small-vessel vasculitides rather than polyarteritis nodosa. The presence of GN indicates some form of small-vessel vasculitis rather than polyarteritis nodosa. Vasculitic pulmonary disease is rare in polyarteritis nodosa but common in MPA, GPA, and EGPA. Peripheral neuropathy or muscle tenderness with arteritis in epineural or skeletal muscle arteries is not a useful differentiating feature because it often occurs in polyarteritis nodosa as well as in the ANCA-associated small-vessel vasculitides. Kawasaki disease causes necrotizing arteritis but is distinguished from polyarteritis nodosa by the presence of the mucocutaneous lymph node syndrome.

Natural History

The natural history of polyarteritis nodosa is difficult to determine because most of the early studies of outcome grouped polyarteritis nodosa with MPA. Polyarteritis nodosa with multisystem involvement has a poor prognosis without therapy. The patient with polyarteritis nodosa usually is treated with corticosteroids and cytotoxic drugs such as cyclophosphamide.[78] The 10-year survival with appropriate treatment is approximately 80%. Approximately 15% of patients who enter remission develop a relapse, which is much less frequent than with MPA. Relapse is more likely if treatment is delayed.

Treatment

Polyarteritis nodosa in patients with no evidence of HBV infection is treated with corticosteroids and cytotoxic drugs, usually cyclophosphamide.[55,76-79] The regimens vary and include treatment approaches similar to those described earlier for MPA and GPA. However, in patients with no risk factors for poor outcome (e.g., age >50; cardiac, gut, or renal involvement), corticosteroids alone may be adequate and are less toxic therapy than corticosteroids combined with cytotoxic agents.

Aggressive immunosuppressive therapy without initial antiviral therapy is contraindicated in patients with HBV-associated polyarteritis nodosa because of potential adverse effects on the outcome of the HBV infection. Short-term corticosteroid treatment combined with antiviral agents and possibly plasma exchange should precede more extensive immunosuppression in such patients.[77,80] The European League Against Rheumatism (EULAR) recommends initial treatment with high-dose corticosteroids, then tapered over 2 weeks, followed by antiviral treatment.[55] The addition of plasma exchange may increase the likelihood of remission.

KAWASAKI DISEASE

Definition

Kawasaki disease is an acute febrile illness that usually occurs in young children, often under 1 year, and is characterized by the mucocutaneous lymph node (MCLN) syndrome (see later discussion).[4,81-83] Necrotizing arteritis is a complication of Kawasaki disease that is present in some but not all patients. Clinically significant renal involvement is very rare; therefore, Kawasaki disease is rarely encountered by nephrologists.

Pathogenesis

The occasional occurrence of Kawasaki disease as an endemic or epidemic disease suggests that the cause may be an infectious agent or an environmental toxin. Both cell-mediated and antibody-mediated mechanisms have been incriminated, including a possible role for antiendothelial antibodies.[83] At present, the etiology and pathogenesis of Kawasaki disease are unproven.

Epidemiology

Kawasaki disease usually occurs in children younger than 5 years and has a peak incidence in the first year of life. It was first described in Japan, but it occurs worldwide. The disease is more common in Asians and Polynesians than in Caucasians and blacks. In Japan, the incidence is 50 in 100,000 children younger than 5 years, with 50% of the children younger than 2.[84] Kawasaki disease occasionally occurs in an endemic or epidemic pattern but usually is sporadic.

Clinical Manifestations

The MCLN syndrome is the characteristic clinical manifestation of Kawasaki disease.[4,83] This includes fever (temperature of usually 38° to 40° C), mucosal inflammation, swollen red tongue (strawberry tongue), polymorphous erythematous rash, indurative edema of the extremities, erythema of palms and soles, desquamation from the tips of digits, conjunctival injection, and enlarged lymph nodes. The frequency of active arteritic lesions peaks during the first week of the illness and is greatly reduced after 1 month. Arteritis most often is manifested as cardiac disease. Thrombosis of inflamed coronary arteries in patients with Kawasaki disease is the most common cause of childhood myocardial infarction. Clinically significant renal disease is uncommon. This is somewhat surprising because autopsy reveals arteritis in renal vessels in up to three fourths of patients.[81]

Pathology

The arteritis of Kawasaki disease involves small and medium-sized arteries. The acute histologic lesion is necrotizing inflammation with less fibrinoid necrosis and more edema than usually observed with polyarteritis nodosa[81] (Fig. 25-14). Aneurysm (pseudoaneurysm) formation and thrombosis may occur. The most frequent site of arteritis is the coronary arteries, followed by the renal arteries.[81] Arteritis most often affects interlobar arteries, occasionally arcuate arteries, and only rarely interlobular arteries.

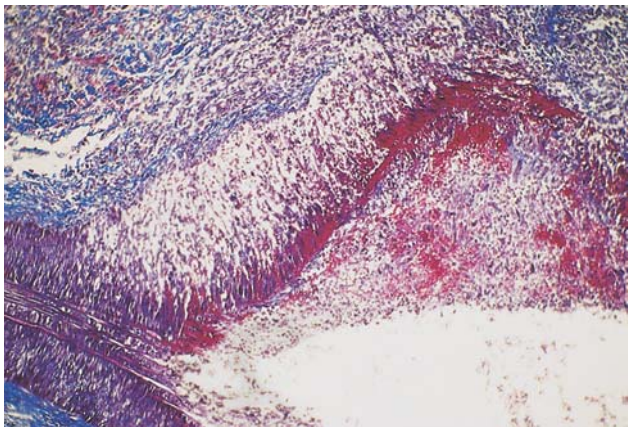

Figure 25-14 Kawasaki disease arteritis affecting renal interlobar artery in young child. The artery wall is intact on the far left. The remainder of the wall has extensive edema, infiltration by mononuclear leukocytes, and a band of fuchsinophilic *(red)* fibrinoid material roughly at the junction between the inflamed intima and muscularis. (Masson trichrome; ×25.)

Differential Diagnosis

Kawasaki disease has sometimes been misdiagnosed as childhood polyarteritis nodosa. The differentiation of Kawasaki disease from polyarteritis nodosa is important because corticosteroid treatment may increase the risk of coronary artery aneurysms in Kawasaki disease. Arteritis in a child younger than 5 years should always raise the possibility of Kawasaki disease. The presence or absence of the MCLN syndrome is the basis for distinguishing between Kawasaki disease and other forms of arteritis.[4]

Natural History

Kawasaki disease usually is self-limited, with an uneventful recovery if treated promptly with intravenous gamma globulins.[82,83] Recurrence is rare. Only about 1% of patients develop severe arteritic complications, usually affecting the coronary arteries.

Treatment

Aspirin and IV gamma globulin are the standard therapy for Kawasaki disease.[82,83] Corticosteroid treatment may increase the risk of adverse coronary artery complications, although the data supporting this are limited.

TAKAYASU ARTERITIS AND GIANT CELL ARTERITIS

Takayasu arteritis and giant cell arteritis affect predominantly the aorta and its major branches.[4,85] Giant cell arteritis has a predilection for the extracranial branches of the carotid artery but can affect arteries in almost any organ. Takayasu arteritis has a predilection for major arteries supplying the extremities. Both diseases cause chronic vascular inflammation, often with a granulomatous appearance that may include multinucleated giant cells. Giant cell arteritis, but not Takayasu arteritis, is associated with polymyalgia rheumatica.

Pathogenesis

The etiology and pathogenesis of giant cell arteritis and Takayasu arteritis are unknown. Because of the histologic changes and the nature of the infiltrating leukocytes, cell-mediated immune mechanisms are incriminated. The inciting antigen or autoantigen has not been identified.

Epidemiology

Takayasu arteritis is seen most frequently in Asia. Giant cell arteritis occurs most often in individuals of northern European ancestry. Takayasu arteritis has a female-to-male ratio of approximately 9:1, and giant cell arteritis, 4:1. Takayasu arteritis usually is diagnosed in those between ages 10 and 20 years and is rare after age 50. Giant cell arteritis is rare before age 50.

Clinical Manifestations

In addition to nonspecific constitutional symptoms, such as fever, arthralgias, and weight loss, the major clinical manifestations of Takayasu arteritis and giant cell arteritis are caused by arterial narrowing and resultant ischemia.[74] The major clinical manifestations of Takayasu arteritis are reduced pulses (95% of patients), vascular bruits, claudication, and renovascular hypertension. Renovascular hypertension is a major cause of morbidity and mortality and results from renal ischemia caused by renal artery stenosis or aortic coarctation.[85,86] Reduced aortic elasticity and impairment of carotid artery baroreceptors also may play a role in some patients. EULAR recommends thorough imaging assessment of the entire major arterial tree when a diagnosis of Takayasu arteritis is suspected.[87]

Headache is the most common presenting symptom in patients with giant cell arteritis. Temporal artery tenderness, nodularity, or decreased pulsation is present in about half of patients. Additional common symptoms include blindness, deafness, jaw claudication, tongue dysfunction, extremity claudication, and reduced pulses. More than half of patients with giant cell arteritis have polymyalgia rheumatica, characterized by stiffness and aching in the neck and the proximal muscles of the shoulders and hips. Clinically significant renal disease is much rarer in giant cell arteritis than in Takayasu arteritis. There are case reports of necrotizing and crescentic GN associated with giant cell arteritis, but these may represent examples of GPA or MPA with temporal artery involvement.

Pathology

The aortitis and arteritis of Takayasu arteritis and giant cell arteritis cannot be confidently differentiated by pathologic examination.[4] Both are characterized in the active phase by inflammation with a predominance of mononuclear leukocytes, often with scattered multinucleated giant cells (Fig. 25-15). The chronic phase is characterized by progressive fibrosis that may cause severe narrowing of vessels, with resultant ischemia. Major renal arteries are often found to be involved at autopsy in both Takayasu arteritis and giant cell arteritis patients. However, clinically significant renal disease is relatively common in Takayasu arteritis but rare in giant cell arteritis. A glomerular lesion characterized by nodular mesangial matrix expansion and mesangiolysis may occasionally be a component of Takayasu arteritis.[88]

Differential Diagnosis

There is a great deal of overlap between the clinical manifestations and pathologic features of Takayasu arteritis and giant cell arteritis. Patient age and presence or absence of polymyalgia rheumatica are the best factors for discriminating between these two vasculitides. Giant cell arteritis also has been called "temporal arteritis," but this is misleading because not all patients have temporal artery involvement, and patients with other types of vasculitis (polyarteritis nodosa, GPA, MPA) can have involvement of the temporal arteries.

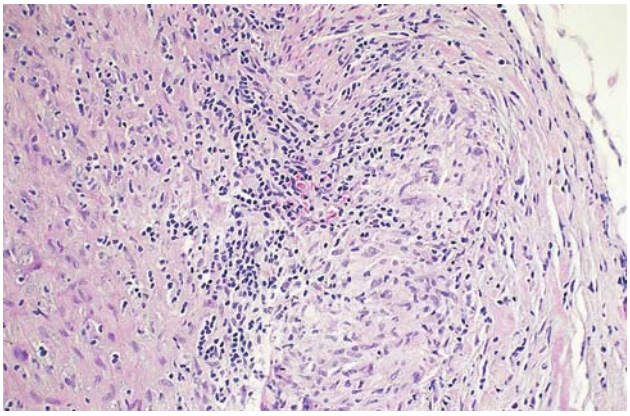

Figure 25-15 Severe giant cell arteritis affecting a main renal artery. This caused marked renal atrophy and renovascular hypertension. (HE stain; ×50.)

Some of the reported examples of necrotizing GN associated with temporal arteritis probably represent GPA or MPA with temporal artery involvement.

Treatment

Corticosteroids are the usual treatment of giant cell arteritis and Takayasu arteritis.[87] EULAR recommends initial daily therapy with prednisolone (1 mg/kg) for 1 month followed by tapering over several months.[87] More prolonged treatment may be dictated by persistent disease activity. Cytotoxic agents such as cyclophosphamide may be required in patients with recalcitrant disease. Patients with giant cell arteritis also should receive low-dose aspirin to protect against thrombotic vascular events.[87]

Management of renal disease is not an issue with typical giant cell arteritis, although rare patients have ischemic renal manifestations. Renovascular hypertension is the major renal problem caused by Takayasu arteritis.[85,86] When bilateral renal artery involvement occurs, angiotensin-converting enzyme (ACE) inhibitors may precipitate renal failure in patients with Takayasu arteritis.[89] When medical management fails, the renovascular hypertension in patients with Takayasu arteritis may be controlled by bypass surgery or angioplasty.[86] Reconstructive vascular surgery should be performed during a quiescent phase of the disease.[87] The management of renovascular hypertension is covered in Chapter 39.

CHAPTER 26

Lupus Nephritis

Gerald B. Appel, David Jayne, and Brad H. Rovin

DEFINITION

Lupus nephritis (LN) is an immune complex glomerulonephritis that is a common and serious feature of systemic lupus erythematosus (SLE), which itself is defined by a combination of clinical and laboratory features.[1,2] The American College of Rheumatology (ACR) criteria for the diagnosis of SLE have been widely used in both epidemiologic and treatment studies (Box 26-1). However, many patients with "lupus-like" conditions and others who meet fewer than four ACR criteria should still be recognized as requiring therapy.

EPIDEMIOLOGY

The incidence and prevalence of lupus and LN are influenced by age, gender, ethnicity, geographic region, diagnostic criteria used, and method of ascertainment, but across populations, clinically important kidney disease will occur in 40% of patients[3-7] (Table 26-1). The peak incidence of lupus is age 15 to 45 years, with women outnumbering men by 10:1. This gender predominance is less pronounced in children and older individuals. Among lupus patients, LN affects both genders equally and is more severe in children and men and less so in older adults. Both lupus and LN are three to four times more common in blacks, Asians, and Hispanics than in Caucasians. Additional risk factors for LN include younger age, lower socioeconomic status, more ACR criteria for SLE, longer disease duration, family history of SLE, and hypertension.

ETIOLOGY AND PATHOGENESIS

Genetics, Environment, and Animal Models

Multiple genes predispose to lupus.[8] This is supported by the clustering in families, racial differences in susceptibility, concordance of SLE in more than 25% of identical twins but only in 5% of fraternal twins, and frequency of positive autoantibodies and other autoimmune disorders in family members of SLE patients. Homozygous deficiency of complement components (C1q, C2, C4) carries a high risk for development of SLE; this is also true for certain FcγRIII receptor polymorphisms. Genome-wide association studies have identified 17 loci associated with an increased risk of SLE that involve genes associated with B cell signaling, Toll-like receptors, and neutrophil function.[8] Environmental factors also play a role in the onset and exacerbation of SLE and LN.[9] Hormonal factors are suggested by the strong female predisposition, the exacerbations during or shortly after pregnancy, and the role of hormonal treatment and ablation in animal models of LN. Whereas exposure to certain medications can produce SLE or a lupus-like syndrome, LN occurs infrequently in these patients. Conclusive evidence for a viral pathogenesis of SLE or LN has yet to be produced. Spontaneous and inducible models of SLE in mice include the NZB B/W F1 hybrid, the BXSB, and the MRL/lpr mice. Some of these models have defective apoptosis that lead to defective clonal deletion and B cell proliferation. SLE can be induced in animals by injection of autoantibodies against DNA, phospholipids, or peptides derived from the Smith antigen.

Autoimmunity in Systemic Lupus Erythematosus

Patients with SLE typically develop a wide range of autoantibodies.[10] Early stages of disease evolution include the defective clearance of apoptotic cells and release of autoantigens from these cells, stimulating interferon-α (IFN-α) and proinflammatory cytokine production. This results in a breakdown of self-tolerance, autoantibody production, and immune complex deposition. Many autoantibodies are directed against nucleic acids and proteins concerned with transcriptional and translational machinery, such as nucleosomes (DNA-histone), chromatin antigens, and small nuclear and cytoplasmic ribonuclear proteins. Polyclonal hyperactivity of B cells along with defective autoregulation of T cells is thought to underlie autoantibody production.[10,11]

A number of mechanisms may contribute to SLE, including failure to remove or to silence autoreactive B and T cells, abnormal exposure to or presentation of self antigens, T cell hyperactivity, increased B cell–stimulating cytokines, and B cell hyperactivity.[10] The failure of apoptotic mechanisms to delete or to silence autoreactive cells (tolerance) may allow clonal expansion of such cells later in life, leading to autoantibody production. Abnormal exposure to self antigen may occur through nuclear autoantigens clustering on the blebs of apoptotic cells, which may be associated with germ-line mutations that lead to clonal expansion of autoreactive cells. Likewise, "antigen mimicry" may occur if exposure to viral or bacterial peptides containing sequences similar to native antigens leads to a similar induction of autoantibody-producing cell lines. The nature of antigen presentation may also be important, with certain nuclear antigens capable of triggering an immunogenic response through interactions with a variety of intracellular Toll-like receptors. In SLE, there is evidence that T cell hyperactivity and failure of T cell tolerance may allow autoreactive T cells to drive B cell proliferation and the production of autoantibodies. Also, proliferation of autoreactive B cells may occur through a variety of disturbances of positive and negative regulatory mechanisms (e.g., stimulation by superantigens) in addition to the mechanisms mentioned. The end result is the loss of tolerance and production of a wide array of autoantibodies.[10,11]

PATHOGENESIS OF LUPUS NEPHRITIS

Autoantibodies are crucial to the pathogenesis of both SLE and LN. In SLE, some autoantibodies, such as those causing autoimmune hemolytic anemia, are directly pathogenic. Other autoantibodies

ACR Criteria for Diagnosis of Lupus

The presence of four or more of the following criteria gives 96% sensitivity and specificity for the diagnosis of lupus:

1. Malar rash
2. Discoid rash
3. Photosensitivity
4. Oral ulcers
5. Nonerosive arthritis
6. Pleuropericarditis
7. Renal disease (proteinuria and/or cellular casts)
8. Neurologic disorder (seizures or psychosis in the absence of precipitating circumstances)
9. Hematologic disorder (hemolytic anemia, leukopenia/lymphopenia, thrombocytopenia)
10. Positive LE cell preparation, raised anti-DNA antibody, anti-Sm present, false-positive antitreponemal test
11. Positive fluorescent antinuclear antibody test

Box 26-1 American College of Rheumatology (ACR) criteria for the diagnosis of lupus.

Renal Manifestations in Patients with Lupus

Manifestation	Prevalence (%)
Proteinuria	100
• Nephrotic syndrome	45-65
Hematuria	
• Microhematuria	80
• Red blood cell casts	10
• Macrohematuria	1-2
Cellular casts	30
Reduced renal function	40-80
• Rapidly progressive glomerulonephritis	10-20
• Acute kidney injury	1-2
Hypertension	15-50
Hyperkalemia	15

Table 26-1 Frequency of kidney manifestations in lupus patients with renal involvement.

combine with antigen to produce immune complexes that if not adequately cleared may deposit in various organs, inciting inflammatory responses.[1] Complement components aid apoptotic clearance and removal of immune complexes, but they are also activated by immune complexes and contribute to the inflammatory cascade. A hallmark of glomerular involvement in LN is the accumulation of immune complexes. Patients with LN have autoantibodies against double-stranded DNA (dsDNA), Sm antigen, C1q, nucleosomes, and other antigens, and there is evidence both for direct binding of anti-DNA antibodies to the glomerular basement membrane (GBM) and for cross-linking of positively charged nucleosome components such as chromatin between autoantibodies and GBM.[12-14] In proliferative LN, DNA and high-affinity complement-fixing antibodies are found in the subendothelial space, and this may be facilitated by cationic histones binding to the negatively charged GBM. In general, mesangial and subendothelial immune deposits are derived from deposition of circulating immune complexes, whereas subepithelial immune complexes may include those formed *in situ*. However, whether deposition of circulating complexes or *in situ* formation is the predominant pathogenic pathway in a given patient is not always clear. The localization of immune complexes within the glomerulus is influenced by size, charge, specificity, and avidity as well as by the clearing ability of the mesangium and local hemodynamics.[12-16] The localization of immune complexes in the glomerulus leads to complement activation and complement-mediated damage, activation of procoagulant factors, leukocyte Fc receptor activation driving leukocyte infiltration into the kidneys with release of their proteolytic enzymes, and activation of cytokines associated with cellular proliferation and matrix formation. Nucleosomes can also activate resident dendritic cells (see later) through binding to Toll-like receptors 2 and 9. Intraglomerular hypertension and activation of coagulation cascades may contribute to the glomerular injury, especially in patients with antiphospholipid antibodies (aPLAs, APA).

The obligatory role of autoantibodies and immune complexes in the pathogenesis of LN has been challenged. In a mouse model of SLE in which B cell secretion of antibodies is prevented, LN still developed, although the glomerular histology was not as inflammatory as in wild-type mice.[17] Also renal biopsies from lupus patients without clinical LN still show immune deposits.[18,19] It is thus unclear why all patients with SLE do not develop LN, and this suggests renal immune complexes may be necessary but not sufficient for the development of the full clinical phenotypes of LN.

T cell subsets appear to contribute to the progression of LN. T helper type 17 (Th17) cells have been observed in human renal biopsies, and by producing interleukin-17 (IL-17) locally, may drive the expression of inflammatory cytokines and chemokines by renal parenchymal cells, recruiting and activating neutrophils and monocytes. Th17 cells in the kidney may reflect a shift away from T regulatory cells ($CD4^+CD25^{hi}FoxP3^+$), which inhibit immune responses and autoantibody production.[20]

There has been increasing recognition of the role of neutrophils in SLE and LN. Neutrophils undergo a novel form of cell death called NETosis in which a chromatin meshwork (a NET) is released.[21] These NETs (neutrophil nets) are a source of autoantigens and are not degraded properly in lupus patients. In addition, lupus patients have an increased number of low-density granulocytes that are more susceptible to NETosis. NET material has been found in LN biopsies, and SLE patients who are nondegraders often had LN.[22,23] The NETs induce production of IFN-α by plasmacytoid dendritic cells, which are also found in LN kidneys.[24,25] IFN-α appears to have a central role in SLE and LN. IFN-α drives dendritic cell maturation to antigen-presenting cells, B cell differentiation to antibody-producing plasma cells, and development of effector and memory T cells.[26-29]

Within the kidney interstitium, T and B cells may associate and in some cases develop germinal centers.[30] These B cells show clonal expansion and somatic hypermutation, suggesting intrarenal autoantibody production, potentially against specific renal antigens. These interactions likely contribute to interstitial inflammation in LN, which is a major determinant of long-term renal survival.[30]

CLINICAL MANIFESTATIONS

Systemic lupus erythematosus can affect virtually any organ of the body. The disease course is characterized by episodes of illness (flares) followed by periods of relative quiescence (remissions). Nonhealing damage is a consequence of inflammation and is a strong predictor of outcome. A number of reliable and reproducible scoring systems have been devised to follow the activity and development of damage of an individual patient with SLE. These include the Systemic Lupus Erythematosus Disease Activity Index (SLEDAI), the British Isles Lupus Assessment Group (BILAG), the Systemic Lupus Activity

Measure (SLAM), and the Systemic Lupus International Collaborating Clinic–American College of Rheumatology (SLICC-ACR) damage score. SLE often results in profound disturbance of quality of life and disruption of economic and reproductive activity.

Renal Manifestations

Renal involvement is usually manifested by proteinuria, active urinary sediment with microhematuria, dysmorphic erythrocytes and erythrocyte casts, and hypertension. In many cases with major renal involvement, the nephritic syndrome develops in association with proliferative glomerulonephritis (GN) and a decline in glomerular filtration rate (GFR). Clinical findings correlate well with histologic glomerular findings (see later discussion). Infrequently, renal disease in SLE presents with tubular disorders such as distal renal tubular acidosis with hypokalemia (type 1 RTA) or hyperkalemia (type 4 RTA) (see Chapter 12), thrombotic disorders associated with a secondary antiphospholipid antibody syndrome (see later and Chapter 28), and fibrillary GN (see Chapter 27).

Extrarenal Manifestations

Patients with active SLE often present with nonspecific complaints of malaise, low-grade fever, poor appetite, and weight loss. Other common features include patchy alopecia; oral or nasal ulcerations; arthralgias and nondeforming arthritis; and a variety of dermal findings, including photosensitivity, Raynaud's phenomenon, and the classic "butterfly" facial rash. Livedo reticularis is seen in up to 15% of cases and may be associated with miscarriages, thrombocytopenia, and APA.[31] Neuropsychiatric involvement presents with headache, nerve palsies, frank coma, and psychoses. Serositis, in the form of pleuritis or pericarditis, affects up to 40% of patients. Pulmonary hypertension can develop silently as a result of multiple pulmonary emboli or intravascular coagulation in association with APA or may be caused by nonthrombotic pulmonary arterial disease. Libman-Sacks endocarditis and much more common mitral valve prolapse can be detected with clinical findings or by echocardiography. Splenomegaly and lymphadenopathy are present in about one fourth of patients. Hematologic abnormalities in SLE include anemia caused by impaired erythropoiesis, autoimmune hemolysis, and bleeding. Thrombocytopenia and leukopenia may be part of the disease process or may result from complications of therapy. Thrombotic events should prompt a search for APA and other procoagulant abnormalities.

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

Whereas the diagnosis of lupus may be obvious in a young female with classic manifestations and serologic markers, less typical presentations can result in multiple physician consultations and diagnostic delay. This is partly a result of the varied features of the disease and the evolution of signs and symptoms over time. Some patients, especially those with membranous LN, may present with renal disease as their initial manifestation. The presence of four or more ACR criteria carries a 96% sensitivity and specificity for lupus (see Box 26-1). However, the ACR diagnostic criteria were developed for clinical studies and do not always prove useful in an individual patient. Other diseases mimicking SLE include fibromyalgia, Sjögren's syndrome, hematologic diseases such as the thrombotic microangiopathies, primary antiphospholipid syndrome, dermatomyositis, and systemic sclerosis (see Chapters 28 and 29). However, SLE may also present with overlapping features of other multisystem or organ-limited autoimmune syndromes. Nephritis has been reported in patients with mixed connective tissue disease associated with the presence of anti-Ro and anti-La antibodies and the absence of anti-dsDNA antibodies. Rheumatoid arthritis can be associated with mesangial proliferative glomerulonephritis or renal disease due to AA (secondary) amyloidosis. Older lupus patients may present with joint deformities typical of rheumatoid arthritis.

Several common forms of glomerulonephritis must be distinguished from LN, since they may have some clinical features in common. These include Henoch-Schönlein purpura, antineutrophil cytoplasmic antibody (ANCA)–associated glomerulonephritis (see Chapter 24), bacterial endocarditis, and cryoglobulinemia. ANCAs of uncertain significance are detected in 20% of LN patients.

Immunologic Tests in Lupus

Antinuclear antibody (ANA), found in more than 90% of untreated patients, is a highly sensitive screen for SLE patients; however, ANAs are nonspecific and found in other rheumatologic and nonrheumatologic diseases as well. Some lupus-like patients with negative ANA test results have APA, and one third of SLE patients will have APA.[32-34] The pattern of ANA (e.g., diffuse, speckled) is not reliable in distinguishing lupus from other rheumatologic diseases. Autoantibodies against dsDNA are more specific, being present in 75% of untreated lupus patients, but are a less sensitive marker. Whereas high titers of anti-dsDNA antibodies correlate with the presence of SLE and are often used to follow the course of LN, antibodies to single-stranded DNA (ssDNA) are found in many rheumatologic conditions and do not correlate with the course of LN. Sm antibodies are strongly associated with the diagnosis of lupus and the presence of nephritis but are present in only about 25% to 30% of patients. Antibodies to C1q (anti-C1q) have been more closely associated with the activity of LN than anti-dsDNA antibodies and may have a prognostic role in the follow-up of patients with LN.[35]

Serum levels of total hemolytic complement and complement components C3 and C4 are often depressed in untreated SLE and especially LN patients. Either both C3 and C4 are depressed or C4 is preferentially depressed in lupus patients, usually reflecting preferential activation of the classical complement pathway. In patients with postinfectious glomerulonephritis (PIGN), C3 glomerulopathies and some idiopathic membranoproliferative GN, C3 is preferentially depressed (see Chapters 21 and 22). Alternatively, low C4 with normal C3 may reflect genetic C4 deficiency in lupus patients or the presence of cryoglobulins.

PATHOLOGY

Although LN may affect all structures of the kidney, glomerular involvement has been the best studied component and correlates well with the presentation, course, and treatment. The systematic classification systems for LN are based on glomerular involvement. The currently used International Society of Nephrology (ISN)/Renal Pathology Society (RPS) classification refines and clarifies some of the deficiencies of the previous WHO classification,[36] and has improved interobserver reproducibility and the predictive value of LN biopsies[37,38] (Table 26-2).

Classification of Lupus Nephritis

Class I of the ISN/RPS classification for LN denotes normal glomeruli by light microscopy but with mesangial immune deposits (Fig. 26-1). All higher classes of LN show mesangial immune deposits in

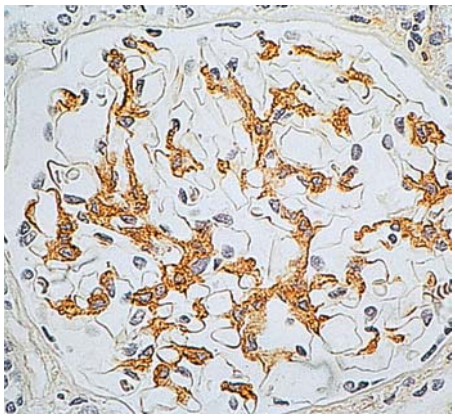

Figure 26-1 ISN/RPS class I: minimal mesangial lupus nephritis. Light microscopy is normal, but immunoperoxidase shows C1q localization (associated with IgG and C3) throughout the mesangial area.

ISN/RPS Classification of Lupus Nephritis

ISN/RPS (2004)	
Class	***Definition***
I	Minimal mesangial LN Normal glomeruli by LM, but mesangial immune deposits by IF
II	Mesangial proliferative LN Mesangial hypercellularity with mesangial immune deposits
III	Focal LN III (A): Purely active lesions: focal proliferative LN III (A/C): Active and chronic lesions: focal proliferative and sclerosing LN III (C): Chronic inactive lesions with glomerular scars: focal sclerosing LN
IV	Diffuse LN IV-S (A) or IV-G (A): Purely active lesions: diffuse segmental (S) or global (G) proliferative LN IV-S (A/C) or IV-G (A/C): Active and chronic lesions: diffuse segmental or global proliferative and sclerosing LN IV-S (C) or IV-G (C): Inactive with glomerular scars: diffuse segmental or global sclerosing LN
V	Membranous LN
VI	Advanced sclerosing LN ≥90% of glomeruli globally sclerosed without residual activity

Table 26-2 Classification of lupus nephritis (LN) using the ISN/RPS classification (2004). In the International Society of Nephrology/Renal Pathology Society (ISN/RPS) classification, the distribution of hypercellularity is assessed as mesangial, endocapillary, or extracapillary (crescentic) and as focal (with <50% glomerular involvement) versus diffuse (with ≥50% glomeruli affected). The distribution of immune deposits by immunofluorescence *(IF)* and electron microscopy *(EM)* is judged as mesangial, subepithelial, or subendothelial; *LM,* light microscopy.

addition to their specific differentiating features. *Class II,* mesangial proliferative LN, is defined as pure mesangial hypercellularity (more than three mesangial cells in areas away from the vascular pole in 3-μm-thick histologic sections) by light microscopy with mesangial immune deposits (Fig. 26-2). *Class III,* focal LN, is defined as focal segmental or global endocapillary or extracapillary glomerulonephritis affecting less than 50% of the total glomeruli sampled (Fig. 26-3). *Class IV,* diffuse LN, has diffuse segmental or global endocapillary or extracapillary GN affecting 50% or more of glomeruli (Fig. 26-4). Both class III and class IV have subendothelial immune deposits. Class IV is subdivided into diffuse segmental (IV-S) proliferation (i.e., >50% of affected glomeruli have segmental lesions) and diffuse global (IV-G) proliferation (i.e., >50% of affected glomeruli have global lesions). Both class III and class IV may have active (proliferative), inactive (sclerosing), or combined active and inactive lesions, subclassified as A, C, and A/C, respectively. *Class V,* membranous LN, is defined by subepithelial immune deposits (Fig. 26-5). The membranous alterations may be present alone or on a background of mesangial hypercellularity and mesangial immune deposits. Patients with additional true focal or diffuse proliferative lesions and subendothelial immune complex deposits are classified as V + III and V + IV under the ISN/RPS classification (see Table 26-2). *Class VI,* advanced sclerosing LN, is defined by global glomerular sclerosis affecting 90% or more of glomeruli.

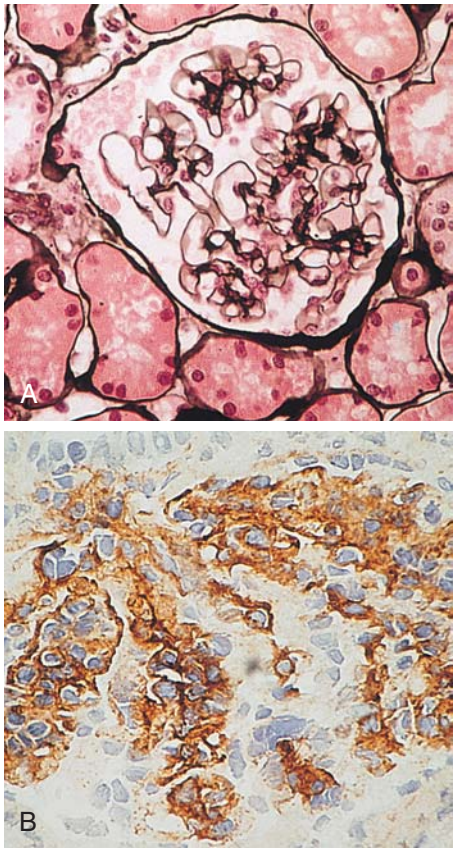

Figure 26-2 ISN/RPS class II: lupus nephritis (mesangial disease). A, Mesangial expansion but little increase in tuft cellularity, and the peripheral capillary walls are normal. (Silver methenamine stain.) **B,** Extensive mesangial IgG deposits shown by immunoperoxidase; the aggregates are just beginning to invade peripheral capillary walls.

On immunofluorescence (IF), IgG is almost always the dominant immunoglobulin, and early complement components such as C4 and especially C1q are usually present along with C3. The presence of all three immunoglobulins, IgG, IgA, and IgM, along with the two complement components, C1q and C3, so called "full-house" staining, is highly suggestive of LN, as is strong C1q staining. Fibrin is often present in the glomerular tuft and especially in crescents.

On electron microscopy (EM) the distribution of immune deposits corresponds to that of IF. Some electron-dense deposits have an organized substructure known as *fingerprinting,* corresponding to the presence of curvilinear microtubular or fibrillar structures

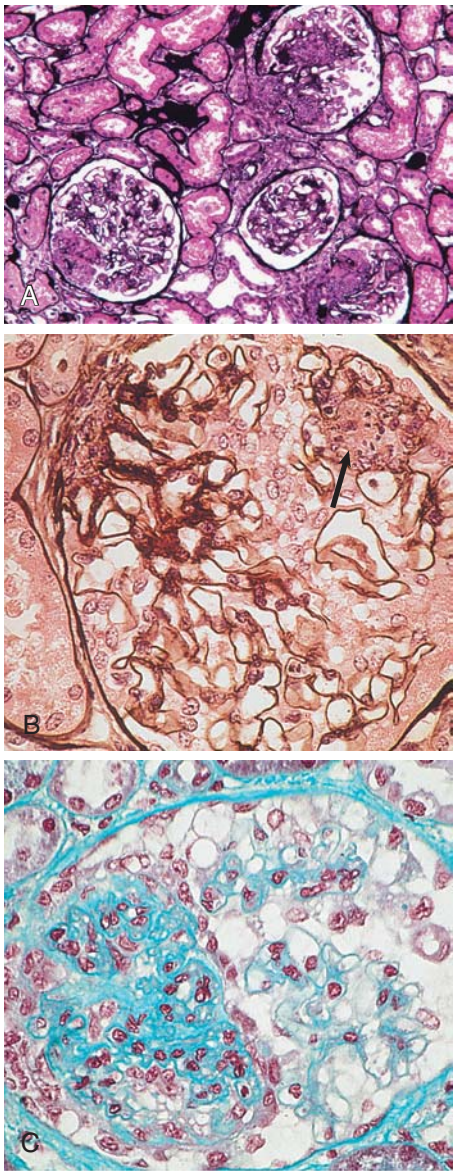

Figure 26-3 ISN/RPS class III: focal proliferative lupus nephritis. A, Low-power magnification shows focal and segmental proliferative lesion–active (class IIIA) with less than 50% of glomeruli affected. (Hematoxylin-eosin [HE] stain.) **B,** Area of focal necrosis containing cellular debris, karyorrhexis (*arrow*), is surrounded by an area of cellular proliferation. (Silver methenamine/HE.) **C,** Major focal and segmental proliferative lesion is affecting almost half the glomerular capillary tuft. (Hematoxylin/lissamine green.)

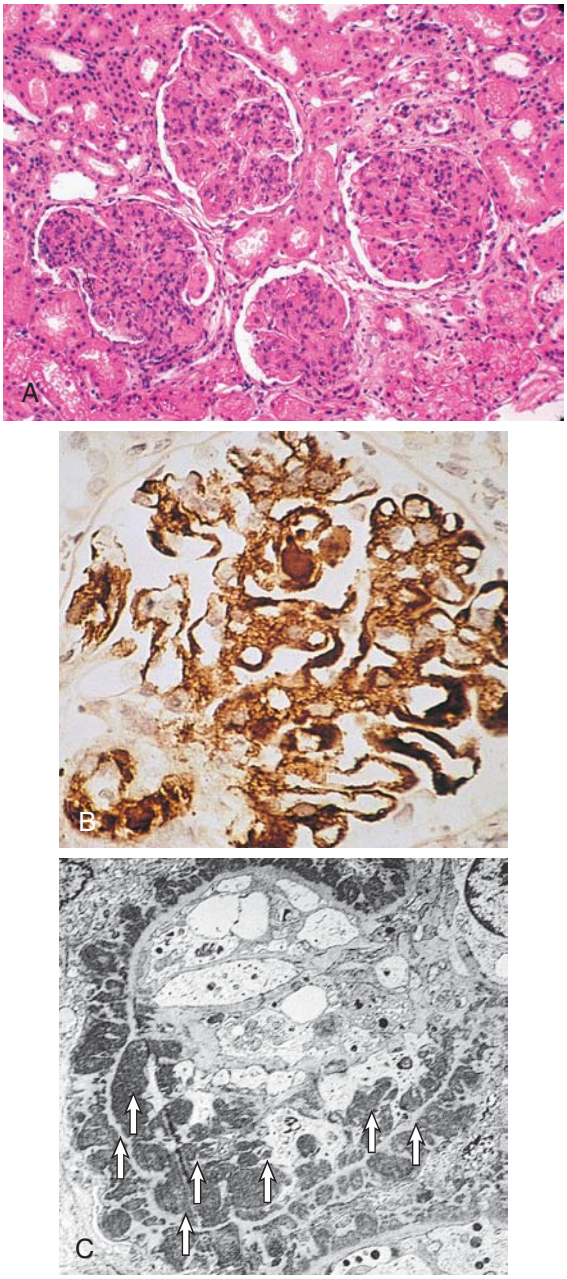

Figure 26-4 ISN/RPS class IV: lupus nephritis. A, Active, diffuse proliferative lupus nephritis. **B,** Immunoperoxidase staining shows dense, irregular aggregates of IgG along the peripheral capillary walls. **C,** Electron microscopy reveals the immune aggregates as electron-dense deposits *(arrows),* predominantly in the subendothelial location.

composed of bands ranging from 10 to 15 nm in diameter. Tubuloreticular inclusions, 24-nm interanastomosing tubular structures located in the dilated cisternae of endoplasmic reticulum of renal endothelial cells, are often found in biopsy specimens of LN patients and are thought to reflect increased interferon expression.

Tubulointerstitial and Vascular Disease

Although LN classification is based on the degree of glomerular involvement, histologic and clinical involvement of other renal compartments is seen in lupus patients.[39,40] This is a deficit of the ISN/RPS system, because interstitial and vascular injury are predictors of kidney outcomes.[41] In about 50% of patients with LN, predominantly those with proliferative glomerular lesions, immune aggregates are found along the tubular basement membranes. Interstitial infiltrates of $CD4^+$ and $CD8^+$ T lymphocytes and monocytes are frequently found. More than half of patients have significant T cell–B cell aggregates in the renal interstitium, and a small percentage have typical-appearing germinal centers.[30] In active disease, infiltration and invasion of the tubules (tubulitis) is found (Fig. 26-6). In chronic disease, the interstitium is expanded by fibrosis and sparser infiltrates. Interstitial inflammation has been correlated with renal dysfunction and hypertension, whereas immune deposition along the tubular basement membranes correlates better with the presence of high anti-dsDNA and depressed serum complement levels. Infrequently, tubulointerstitial nephritis is seen in the absence of glomerular disease and may produce acute kidney injury or RTA.

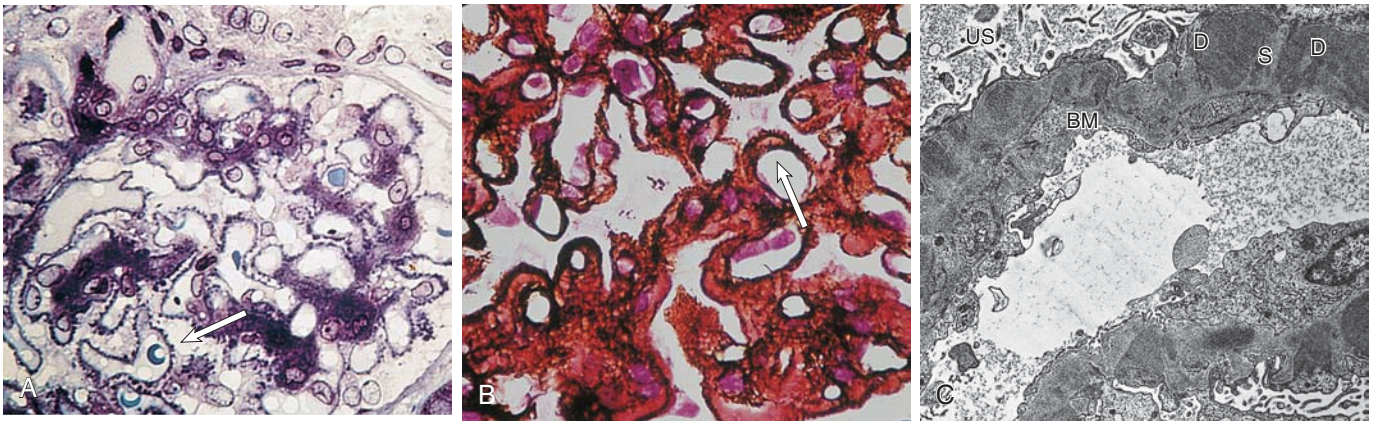

Figure 26-5 ISN/RPS class V: membranous lupus. A, Thick (~0.5 mm) araldite-embedded section stained with toluidine blue shows not only the extramembranous material in dark blue (*arrow*) but also the presence of mesangial deposits, which are common in lupus membranous nephropathy. **B,** Silver methenamine–stained section shows some double contouring of the silver-positive basement membrane *(arrow)* and subendothelium-deposited material as well as the characteristic silver-positive spikes of basement membrane–like material. **C,** Electron micrograph shows the predominantly subepithelial electron-dense deposits *(D)* separated by protrusions of basement membrane material (spikes, *S*); *BM*, basement membrane; *US*, urinary space.

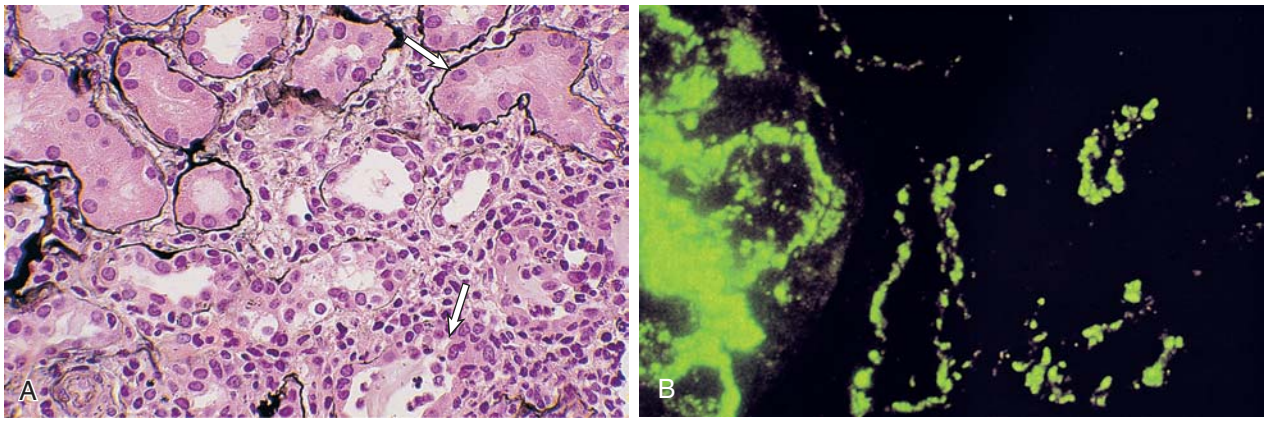

Figure 26-6 Interstitial lupus nephritis. A, Interstitial infiltrate invading and destroying tubules (tubulitis). Tubular basement membranes, which stain black with silver, are digested in the areas of tubulitis *(arrow)*. **B,** Immunofluorescence shows aggregates of C3 in the tubular basement membrane *(right)* as well as within the glomerulus *(left)*. Such tubular basement membrane aggregates are common in lupus nephritis, being found in 60% to 65% of biopsy specimens overall and with increasing frequency from class II (20%) to class IV (75%).

A number of vascular lesions may be seen in lupus patients[40] (Fig. 26-7). True vasculitis is extremely rare. More often, there are vascular immune deposits seen on IF or EM, or a fibrinoid noninflammatory necrotizing lesion of the vessels in patients with severe proliferative nephritis, or a thrombotic microangiopathy. Thrombotic microangiopathy is most often found in patients who are APA positive with prior evidence of coagulation events and may occur in conjunction with a proliferative GN.[32-34]

Transformation of Histologic Appearance and "Silent" Lupus Nephritis

Serial biopsy specimens often show transformation from one to another histologic glomerular class.[42] Some patients with increased clinical activity will transform from a more benign or less proliferative class (ISN class II or V) to a more active proliferative lesion (ISN class III or IV). This is often heralded by increasing proteinuria and active urinary sediment. With successful treatment, other patients will transform from a proliferative class (ISN class III or IV) to a more predominant membranous pattern (ISN class V).

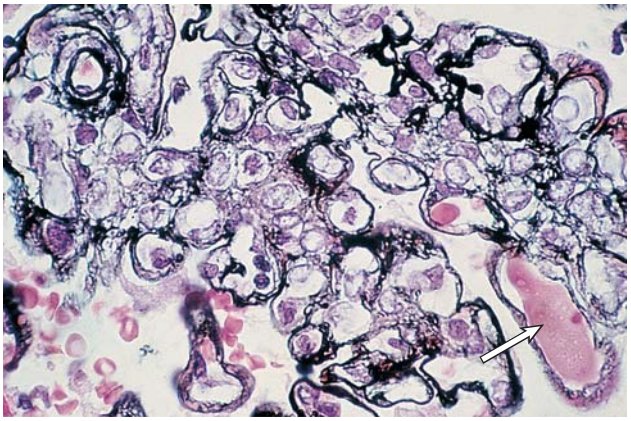

Figure 26-7 Vascular damage in lupus nephritis. Thrombus *(arrow)* occludes a glomerular capillary loop in this class IV biopsy specimen. Such a thrombus contains platelets and cross-linked fibrin as well as immunoglobulins and thus has some characteristics of true thrombus. (Silver methenamine/hematoxylin stain.)

Extremely uncommon are patients who have active proliferative LN on biopsy but no clinical or urinary sediment changes to indicate active disease, with normal anti-dsDNA and serum complement levels, so-called silent LN. If the urine sediment is carefully checked, most patients with proliferative lesions will have microhematuria and often erythrocyte casts.

Clinical and Histopathologic Correlations and Other Correlates of Outcome

Patients with ISN class I biopsies usually have no evidence of clinical renal disease. Likewise, patients with ISN class II may have elevated anti-dsDNA or low complement levels, but in general, their urinary sediment is inactive, hypertension is infrequent, the GFR is preserved, and proteinuria is rarely above 1 g/24 h. Patients with class I and class II biopsy findings have an excellent renal prognosis unless they transform to another pattern. However, patients with LN (especially classes I and II) may be more susceptible to non–immune complex podocyte injury (lupus podocytopathy) that shows a histologic pattern of minimal change disease (MCD) or focal segmental glomerulosclerosis (FSGN), and is often accompanied by nephrotic-range proteinuria.[43]

Patients with active ISN class IIIA or IIIA/C often have microhematuria, hypertension, low complement levels, and proteinuria. From one fourth to one third of patients will have the nephrotic syndrome, and up to one in four will have an elevated serum creatinine concentration at renal biopsy. Patients with focal glomerular scarring (ISN class IIIC) usually have hypertension and reduced renal function but without active urinary sediment. Patients with mild proliferation in only a few glomeruli generally respond well to therapy, with less than 5% progressing to renal failure during 5 years of follow-up. Others with more glomerular involvement or with necrotizing features and crescent formation have a prognosis similar to that of class IVA patients. Although some have suggested patients with "severe" focal segmental proliferative class III have a worse prognosis than do those with diffuse proliferative class IV lesions, this has not been supported by most investigators.[44]

Patients with ISN class IVA typically have high serologic activity (low serum complement and high anti-dsDNA–binding activity) along with active urinary sediment, hypertension, heavy proteinuria, and reduced GFR. Class IV diffuse proliferative disease carries the worst renal prognosis in most series, although this is greatly influenced by prognostic features such as racial background, socioeconomic factors, and renal features at presentation. Patients with segmental diffuse proliferative class IV-S may fare worse than those with diffuse global involvement class IV-G, although this remains controversial.[37]

Patients with ISN class V typically present with proteinuria and features of the nephrotic syndrome. At biopsy, however, up to 40% will have subnephrotic proteinuria, and up to 20% will have less than 1 g/24 h of proteinuria. Patients with ISN class V typically have less clinical renal and serologic activity. Some develop what appears to be idiopathic nephrotic syndrome before developing other features of lupus. Nephrotic ISN class V patients are predisposed to thrombotic complications, such as renal vein thrombosis and pulmonary emboli. Ten-year renal survival rates are 75% to 85%.

Advanced sclerotic LN, ISN class VI, is usually the result of "burnt-out" class III or class IV LN. Many patients will nevertheless have persistent microhematuria and some proteinuria along with hypertension and a decreased GFR.

Other Histologic Prognostic Factors

Features of reversible (active) or irreversible (chronic) damage on biopsy may be able to predict the course of LN patients. Some investigators have found that patients with a higher *activity index* or *chronicity index* are more likely to progress to renal failure[45,46] (Table 26-3). Similar to other types of GN, the renal prognosis is poor if biopsy specimens show extensive glomerulosclerosis or interstitial fibrosis.[41] Whereas there is disagreement about the value of the individual activity index or chronicity index, patients with high degrees of both activity and chronicity on biopsy (activity index >7 plus chronicity index >3) fare poorly, as do those with the combination of cellular crescents and interstitial fibrosis on biopsy. Persisting inflammation with subendothelial and mesangial deposits on repeated renal biopsy, especially with cellular crescents or macrophages in the tubular lumina, is more strongly predictive for the development of renal failure.[47]

NATURAL HISTORY

The natural history of LN in the modern era is unknown because patients with severe renal involvement receive therapy directed at their renal lesions. Fifty years ago, few patients with severe LN survived more than a few years, and half of those with even less severe forms of LN died within 5 years. Most patients now have a gratifying response to early treatment, followed by relatively quiescent disease under continuing immunosuppression that eventually can be tapered (Table 26-4). Some patients will continue to have no disease activity; others will relapse with time. The frequency of relapse depends not only on the underlying disease severity, but also on the intensity and duration of continued immunosuppression.

Point System in Calculating Lupus Nephritis Biopsy Activity and Chronicity

	Lesions Contributing to Activity Index						Lesions Contributing to Chronicity Index			
Semiquantitative Lesion Score*	***Cellular Crescents***	***Glomerular Necrosis-Karyorrhexis***	***Glomerular Neutrophils***		***Large Subendothelial Immune Deposits***	***Interstitial Inflammation***	***Glomerular Sclerosis***	***Fibrous Crescent***	***Tubular Atrophy***	***Interstitial Fibrosis***
None	0	0	0	0	0	0	0	0	0	0
Mild	2	2	1	1	1	1	1	1	1	1
Moderate	4	4	2	2	2	2	2	2	2	2
Severe	6	6	3	3	3	3	3	3	3	3

1970-1979	82	67	55
1980-1989	86	82	80
1990-1995	92	82	82
2000-2010	95-100	95-100	90-95

Table 26-4 Survival in lupus and lupus nephritis. Five-year actuarial survival for lupus, lupus nephritis, and World Health Organization class IV nephritis during the periods shown. *Weighted mean of published series. *(Data from references 62, 80, and 105.)*

End-stage renal disease (ESRD) now affects 8% to 15% of patients with LN.[5] Rare patients with progressive LN leading to dialysis may regain enough renal function to terminate dialysis. A renal biopsy is often useful to determine whether the disease is still active and potentially treatable or all chronic and irreversibly scarred.

In patients with active LN, fatal infections, often associated with persistent extrarenal disease activity, are the most common cause of death. Studies confirm that almost half of all lupus deaths are the result of excess cardiovascular mortality, often later in the course of the disease and particularly from premature myocardial ischemia.

Multiple factors have been associated with outcomes in LN. Epidemiologic predictors include race, with blacks and Hispanics having worse outcomes.[48-51] Persons of Southeast Asian descent have more severe disease than other Asians or Caucasians. Male gender, younger age (<24 years), and lower socioeconomic status, independent of race, are associated with a worse renal outcome.[50,51] Laboratory outcome predictors include the histologic features previously discussed, higher baseline serum creatinine concentration or greater baseline proteinuria, hypertension, severe anemia, thrombocytopenia, and hypocomplementemia with elevated anti-dsDNA levels. Across several prospective and retrospective trials, the most consistent predictor of poor long-term renal prognosis was an elevated serum creatinine at diagnosis. Adverse clinical management predictors include delay in the onset of therapy, prolonged disease course, failure to reduce proteinuria with treatment, and LN relapses.

TREATMENT

It is useful to divide the treatment of patients with active proliferative LN into an initial phase and a maintenance phase. The *initial phase* deals with acute life- or organ-threatening disease. The *maintenance phase* focuses on the long-term management of chronic, more indolent disease, protection from the side effects of therapy, prevention of flares and slowing or preventing progressive renal failure.

The ISN/RPS biopsy classification should guide initial therapy[52] (see Table 26-2). In general, patients assigned to ISN class I and class II need no therapy directed at the kidney. The majority will have a benign long-term kidney outcome, and the potential toxicity of any immunosuppressive regimen will negatively alter the risk/benefit ratio of treatment. Extrarenal manifestations should be treated with immunosuppression if indicated. An exception is the group of lupus patients with lupus podocyte injury, who often respond to a short course of high-dose corticosteroids similar to patients with MCD or FSGN.[43,53] It is in patients with active focal proliferative LN (ISN class IIIA and IIIA/C), active diffuse proliferative LN (ISN class IVA and IVA/C), and membranous lupus (ISN class V) that combination corticosteroid and immunosuppressive therapy is most widely used.

Although the goal of initial therapy is to induce a complete renal remission, this only occurs in 30% to 40% of LN patients by 12 months. Studies have varied in their definition of remission, but this typically requires a reduction in proteinuria below 0.5 g/24 h or urine protein-creatinine ratio below 0.5 g/g, absence of glomerular hematuria or red blood cell (RBC) casts, and normalization or stabilization of GFR. Subsequent flares are defined as *proteinuric* by an isolated increase in proteinuria, typically at least a doubling and to more than 1 g/24 h; or as *nephritic*, by a reproducible increase in serum creatinine of at least 30% (or a decrease in GFR by at least 10%) and an active urine sediment with an increase in glomerular hematuria of 10 or more RBCs per high-power field regardless of changes in proteinuria.[52]

Evidence in support of different therapeutic agents and regimens has emerged from clinical trials conducted during the last 30 years. It is important to treat many of these conclusions with caution, however, because of small study size and uncontrolled or nonblinded methods and a heterogeneous LN presentation and response to therapy. Therapeutic toxicity is a major contributing factor to mortality and morbidity; thus, claims of efficacy must be carefully balanced against adverse events. Other factors, such as ethnicity, referral practice, center experience, and use of concomitant medications, vary between studies and over time, which reduces the generalizability of some study results. Consensus statements have addressed the methodology and terminology used in clinical studies of LN.[52,54,55]

In addition to the immunosuppressive regimens discussed next, the renoprotective measures outlined in Chapter 80 should be used as appropriate. In addition, unless contraindicated, all LN patients should be treated with hydroxychloroquine.

Proliferative Lupus Nephritis: Initial Phase

Corticosteroids

Corticosteroids used in conjunction with other immunosuppressives are commenced at high dose, either prednisone (or prednisolone) at 0.5 to 1 mg/kg/day ideal body weight (no more than 80 mg/day), then tapered stepwise to approximately 10 mg/day by 3 to 6 months. In severe disease, oral corticosteroids may be preceded by intravenous (IV) methylprednisolone infusions (0.5 to 1.0 g daily for 1 to 3 days). Cosmetic effects, risk of gastrointestinal ulceration, risk of osteonecrosis, hypertension, psychoses, and enhanced risk of infectious complications have led to attempts to minimize prolonged courses of high-dose corticosteroid therapy in lupus patients. For example, a randomized comparison of 1.0 versus 0.5 mg/kg/day of prednisone, both with enteric mycophenolic acid, found a nonsignificant increase in partial responses, but almost a doubling of severe adverse events with the higher prednisone dose. A study using cyclophosphamide as initial therapy, but without high-dose corticosteroids, in a Caucasian population with mild-moderate disease showed complete and partial remission rates at 2 years comparable to patients treated with cyclophosphamide and high-dose corticosteroids.[56] Preliminary results of a pilot trial using anti–B cell therapy plus two doses of IV methylprednisolone followed by mycophenolate mofetil (MMF) alone have been encouraging and suggest that virtually steroid-free regimens for LN may be possible.[57]

Immunosuppressives

Although corticosteroids are effective in controlling proliferative LN, a landmark study showed that over the long term, kidney function

was better preserved and there were fewer LN relapses if corticosteroids are combined with cyclophosphamide during initial therapy.[58] Importantly, this outcome was not apparent for 3 to 5 years, highlighting the need for long-term follow-up in assessing initial LN therapies. Both daily oral and IV pulses of cyclophosphamide are effective in LN. However, IV cyclophosphamide given as six monthly pulses (0.5 to 1 g/m^2) has been the accepted standard of care for several years.[59] Early oral cyclophosphamide regimens exposed patients to high cumulative doses and serious toxicity; a lower-dose, shorter-duration oral regimen has shown efficacy, dose exposure, and tolerability comparable to IV cyclophosphamide.[60] A true low-dose cyclophosphamide protocol of 500 mg given intravenously every 2 weeks for 3 months (six pulses) followed by azathioprine had similar efficacy in a Northern European cohort as a standard regimen of six monthly pulses of cyclophosphamide followed by quarterly infusions.[61] The low-dose regimen, known as the "Eurolupus protocol" (Euro-Lupus Nephritis Trial), had less toxicity with fewer infections. Subsequent reports after 5 and 10 years continued to find no differences in outcome between treatment groups, but with a much lower cumulative dose of the alkylating agent with the Eurolupus regimen.[62] Although this regimen was initially tested in a mainly Caucasian population, a recently completed trial showed that remission induction with low-dose cyclophosphamide was similar in Caucasians, African Americans, and Hispanics.[62a]

Several randomized clinical trials involving multiethnic cohorts showed that oral MMF plus corticosteroids for 6 months, followed by maintenance therapy (see later), is at least as effective and in some cases more effective than six monthly pulses of cyclophosphamide plus corticosteroids followed by maintenance therapy.[63-65] No benefit on mortality or severe infection rates has been seen with MMF, although the risk of amenorrhea is lower and gastrointestinal toxicity is more frequent. Longer-term follow-up of the randomized trials has found no differences in renal outcome, but one study of 227 patients found a non-significant increase in renal flares with MMF as compared to cyclophosphamide induction.[66] Differences in response between ethnic and geographic subgroups have been suggested but not confirmed, including better responses to MMF in American blacks and worse responses to MMF in Chinese.[67] This latter observation is in line with a retrospective analysis of a Korean cohort, where remissions were similar for MMF and cyclophosphamide, but more relapses and ESRD were seen in the MMF group.[68] Patients presenting with marked renal impairment are at high risk of progressing to ESRD and for infective comorbidity; no convincing differences in outcome between MMF and cyclophosphamide induction have been seen for this subgroup. The optimal MMF dosing and adjustments for different patient subgroups remains unclear, but there is increasing evidence for mycophenolic acid monitoring in guiding MMF dosing.

Three organizations recently developed evidence-based guidelines for LN therapy.[52,54,55] Although the groups were independent, their recommended guidelines were fairly consistent. The guidelines are synthesized in the treatment algorithm presented in Figure 26-8.

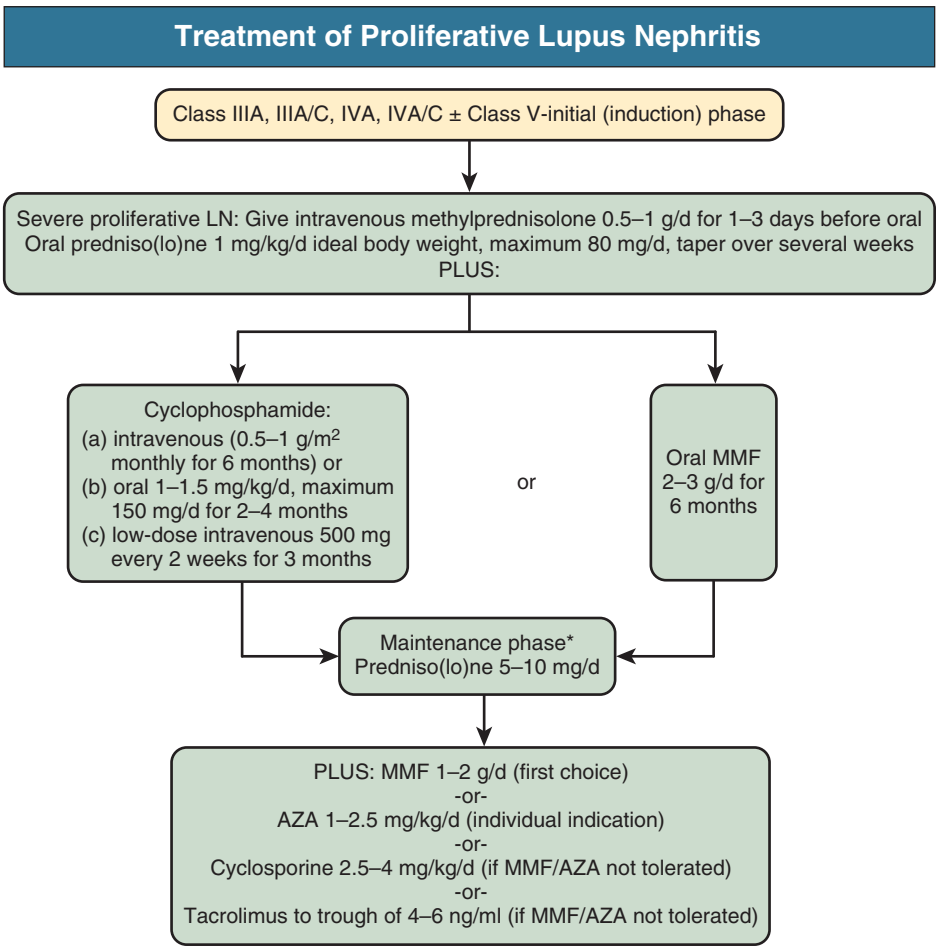

Figure 26-8 Treatment of proliferative lupus nephritis. *AZA,* Azathioprine; *MMF,* mycophenolate mofetil.

Other Immunosuppressive Strategies

Azathioprine (AZA) and calcineurin inhibitors (CNIs) have been used in combination with corticosteroids for the induction of remission in proliferative LN. A randomized trial comparing AZA with cyclophosphamide found no difference in eventual outcome but more relapses and more patients doubling their serum creatinine concentration in the AZA group.[69] Although AZA has not been recommended as first-line therapy by the major LN guidelines, it remains an option when MMF or cyclophosphamide are unavailable or contraindicated. Similarly, the CNIs tacrolimus and cyclosporine tested as alternatives to cyclophosphamide for the initial treatment of proliferative LN have compared favorably in short-term responses.[70,71] Larger and longer-term prospective trials of CNIs in proliferative LN are warranted.

Biologic Agents

Rituximab, an anti-CD20 monoclonal antibody that depletes B cells, has led to improved disease control in LN patients with relapsing or refractory disease in retrospective or nonrandomized trials. However, in a large randomized, prospective trial, when added to MMF and corticosteroids for induction of remission, rituximab did no better than placebo.[72] Of note, no safety concerns with rituximab were seen in this trial. The position of rituximab in LN therapy is currently uncertain, and it may be considered when other therapies have failed.

Abatacept, a fusion protein of CTLA4 and the immunoglobulin heavy chain, blocks T and B cell costimulation, but in combination with MMF and corticosteroids was no better than placebo. However, a retrospective analysis of the abatacept data using different definitions of remission suggested that the drug may have been effective with somewhat less stringent criteria.[73]

Other pathogenic mediators currently being targeted in SLE or LN with monoclonal antibodies are the B cell–stimulating cytokine BAFF, IFN-α, IL-6, and TWEAK, a proinflammatory cytokine and member of the tumor necrosis factor superfamily.

Resistant Proliferative Lupus Nephritis

There is no uniformly accepted definition of resistant or refractory LN. One retrospective analysis of a large randomized clinical trial suggested that success at 6 months was more likely if at 2 months, patients showed a decline in proteinuria by at least 25% and normalization of serum complement levels if low at the start of therapy.[74] Figure 26-9 outlines therapies that have been attempted for "refractory disease." Most of the studies were uncontrolled, small, and retrospective. Rituximab has had some success in this population with refractory disease.[75]

Although no benefit was seen after the addition of plasma exchange for routine remission induction in LN, the removal of circulating antibodies and other immune reactants may be considered for patients with high serologic activity and progressive refractory nephritis. Intravenous immunoglobulin and CNIs have shown benefit in small series of patients with resistant LN.[76,77] For patients with life-threatening resistant disease, small pilot studies have used total lymphoid irradiation and immunoablation by high-dose cyclophosphamide and antithymocyte globulin, with or without reconstitution with autologous stem cells. These approaches have led to sustained treatment-free remissions but are toxic and have treatment-related mortality, and their role in SLE remains to be seen.[78]

Renal Response to Initial Therapy

Achieving a remission of LN predicts an improved long-term outcome. In one study, the 5-year patient and 5-year renal survival were 95% and 94%, respectively, for the group achieving remission and only 69% and 45%, respectively, for the group not achieving a remission.[79] Partial remission was also associated with improved outcomes. Predictors of remission included lower baseline serum creatinine concentration, lower baseline urinary protein excretion, better renal histologic class, lower chronicity index, stable GFR after 4 weeks of therapy, and Caucasian race.

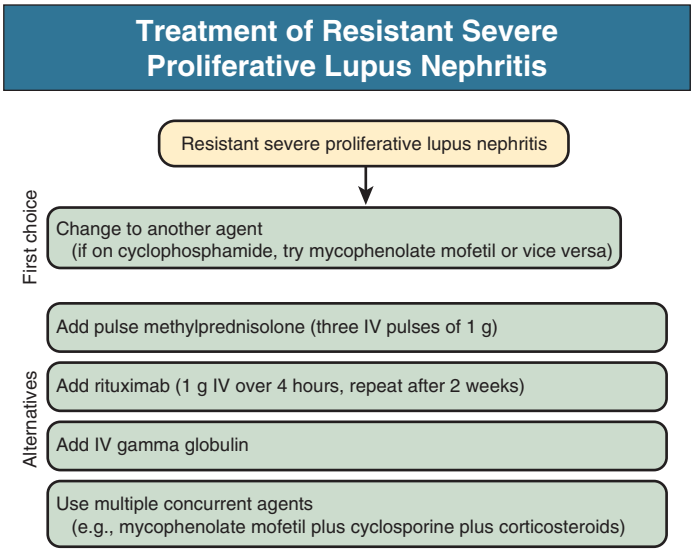

Figure 26-9 Treatment of resistant proliferative lupus nephritis.

Multiethnic studies showed that complete and partial renal responses to MMF or cyclophosphamide ranged from 18% to 85% at 6 months and 32% to 85% at 12 months.* Because the definition of "complete remission" often includes total absence of abnormal proteinuria or hematuria, looking at data after 1 year or longer is often a more reliable predictor of outcome. In general, about half of treated LN patients achieve a complete or partial response by 1 year, and an additional 25% by 2 years.† Thus, even with the best current therapies, time to remission is long, and remission rates are suboptimal, leaving room for improvement with add-on drugs or novel alternative therapies.

Proliferative Lupus Nephritis: Maintenance Therapy

After the initial treatment of proliferative LN, maintenance therapy continues for the long term to prevent renal flares and the development of chronic kidney disease. Early investigations showed maintenance cyclophosphamide was superior to corticosteroids alone.[58,84] Subsequent work demonstrated that less intense maintenance immunosuppression with AZA or MMF was as effective and significantly improved patient morbidity and survival.[59] Because it often takes several months for proteinuria and serum creatinine to decline to baseline levels following initial therapy,[60] the early clinical importance of maintenance therapy is to consolidate renal responses into complete and partial remissions using drugs with a lower side effect profile.

Corticosteroids tapered from the initial treatment period are generally continued during the maintenance period, but the dose is limited (e.g., prednisone 5 to 15 mg/day) (see Fig. 26-8). Both daily and alternate-day regimens have been used. There is no consensus on the optimal duration of corticosteroid therapy.

*References 45, 59-61, 63, 64, 69, 80, 81.
†References 60, 61, 64, 69, 82, 83.

Two randomized clinical trials recently compared AZA (2 mg/kg/day) and MMF (2 g/day) as maintenance drugs. In a trial of 227 multiethnic patients, MMF was significantly better than AZA at preventing renal flares and ESRD and preserving renal function over 3 years after initial therapy with cyclophosphamide or MMF.[66] In a study of 105 patients, mainly European Caucasian, AZA and MMF were as effective at preventing renal flares over 4 years from initial treatment as low-dose cyclophosphamide.[85] Although MMF appears to be the maintenance drug of choice for most LN patients, therapy should be individualized. In some patients, AZA may be appropriate, such as for the patient in complete remission who wants to become pregnant. Two randomized trials compared the CNIs tacrolimus and cyclosporine to AZA for maintenance.[86,87] Although both trials were underpowered, and the tacrolimus trial had only 6 months of follow-up, both demonstrated the CNIs were as effective as AZA in preventing renal flares. Given less data for tacrolimus and cyclosporine, CNIs should probably be reserved for patients who cannot take MMF or AZA. Maintenance therapy should be continued for a minimum of 3 to 4 years unless there is a contraindication.

Figure 26-8 summarizes disease-specific treatment recommendations for both induction and maintenance phases of proliferative LN therapy. General renoprotective measures should follow the agents outlined in Chapter 80. Many believe that an antimalarial agent such as hydroxychloroquine should be used in all lupus patients unless a contraindication exists. Aside from the antimalarials,[88] other agents used to treat extrarenal findings in lupus patients (e.g., NSAIDs, androgens, fish oil) have not shown benefit in patients with LN.

Membranous Lupus Nephropathy

The treatment of pure ISN/RPS class V LN remains controversial. For patients with subnephrotic proteinuria, renoprotective and antiproteinuric therapies should be used. Some patients with subnephrotic proteinuria will benefit from immunosuppressives, but these should be considered for all patients with nephrotic syndrome or renal impairment. The only small, randomized controlled trial in patients with class V LN compared cyclophosphamide or cyclosporine to corticosteroids alone.[89] The patients had preserved GFR but a mean proteinuria of almost 6 g daily. At last follow-up, there were more complete and partial remissions in the cyclophosphamide and cyclosporine groups than in the prednisone group. Remissions occurred more quickly in the cyclosporine group, but there were fewer relapses in the cyclophosphamide group. Patients who relapsed or failed to respond to cyclosporine could subsequently be brought into remission with IV cyclophosphamide. Two recent trials of MMF versus IV cyclophosphamide as initial therapy of LN included 84 patients with pure membranous nephropathy among the 510 patients enrolled.[90] Remissions, relapses, and courses were similar in the patients treated with oral MMF and IV cyclophosphamide. Azathioprine along with corticosteroids has also been successful in some patients with membranous LN, but these studies have all been observational or retrospective.[91]

Membranous nephropathy is often diagnosed in association with proliferative forms of LN. In these patients, treatment is directed at the proliferative component. An alternative approach for the treatment of ISN class V + class III or class IV LN, called multitargeted therapy, combines low doses of corticosteroids, MMF, and a CNI[82] and has shown success in an Asian cohort.

Thus, for patients with membranous nephropathy who have subnephrotic levels of proteinuria and a preserved GFR, we recommend either conservative therapy with angiotensin-converting enzyme inhibitors or angiotensin receptor blockers and statins, or a short course of corticosteroids or a CNI. For fully nephrotic patients and those at higher risk for progressive disease, MMF, AZA, or a CNI is preferred, with cyclophosphamide reserved for refractory cases (Fig. 26-10).

Long-Term Monitoring of Lupus Nephritis Patients

The relapse rate for LN ranges from 35% to 60%, depending on the population studied, the criteria for relapse, and the maintenance therapy used.[92-94] An increase in anti-dsDNA antibody levels and a fall in serum C3 and C4 may predict an impending LN flare in some patients, but better biomarkers to predict flare are needed.[95] Treating positive serology in the absence of clinical lupus activity is not recommended. However, a normal anti-dsDNA level suggests a lower risk of relapse after treatment reduction or withdrawal in the chronic phase of maintenance therapy.[96] A stable GFR and no proteinuria also predict successful discontinuation of immunosuppressives.

Patients with SLE who have had LN should have blood pressure, GFR/serum creatinine, proteinuria, and urinary sediment monitored quarterly.[54] Serologies such as C3 and C4 levels and anti-dsDNA should also be monitored quarterly or biannually, respectively. Surveillance kidney biopsies are not generally done, but a repeat biopsy at the time of a suspected LN flare will confirm the diagnosis of increased activity and will identify changes in histologic class. A repeat biopsy for persisting proteinuria or a declining GFR not clearly caused by a flare will identify whether there are active lesions potentially modifiable by restarting, changing, or increasing immunosuppressive therapy, or if the abnormalities are caused by chronic scarring that requires only renoprotective therapies (see Chapter 80).

ANTIPHOSPHOLIPID ANTIBODY SYNDROME, ATHEROSCLEROSIS, AND PREGNANCY IN LUPUS NEPHRITIS

Intrarenal clotting caused by the antiphospholipid antibody syndrome is found in 30% of patients with SLE and may occur in the presence or absence of LN.[32,33] Most such patients have a lupus anticoagulant or anticardiolipin antibody, but up to 15% of patients have neither.[34] The risk of thrombotic episodes is highest with lupus anticoagulant and somewhat lower with anti–β_2-glycoprotein 1 and anticardiolipin antibodies. The exact mechanisms for the thrombotic tendency remain unclear but may include abnormal endothelial function, enhanced platelet aggregation, reduced production of prostacyclin and other endothelial anticoagulant factors, and activation of plasminogen. The clinical manifestations and treatment of patients with APS are discussed further in Chapter 28, but the mainstay of treatment is not immunosuppression as for LN, but rather anticoagulation and hydroxychloroquine.

Patients with lupus have increased risk of atherosclerotic complications compared with age-matched controls and greater atherosclerotic plaque burden, which contribute significantly to morbidity and mortality in SLE.[97,98] Young women with SLE have a risk of heart attack that is 50 times greater than that of healthy women, and even older women with SLE have 2.5 to 4 times the risk of myocardial infarction (MI).[99] After adjustment for all traditional cardiovascular risk factors, SLE patients have a 7- to 10-fold higher risk of nonfatal MI and a 17-fold higher risk of fatal MI.[100] Chronic kidney disease, a frequent outcome of LN, is also a nontraditional cardiovascular risk factor.[101] Reduction of atherosclerotic risk should be focused on control of blood pressure (goal of 130/80 mm Hg), the use of statins and antimalarials to correct lipid abnormalities,[102] and the reduction of inflammatory disease activity.

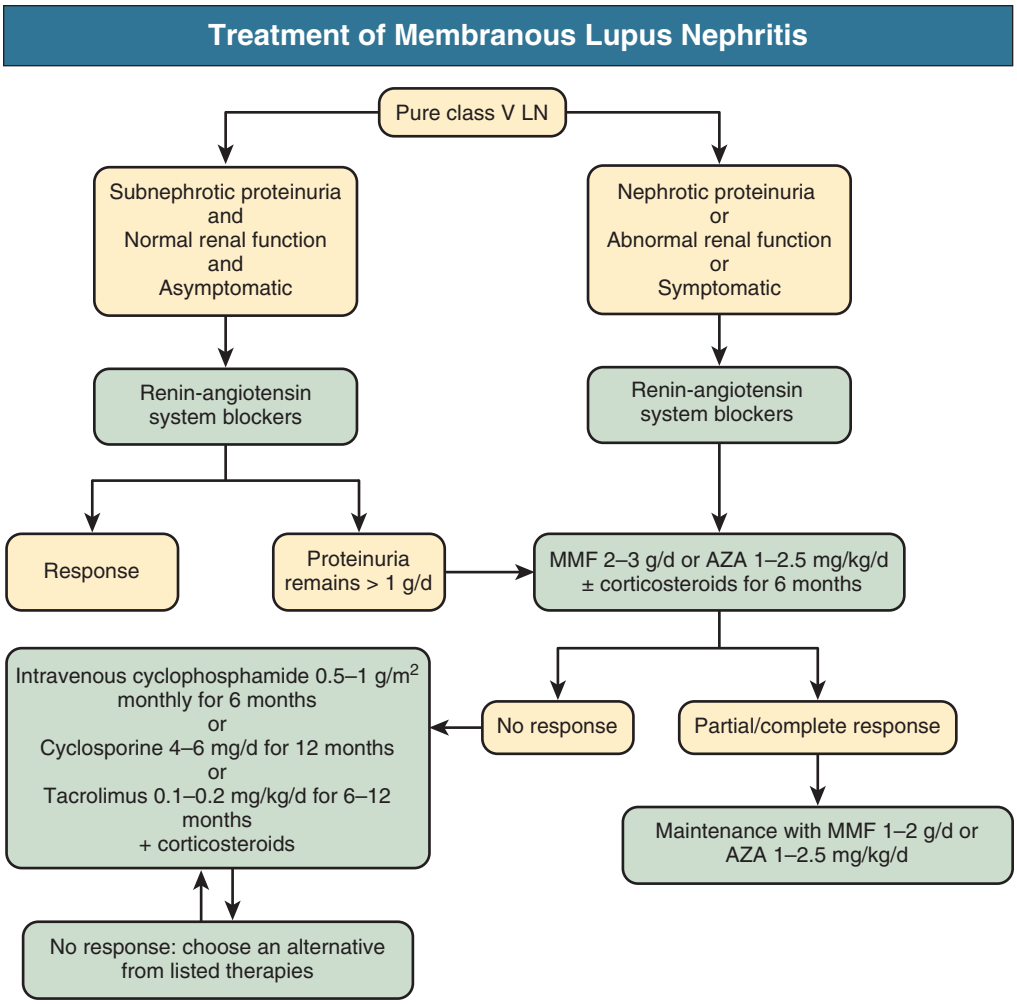

Figure 26-10 Treatment of membranous lupus nephritis. *AZA,* Azathioprine; *MMF,* mycophenolate mofetil.

The effects of SLE and LN on pregnancy and fetal outcomes, and the effects of pregnancy on LN activity, are discussed in Chapter 45.

END-STAGE RENAL DISEASE AND RENAL TRANSPLANTATION

About 10% to 15% of lupus patients develop ESRD, and lupus represents only 1% to 2% of patients with ESRD.[103] Extrarenal lupus will be inactive in many patients by the time they reach ESRD, but some may still have active extrarenal disease that requires immunosuppression while receiving renal replacement therapy. Survival of lupus patients on dialysis is comparable to that of other primary renal diseases.[103]

Transplantation of lupus patients can be performed with only a few extra precautions. Most centers defer transplantation until lupus activity is quiescent for 6 months. For patients who are clinically inactive but retain serologic activity with elevated anti-DNA antibody levels, starting transplant immunosuppressives prophylactically several weeks to 1 month before living donor transplantation may suppress the serologic activity. Allograft thrombosis (arterial, venous, or intraglomerular) may occur after transplantation, especially in patients with APA. APA-positive patients with a prior thrombotic event should be anticoagulated shortly after transplantation. Outcomes in SLE patients undergoing transplantation are similar to those of patients with other diseases.[104] Recurrent LN occurs in 2% to 11% of transplanted kidneys (see Chapter 108).

CHAPTER 27

Renal Amyloidosis and Glomerular Diseases with Monoclonal Immunoglobulin Deposition

Pierre M. Ronco, Pierre Aucouturier, and Bruno Moulin

The glomerular capillaries are a favorite site for the deposition of abnormal proteins. In most patients, the resulting diseases are caused by a monoclonal immunoglobulin or subunit thereof and can be classified into two categories by electron microscopy (Table 27-1). The first category includes diseases with fibril formation, mainly amyloidosis, and diseases with microtubule formation, including cryoglobulinemic glomerulonephritis (see Chapter 21) and immunotactoid glomerulonephritis. The second disease category is characterized by nonorganized electron-dense granular deposits. These deposits are localized along basement membranes in most tissues, especially in the kidney, and define a disease now termed *monoclonal immunoglobulin deposition disease* (MIDD). In some cases, monotypic immune complex–like deposits are observed in the setting of proliferative glomerulonephritis.

RENAL AMYLOIDOSIS

General Characteristics of Amyloidosis

Definition

Amyloidosis is a generic term for a family of diseases defined by morphologic criteria. The diseases are characterized by the deposition in extracellular spaces of a proteinaceous material. Amyloid deposits are composed of a felt-like array of 7.5- to 10-nm-wide rigid, linear, nonbranching, aggregated fibrils of indefinite length.[1] One amyloid fibril is made of two twisted 3-nm-wide filaments, each displaying the typical "cross-β" structure,[1] where antiparallel β-sheets are perpendicular to the filament axis.

Amyloid Precursor–Based Classification

Amyloidoses are classified by the type of precursor protein that composes the main component of fibrils[2] (Table 27-2). The amyloidogenic propensity is related to the ability of this precursor to form intermolecular β-sheets. Besides these structural properties, which may relate to genetically transmitted mutations, the amyloidogenic potential is enhanced by overproduction or impaired clearance of the precursor.

Renal amyloidoses mostly include immunoglobulin light-chain (AL) and systemic secondary (AA) amyloidoses. Other precursors, such as transthyretin, fibrinogen, apolipoprotein A-I, and lysozyme, are responsible for rare familial cases.

Other Components of All Amyloid Fibrils

Glycosaminoglycans (GAGs) are tightly associated with amyloid fibrils. GAGs are polysaccharide chains made of repeating hyaluronic acid–hexosamine units normally linked to a protein core, thus forming proteoglycans. Proteoglycans, mostly of the heparan sulfate type, appear to induce and to stabilize the β-pleated amyloid structure.

Another constituent of all amyloid deposits is serum amyloid P component (SAP). SAP is resistant to proteolytic digestion, and coating of amyloid fibrils with SAP could result in their protection from catabolism. The high affinity of SAP toward amyloid was exploited for scintigraphy with [^{123}I]-SAP. CPHPC (R-1-[6-[R-2-carboxy-pyrrolidin-1-yl]-6-oxo-hexanoyl] pyrrolidine-2-carboxylic acid) is a proline-derived small compound that specifically binds to SAP and allows rapid decreases in serum SAP levels.[3] The combination of CPHPC with an SAP-antibody targets amyloid deposits and enables their elimination by recruiting phagocytic cells in a mouse model of AA amyloidosis. A clinical trial using CPHPC combined with an anti-SAP antibody is underway.[4]

General Mechanisms of Fibrillogenesis

Amyloidogenesis involves a nucleation-dependent polymerization process. Formation of an ordered nucleus is the initial and thermodynamically limiting step, followed by addition of monomers and elongation of the fibrils.[5] Fibrillogenesis may involve several mechanisms of processing of the amyloid precursor, including partial proteolysis and conformational modifications. Conformational changes lead to a soluble, partially folded intermediate, whose subsequent ordered self-assembly results in fibril formation. Macrophages have a central role in AA amyloidosis by providing the intralysosomal processing of the precursor. In AL amyloidosis, the variable domain of the light chain V_L is the main component, which suggests a role of partial proteolysis of the light-chain precursor.

Pathology

On light microscopy, the deposits are extracellular, eosinophilic, and metachromatic, inducing a change in color of dyes (e.g., crystal violet). After Congo red staining, the deposits appear faintly red (Fig. 27-1, *A*) and show characteristic apple-green birefringence under polarized light (Fig. 27-1, *B*). Metachromasia is also observed with crystal violet, which stains the deposits red.

The earliest lesions are located in the mesangium (Fig. 27-1, *A*), along the glomerular basement membrane (GBM), and in the blood vessels. Mesangial deposits are primarily in the mesangial matrix and spread from lobule to lobule until eventually the whole mesangial area is replaced. Amyloid deposits may also infiltrate the GBM or may be localized on both its sides. When subepithelial deposits predominate, spikes similar to those seen in membranous nephropathy may be observed. Advanced amyloid typically produces a nonproliferative, noninflammatory glomerulopathy and marked enlargement of the kidney. The amyloid deposits replace the normal glomerular architecture, resulting in loss of cellularity. When glomeruli become massively sclerotic, the deposits may be difficult to demonstrate by Congo red staining. In this case, electron microscopy (EM) may be helpful, as well as in the very early stages, which may not be detected by light microscopy examination in patients presenting with the

nephrotic syndrome. Amyloid deposits are characterized by randomly oriented, nonbranching fibrils with an 8- to 15-nm diameter (Fig. 27-2).

Except for fibrinogen amyloidosis, which characteristically does not affect renal vessels, the media of the blood vessels is prominently involved at early stages. Vascular involvement may predominate and occasionally occurs alone, particularly in AL amyloidosis. Deposits may also affect the tubules and the interstitium, leading to atrophy and disappearance of the tubular structures and to interstitial fibrosis.

Given the heterogeneity of amyloidoses, immunohistology should be routinely performed (Fig. 27-1, *C*). Immunohistochemical classification of amyloid type is possible in most cases. Immunohistology with antibodies specific for immunoglobulin chains may be more difficult to interpret than that with anti-AA antiserum, perhaps because of the absence or inaccessibility of light-chain epitopes. Alternative techniques such as immuno-EM[6] and mass spectrometry–based proteomic analysis of deposits after laser microdissection, which are still used only at highly specialized centers, will likely decrease the percentage of nontypeable amyloidosis.[7,8] A genetic cause should be sought by DNA sequencing in all patients with amyloidosis in whom confirmation of the amyloid precursor cannot be obtained by other techniques.[9]

Glomerular Diseases with Tissue Deposition or Precipitation of Monoclonal Immunoglobulin Components

Immunoglobulin Deposits	Glomerular Disease

	Monoclonal immunoglobulin deposition disease: light-chain, heavy-chain, and light-plus-heavy-chain deposition diseases Immune complex–like proliferative glomerulonephritis

Table 27-1 Glomerular diseases with tissue deposition or precipitation of monoclonal immunoglobulin components.

Immunoglobulin-Associated Amyloidosis (AL Amyloidosis)

Free immunoglobulin subunits, mostly light chains, secreted by a single clone of B cells, are the cause of the most frequent and severe amyloidosis affecting the kidney. Studies on the mechanisms of AL amyloidogenesis are made particularly difficult by the unique structural heterogeneity of the precursor: each monoclonal light chain is different from all others, so each patient is unique. The involvement of an immunoglobulin heavy chain in amyloidosis (AH and AHL amyloidosis) remains extremely rare, and its diagnosis

Classification of Amyloidoses

Amyloid Protein*	Precursor	Distribution	Type	Syndrome or Main Involved Tissues
AA	Serum amyloid A	Systemic	Acquired	Secondary amyloidosis, reactive to chronic infection or inflammation, including hereditary periodic fever (FMF, TRAPS, HIDS, FCU, and MWS)
AApoAI	Apolipoprotein A-I	Systemic	Hereditary	Liver, kidney, heart, skin, larynx
AApoAII	Apolipoprotein A-II	Systemic	Hereditary	Kidney, liver, adrenal glands, spleen, skin
Aβ	Aβ protein precursor	Localized Localized	Acquired Hereditary	Sporadic Alzheimer disease, aging Prototypic hereditary cerebral amyloid angiopathy, Dutch type
Aβ2M	β2-Microglobulin	Systemic	Acquired	Chronic hemodialysis
ABri	Abri protein precursor	Localized or systemic?	Hereditary	British familial dementia
ACys	Cystatin C	Systemic	Hereditary	Icelandic hereditary cerebral amyloid angiopathy
AFib	Fibrinogen Aα chain	Systemic	Hereditary	Kidney
AGel	Gelsolin	Systemic	Hereditary	Finnish hereditary amyloidosis
AH	Immunoglobulin heavy chain	Systemic or localized	Acquired	Primary amyloidosis, myeloma associated
AL	Immunoglobulin light chain	Systemic or localized	Acquired	Primary amyloidosis, myeloma associated
ALECT2	Leukocyte chemotactic factor 2	Systemic	Acquired?	Kidney, liver, adrenal glands
ALys	Lysozyme	Systemic	Hereditary	Kidney, liver, spleen, adrenal glands
APrP	Prion protein	Localized Localized	Acquired Hereditary	Sporadic (iatrogenic CJD, new variant CJD) (alimentary?) Familial CJD, GSSD, FFI
ATTR	Transthyretin	Systemic	Acquired Hereditary	Senile heart, vessels Prototypical FAP

Table 27-2 Classification of amyloidoses. *Entries in boldface indicate amyloid types with kidney involvement. The following proteins may also cause amyloidosis: calcitonin, islet-amyloid polypeptides, atrial natriuretic factor, prolactin, insulin, lactadherin, keratoepithelin, and Danish amyloid protein (which comes from the same gene as ABri and has an identical N-terminal sequence). *CJD,* Creutzfeldt-Jakob disease; *FAP,* familial amyloidotic polyneuropathy; *FCU,* familial cold urticaria; *FFI,* fatal familial insomnia; *FMF,* familial Mediterranean fever; *GSSD,* Gerstmann-Sträussler-Scheinker disease; *HIDS,* hyper-IgD syndrome; *MWS,* Muckle-Wells syndrome; *TRAPS,* tumor necrosis factor receptor–associated periodic syndrome. *(Modified from reference 2.)*

is greatly enhanced by the use of laser microdissection and mass spectrometry.[10]

Pathogenesis

Determinant factors are borne by the precursor light chain. In AL amyloidosis, or primary amyloidosis, there is a striking overrepresentation of the lambda (λ) isotype, which is twofold to fourfold more common than the kappa (κ) isotype. A rarely expressed homology family of light-chain variable regions, the $V_{\lambda VI}$ variability subgroup, is found only in amyloid-associated monoclonal immunoglobulins.

Amyloidogenicity is associated with physicochemical features that include low-molecular-mass light-chain fragments in the urine, abnormal disulfide bonding of light chains, and low isoelectric point (pI). An analysis of almost 200 light-chain sequences identified 12 positions in κ chains and 12 in λ chains where certain residues were associated with amyloidosis. Four structural risk factors were shown to define most fibril-forming κ light chains.[11] Because of their high dimerization constants, light chains from patients with AL amyloidosis may behave as antibodies with affinity for extracellular structures that could favor a nucleation process.

The tropism of organ involvement may be influenced both by the germ-line gene used for the light-chain variable region (V_L) and by somatic mutations occurring in the secreting clone.[12] Patients expressing a monoclonal light chain of the $V_{\lambda VI}$ subgroup are more likely to present with dominant renal involvement and less frequent cardiac and multisystem disease.[13] Patients with κ light chains are more likely to have dominant hepatic involvement. In addition, organ-specific environmental factors are also involved. For example, high intrarenal concentrations of urea enhance fibril formation by reducing the nucleation lag time.

Amyloid light chains may contribute directly to the pathogenesis, independent of extracellular fibril deposition. In the heart and the kidney at least, the infiltration alone does not correlate well with clinical manifestations. Light chains from amyloid patients incubated with mesangial cells induce a macrophage-like phenotype, whereas those from light-chain deposition disease patients induce a myofibroblast-like phenotype.[14]

Epidemiology

The incidence of AL amyloidosis is nine per 1 million population per year. Fewer than one in four patients with AL amyloidosis is considered to have an overt immunoproliferative disease, which usually is multiple myeloma, although other forms are seen, such as Waldenström macroglobulinemia. Amyloid deposits are found in approximately 10% of all patients with myeloma and in 20% of those with pure light-chain myeloma. The apparent prevalence of myeloma depends on the diagnostic criteria used. Epidemiologic characteristics of *primary* amyloidosis, that is, amyloidosis without overt immunoproliferative disease, and myeloma are not significantly different. The median age at diagnosis is 64 years in patients with primary amyloidosis, with a slight predominance of male patients, and about 10% of patients are less than 50 years old.[15]

Clinical Manifestations

The main clinical symptoms at presentation are weakness and weight loss (Table 27-3). Except for bone pain, the initial symptoms in patients with and without myeloma are similar. However, nephrotic syndrome, orthostatic hypotension, and peripheral neuropathy are more frequent in patients with AL amyloidosis without myeloma.[16] Amyloidosis is also different from many types of kidney disease in that the kidneys are often enlarged and hypertension is absent even when renal function is impaired. Proteinuria, mainly albuminuria, occurs in the absence of microhematuria. Indeed, the presence of hematuria should prompt examination for a bleeding lesion in the urinary tract. Renal manifestations may also include renal tubular acidosis (mostly as a part of Fanconi syndrome; see Chapter 50) and polyuria-polydipsia (resulting from urinary concentration defect), when amyloid deposits occur around proximal tubules and Henle loops (or collecting ducts), respectively.

AL amyloidosis may infiltrate almost any organ other than the brain and therefore can be responsible for a wide variety of clinical manifestations. Restrictive cardiomyopathy is found at presentation

Clinical Presentation in 474 Patients with Proven AL Amyloidosis	
Features	**Percentage**

in up to one third of patients and causes death in about one half. Infiltration of the ventricular walls and the septum may be recognized by echocardiography. Amyloid may also induce arrhythmias and the sick sinus syndrome. Amyloid deposits in the coronary arteries may result in angina and myocardial infarction. Cardiac troponins and N-terminal pro–brain natriuretic peptide (NT-proBNP) are sensitive markers of myocardial dysfunction and powerful predictors of overall survival in patients with AL amyloidosis.

Involvement of the gastrointestinal (GI) tract is common and can cause motility disturbances, malabsorption, hemorrhage, or obstruction. Macroglossia may interfere with eating and obstruct airways (Fig. 27-3). Abnormalities of hepatic function are usually mild. Hyposplenism, diagnosed by abnormal peripheral smear and liver spleen scan and often associated with splenomegaly, predisposes to fatal bacterial infections. Peripheral nerve involvement may result in a painful sensory polyneuropathy, followed later by motor deficits. Autonomic neuropathy causing orthostatic hypotension, lack of sweating, GI disturbances, bladder dysfunction, and impotence may occur alone or together with peripheral neuropathy. Orthostatic hypotension is one of the major hampering complications of AL amyloidosis, with some patients being bedridden. Skin involvement may take the form of purpura, characteristically around the eyes (Fig. 27-4), and ecchymoses, papules, nodules, and plaques, occurring usually on the face and upper trunk. AL amyloidosis may also infiltrate articular structures and mimic rheumatoid or an asymmetric seronegative synovitis. Infiltration of the shoulders may produce severe pain and swelling (shoulder pad sign).

A rare but potentially serious manifestation of AL amyloidosis is an acquired bleeding diathesis that may be associated with deficiency of factor X or factor IX or with increased fibrinolysis. It should be systematically sought before any biopsy of a deep organ. Widespread vascular deposits may also be responsible for bleeding. Prothrombin time and activated partial thromboplastin time measurements as well as determination of bleeding times are required to assess bleeding diathesis.

Monoclonal light chains can be detected by immunoelectrophoresis in 73% of the urine samples of patients with AL amyloidosis. The λ isotype is twice as frequent as the κ, contrasting with the 1:2 ratio of λ to κ observed in myeloma alone. With the use of more sensitive immunochemical techniques, a monoclonal immunoglobulin is found in the serum or the urine in almost 90% of patients. Immunochemical techniques combined with serum free light-chain (FLC) assays detect an abnormal result in 99% of patients.[17]

AL amyloidosis associated with IgM paraproteinemia characterizes a distinctive subset of patients who have a wider variety of underlying, often lymphoid clonal disorders (including 75% Waldenström macroglobulinemia), usually low-level FLC with a predominance of κ isotype, and higher prevalence of lymph node (31% vs. 3%) and lung (17% vs. 2%) involvement compared with patients with non-IgM monoclonal component.[18,19]

Diagnosis

AL amyloidosis should be considered in any patient who presents with nephrotic-range proteinuria with or without renal impairment,

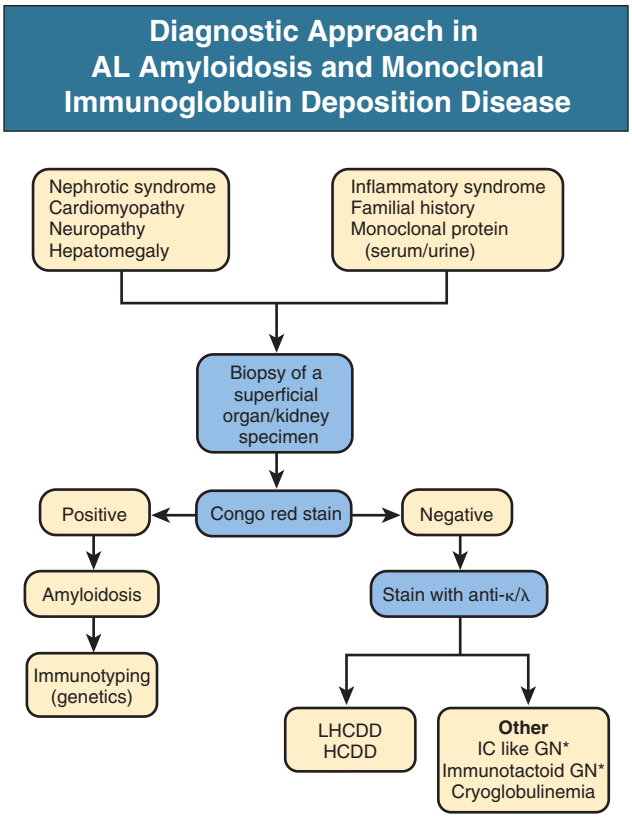

Figure 27-5 Algorithm of diagnostic procedures in light-chain (AL) amyloidosis and monoclonal immunoglobulin deposition disease (MIDD). *No extrarenal manifestation. *GN,* Glomerulonephritis; *IC,* immune complex; *HCDD,* heavy-chain deposition disease; *LHCDD,* light- and heavy-chain deposition disease.

nondilated cardiomyopathy, peripheral neuropathy, hepatomegaly, or autonomic neuropathy, whether or not a paraprotein can be detected in the serum or urine (Fig. 27-5). Particular vigilance should be maintained in patients with multiple myeloma or monoclonal gammopathy of undetermined significance (MGUS), especially of the λ isotype. Initial investigation should confirm the diagnosis of amyloidosis on tissue biopsy, followed by investigations to establish the type of amyloid present and the extent of organ involvement.

All patients require immunofixation of serum and urine (including serum-free light chains) in an attempt to demonstrate the presence of a monoclonal light chain and quantitation of serum FLC. A bone marrow specimen is necessary because 10% of patients will not have a demonstrable monoclonal light chain by immunofixation, and a clone of plasma cells detected in the bone marrow by immunohistochemistry is strong evidence of AL amyloidosis.

Biopsy of an affected organ is usually diagnostic, but less invasive alternatives should be preferred first. Biopsies of salivary glands or of subcutaneous abdominal fat yield positive results in 80% to 90% of cases. Rectal biopsy is diagnostic in more than 80%, provided the biopsy specimen contains submucosal vessels in which early deposits are located. Bone marrow biopsy specimens should be stained with Congo red for the presence of amyloid, and involvement of the bone marrow (observed in about 50% of patients) is strongly suggestive of the AL type. Evaluation of adequate specimens in experienced laboratories is necessary to maintain high diagnostic sensitivity and specificity.

It is not always easy to be certain that amyloidosis is of the AL type because immunohistochemical staining for immunoglobulin light chains may not be diagnostic, and the presence of a monoclonal component is strong but not conclusive evidence of the AL type. Caution is required when patients have an intact monoclonal immunoglobulin in the serum without evidence of FLC in the serum and urine. In those cases, hereditary forms of amyloidosis should be considered because they may produce clinical syndromes indistinguishable from AL and may coexist with MGUS.[9] In cases of doubt, DNA analysis and amyloid fibril sequencing by mass spectrometry are necessary.

Treatment and Outcome

AL amyloidosis is among the most severe complications of plasma cell proliferative disorders. Cardiac involvement responsible for congestive heart failure (CHF) and arrhythmias accounts for at least 40% of deaths. Therapy is aimed at annihilation of the plasma cell clone: "partial response" is now defined by a 50% or greater reduction in the difference between involved FLC (secreted by the plasma cell clone) and uninvolved FLC (the other isotype; dFLC), "very good partial response" by dFLC less than 40 mg/L, and "complete response" by the absence of detectable monoclonal immunoglobulin with normal serum FLC and κ/λ ratio.[20] In the responders, gradual regression of AL amyloid deposits is possible. Clinical improvement does not parallel regression of amyloid load.[21] Scintigraphy after injection of [^{123}I]-SAP component may be helpful for monitoring the extent of systemic amyloidosis, but this technique is available in a few centers only.

Only 15 years ago, overall survival in patients with AL amyloidosis was poor under a combination of melphalan plus prednisone (MP), compared with no treatment or colchicine therapy alone.[22,23] The prognosis of the disease has been transformed with the development of new strategies derived from myeloma treatment. High-dose melphalan followed by autologous stem cell transplantation (HDM/SCT) was introduced,[24] but treatment-related mortality (TRM) was consistently higher than in similarly treated patients with multiple myeloma: TRM was 11% for all patients over 15 years, and 5% in the last 5 years, but with improved patient selection and experienced management.[25] Despite its efficacy, HDM/SCT in AL amyloidosis generally remains restricted to those less than 65 years old, with up to two organs involved and without cardiac amyloidosis. Its place as first-line therapy in systemic AL amyloidosis is questionable.

High-dose dexamethasone-based regimens offer efficacy close to that of HDM/SCT but with much lower TRM.[26,27] M-Dex consists of oral melphalan (10 mg/m^2/day) and dexamethasone (40 mg/day) in 4-day cycles each month. The M-Dex combination is more rapidly effective than MP and may be used even in patients with advanced disease.[26] In a randomized prospective trial, M-Dex achieved similar hematologic and organ responses as HDM/SCT, but the 100-day mortality rate was higher in the HDM/SCT group.[27] In an intention-to-treat analysis, median survival was 57 months in the M-Dex group compared with 22 months in the HDM/SCT group after a median follow-up of 3 years. Problems of the trial included that (1) only 37 of the patients who were randomly assigned to HDM/SCT actually underwent the treatment and (2) TRM in the HDM group (24%) was higher than that reported in single-center studies from amyloidosis referral centers (4% to 14%). The high mortality was likely the result of enrollment of patients who had severe organ dysfunction and would not be eligible for HDM/SCT at many referral centers. A subset analysis of patients with low risk for an adverse outcome of intensive treatment also showed similar survival at 3 years of 80% in the M-Dex group versus 58% in the HDM/SCT group. Furthermore, patients who survived for at least 6 months after randomization and who received their assigned treatment had similar (20% to 30%) mortality.

On the basis of these findings, the following recommendations are proposed: (1) patients with severe organ dysfunction should receive M-Dex as first-line treatment, and (2) patients with less severe disease are eligible for M-Dex or HDM/SCT (still considered the reference treatment in U.S. centers). Patients should be carefully monitored by assessment of FLC, as well as of high-sensitivity cardiac troponin T and serum NT-proBNP levels in case of cardiac involvement. In those who do not show hematologic and NT-proBNP response after 3 to 6 months, treatment should be changed to alternatives, such as regimens based on thalidomide, lenalidomide, or the proteasome inhibitor bortezomib. These novel agents combined with dexamethasone induce rapid hematologic responses in most patients, even in those with refractory or relapsing disease. Bortezomib results in clonal response rates of 70% to 90% of patients, including about 40% complete remission (combined M-Dex plus bortezomib is currently being compared with M-Dex in an international randomized trial). Bortezomib may also be combined with cyclophosphamide and dexamethasone, with good tolerance and impressive response rates. Bortezomib should be used with caution in patients with advanced amyloid heart disease.

Dialysis and Transplantation

Most studies of the clinical course and outcome of dialysis patients include both AL and AA amyloidosis. Patient survival is about 70% at 1 year and decreases to 30% to 44% at 5 to 6 years. Median survival is shorter in patients with AL amyloidosis (26 to 39 months) than with AA amyloidosis; sepsis and cardiac deaths are the main causes of mortality.[28,29]

Cardiac amyloid is the most important predictor of mortality in dialysis patients with AL amyloidosis.[29,30] The management of patients with AL amyloid on hemodialysis (HD) is often complicated by persistent hypotension, GI hemorrhage, chronic diarrhea, and difficulties in the creation and maintenance of vascular access. Peritoneal dialysis (PD) could have several advantages over HD in the management of end-stage renal amyloidosis, including avoidance of vascular access and deleterious effects on blood pressure, although PD may induce protein loss in the dialysate and thus aggravate malnutrition. However, survival of AL and AA amyloidosis patients treated with PD is similar to that of patients receiving HD.

Kidney transplantation is limited by the severity of heart involvement and the recurrence of deposits in the transplanted kidney. It may be offered to select patients who have achieved persistent hematologic remission, at least for 1 year.[31] When solid-organ transplantation is considered (heart, liver, kidney), it should be preceded or followed by chemotherapy to avoid systemic progression and amyloid recurrence on the transplanted organ.[32,33] Patient survival was 9 years in those who had achieved at least a partial clonal response after kidney transplantation, versus 5 years in those who had no response.[34]

Secondary-Associated Amyloidosis (AA Amyloidosis)

Epidemiology

AA amyloidosis, or secondary amyloidosis, develops in 5% of patients with sustained elevation of serum amyloid A protein (SAA). Patients at risk are those with a long duration of chronic inflammatory disease (median 17 years),[35] high magnitude of acute-phase SAA response, homozygosity for SAA1 genotype, familial Mediterranean fever trait (heterozygosity for variant pyrin), and family history of AA amyloidosis.

An important epidemiologic aspect of AA amyloidosis is the changing spectrum of underlying disease. Pyogenic and granulomatous infections, especially tuberculosis, account for far fewer cases at present (15%) than previously.[35] In these patients, antibiotic treatment efficiently prevents AA amyloidosis by suppressing its cause. In contrast, the prevalence of chronic inflammatory arthritis has increased dramatically (60%).[35] However, it may be expected that effective disease-modifying treatments, including anti–tumor necrosis factor α (TNF-α) and rituximab, will induce a decline in the incidence of AA amyloidosis complicating rheumatoid arthritis, similar to AA amyloidosis in patients with Hodgkin disease, which has virtually disappeared with more efficient treatment of the hematologic disease. AA amyloidosis can be observed in a variety of other conditions, such as inflammatory bowel disease, non-ANCA systemic vasculitis, neoplasia, and immunodeficiency states. Hereditary AA amyloidoses associated with familial recurrent fever syndromes account for an increasing proportion of cases, about 10% in recent series.

Clinical Manifestations

Table 27-4 provides clinical features of AA amyloidosis.[35] The main target organ is the kidney, which is affected in almost all patients with AA amyloidosis. Presentation may be acute with nephrotic syndrome or very insidious. Proteinuria is absent in about 5% of cases. GI disturbances (e.g., diarrhea, constipation, malabsorption) and hepatosplenomegaly are the next most common manifestations. In contrast to AL amyloidosis, CHF, peripheral neuropathy, macroglossia, and carpal tunnel syndrome occur infrequently.

Diagnosis

Because half of patients in whom amyloid was found on renal tissue at autopsy had been reported to have proteinuria before death, some

recommend a systematic search for amyloidosis in patients with active, long-lasting inflammatory arthritis, even in the absence of proteinuria and chronic kidney disease (CKD). The identification of even asymptomatic amyloid deposits should prompt more effective control of inflammation. Although findings on kidney biopsy are positive in almost 100% of symptomatic patients, less invasive biopsy procedures should be attempted first. Biopsies of accessory salivary glands and abdominal fat yield positive results in more than 80% of patients. Immunohistochemical staining using antibodies to SAA is required to confirm that Congo red–positive amyloid deposits are of the AA type. SAP scintigraphy shows that bones are not affected (unlike AL amyloidosis).

Natural History and Treatment

Survival time of patients with AA amyloidosis is 133 months, much longer than with AL amyloidosis.[35] Main causes of death are infections and dialysis-related complications but not cardiac complications. Amyloid load and clinical outcome relate to circulating concentrations of SAA. The relative risk of death among patients with an SAA concentration below 4 mg/l is almost 18 times lower than among patients with an SAA concentration of 155 mg/l or greater. Even a very modest elevation in the SAA concentration of 4 to 9 mg/l is associated with a risk of death increased by a factor of 4. These data emphasize the importance of vigorous treatment of the underlying inflammatory disease. SAA (preferable to C-reactive protein) levels should be monitored monthly and maintained at a target value of less than 4 mg/l.[35]

Amyloid deposits regress in 60% of patients who have a median SAA concentration below 10 mg/l, and survival in these patients is superior to survival when amyloid deposits do not regress. Other factors associated with increased mortality are older age and end-stage renal disease (ESRD).

Eprodisate, a member of a newer class of compounds interfering with interactions between amyloidogenic proteins and GAGs, thus inhibiting polymerization of amyloid fibrils, slowed decline of renal function in patients with AA amyloidosis.[36] However, eprodisate had no beneficial effect on proteinuria, ESRD, amyloid content of abdominal fat, or mortality risk. The combination of CPHPC and SAP antibody is currently under evaluation (see previous discussion). Emphasis should remain on treatment of the underlying inflammatory disorder.

Most described patients receiving renal transplantation in AA amyloidosis are those with rheumatic diseases. Amyloid deposits recur in about 10% of the grafts. Infections and cardiovascular events are the main cause of early death and require careful management.[37]

Familial Mediterranean Fever and Other Hereditary Recurrent Fever Syndromes

Familial Mediterranean fever (FMF) represents a particular type of AA amyloidosis and is the most frequent cause of familial amyloidosis. Colchicine has proved to be efficient in its prevention and treatment. FMF is usually transmitted as an autosomal recessive disorder and occurs most often in Sephardic Jews and Armenians. It is caused by mutations of the gene *(MEFV)* encoding a protein called pyrin, or marenostrin.[38] Clinically, there are two independent phenotypes. In the first, brief, episodic, febrile attacks of peritonitis, pleuritis, or synovitis occur in childhood or adolescence and precede the renal manifestations. In the second phenotype, renal symptoms precede and may long be the only manifestation of the disease. The attacks are accompanied by dramatic elevations of acute-phase reactants, including SAA. Amyloid deposits are responsible for severe renal lesions with prominent glomerular involvement, leading to ESRD at a young age, and for early death. Colchicine can prevent the development of proteinuria, may occasionally reverse the nephrotic syndrome, and may prevent the glomerular filtration rate (GFR) decline in patients with non-nephrotic proteinuria. It is less effective in preventing progression in patients with nephrotic syndrome or renal impairment. The minimum daily dose of colchicine for prevention of amyloidosis is 1 mg, and patients with clinical evidence of amyloidotic kidney disease should receive daily doses of 1.5 to 2 mg. However, about 10% of patients are unresponsive to colchicine. Interleukin-1 receptor (IL-1R) antagonists are second-line agents. In patients with intolerance of colchicine, the drug should be stopped, then reintroduced at lower doses.

The recent identification of genes responsible for syndromes of periodic fever with amyloidosis has led to a molecular diagnosis of hereditary AA amyloidosis. These syndromes include the TNF receptor–associated periodic syndrome, the Muckle-Wells syndrome, and the familial cold autoinflammatory syndrome. Only a few cases of systemic AA amyloidosis have been reported in the hyperimmunoglobulinemia D with periodic fever syndrome. Most of these conditions can be controlled by means of anti–IL-1 or anti-TNF agents.[39]

MONOCLONAL IMMUNOGLOBULIN DEPOSITION DISEASE

History and Definition

It was known from the late 1950s that nonamyloidotic forms of glomerular disease "resembling the lesion of diabetic glomerulosclerosis" could occur in multiple myeloma. Subsequently, monoclonal light chains were detected in these lesions.[40]

In clinical and pathologic terms, light-chain, light- and heavy-chain, and heavy-chain deposition disease (LCDD, LHCDD, and HCDD, respectively) are similar and may therefore be referred to as monoclonal immunoglobulin deposition disease (MIDD). These forms differ from amyloidosis in that the deposits lack affinity for Congo red and do not have a fibrillar organization. The distinction also relates to different pathophysiology of amyloid, which implicates one-dimensional elongation of a pseudocrystalline structure, and MIDD, which rather involves a one-step precipitation of immunoglobulin chains.

Epidemiology

Light-chain deposition disease is found in 5% of myeloma patients at autopsy, whereas the prevalence of AL amyloidosis is about 11%. LCDD and HCDD may occur in a wide range of ages (28 to 94), with a male preponderance (Table 27-5). More than 20 patients with HCDD have been described so far, but the disease is most likely underdiagnosed.

Pathogenesis

Light-chain deposition may require light chains with distinct properties that favor deposition in tissues. Various properties of light-chain variable domains may contribute to MIDD pathogenesis[41]:

- Restricted use of three κ germ-line genes, with an apparent overrepresentation of the rare $V_{\kappa IV}$ variability subgroup.
- Size abnormalities of light chains, present in one third of patients.
- Unusual amino acid substitutions in LCDD light chains may modify the light-chain conformation or be responsible for hydrophobic interactions between V domains or between V domains and extracellular matrix proteins.

Clinical Features in Patients with MIDD		
Characteristics	**LCDD/LHCDD**	**HCDD**
Male-to-female ratio	1.5	0.7
Age, yr (range)	57 (28-94)	56 (26-79)
Hypertension (%)	53	90
Renal failure (serum creatinine ≥130 µmol/l) (1.47 mg/dl) (%)	93	85
Nephrotic syndrome* (%)	35	50
Hematuria (%)	45	88
Nodular glomerulosclerosis (%)	31-100	96
Multiple myeloma (%)	52	22
Monoclonal protein (blood or urine) (%)	84	56†

Table 27-5 Clinical, histologic, and laboratory features in patients with monoclonal immunoglobulin deposition disease (MIDD). *Proteinuria ≥3 g/day. †Including two cases with only free κ chain. *LCDD,* Light-chain deposition disease; *LHCDD,* light- and heavy-chain deposition disease; *HCDD,* heavy-chain deposition disease. *(From reference 66.)*

- When pathogenic light chains were undetected in serum and urine, they were found to be *N*-glycosylated, suggesting that glycosylation increases their propensity to precipitate in tissues. However, as in AL amyloidosis, extrinsic conditions may also contribute to aggregation of the light chain. The same light chain can form granular aggregates or amyloid fibrils, depending on the environment, and different, partially folded intermediates of the light chain may be responsible for amorphous or fibrillar aggregation pathways.[42]

Heavy-chain deposition disease may also be associated with unique heavy chains. A deletion of the first constant domain C_H1 was found in deposited or circulating heavy chains in patients with γ-HCDD.[41,43] In the blood, the deleted heavy chain either was associated with light chains or circulated in small amounts as a free unassembled subunit.[44] It is likely that the C_H1 deletion facilitates the secretion of free heavy chains that are rapidly cleared from the circulation by organ deposition. The variable V_H domain also is probably required for tissue precipitation.

A striking feature of LCDD and HCDD is extracellular matrix accumulation. Nodules are made of normal matrix constituents. In cultured mesangial cells, LCDD light chains enhance the production of tenascin-C and of profibrotic cytokines, such as transforming growth factor β and platelet-derived growth factor.[45]

Clinical Manifestations

A systemic disease with immunoglobulin chain deposition in a variety of organs, MIDD leads to various clinical manifestations, but visceral immunoglobulin chain deposits may be totally asymptomatic and found only at autopsy.[41]

Renal Manifestations

Renal involvement is a constant feature of MIDD, and renal symptoms, mostly proteinuria and CKD, often dominate the clinical presentation[41,46,47] (Table 27-5). In 18% to 53% of LCDD patients, albuminuria is associated with the nephrotic syndrome. In about one fourth, however, albuminuria is less than 1 g/day, and these patients exhibit mainly a tubulointerstitial syndrome. Albuminuria is not correlated with the presence of nodular glomerulosclerosis, at least initially, and may occur in the absence of significant glomerular lesions on light microscopy. Hematuria is more common, especially in HCDD, than would be expected for a nephropathy in which cell proliferation is usually modest.

The high prevalence, early appearance, and severity of CKD are other salient features of LCDD. In most cases, GFR declines rapidly, which is a main reason for referral. CKD occurs with comparable frequency in patients with either low or high protein excretion and may present in the form of subacute tubulointerstitial nephritis or rapidly progressive glomerulonephritis (RPGN), respectively. The prevalence of hypertension is variable, but it must be interpreted according to associated medical history. Renal features of patients with HCDD are basically similar to those seen in LCDD and LHCDD, with a higher prevalence of hypertension and hematuria; extrarenal manifestations occur less often (Table 27-5).

Extrarenal Manifestations

Liver and cardiac involvement occurs in about 25% of patients with LCDD and LHCDD. Liver deposits are constant. They are either discrete and confined to the sinusoids and basement membranes of biliary ductules without associated parenchymal lesions or massive with marked dilation and multiple ruptures of sinusoids, resembling peliosis. Hepatomegaly with mild alterations of liver function test results is the most common symptom, but patients may also develop life-threatening hepatic insufficiency and portal hypertension.

Cardiac involvement is also frequent in LCDD and may be responsible for cardiomegaly and severe heart failure. Arrhythmias, conduction disturbances, and CHF are seen. Echocardiography and catheterization may reveal diastolic dysfunction and reduction in myocardial compliance similar to that found in cardiac amyloidosis.

Deposits may also occur along the nerve fibers and in the choroid plexus as well as in the lymph nodes, bone marrow, spleen, pancreas, thyroid gland, submandibular glands, adrenal glands, GI tract, abdominal vessels, lungs, and skin. They may be responsible for peripheral neuropathy (20% of the reported cases), GI disturbances, pulmonary nodules, amyloid-like arthropathy, and sicca syndrome. Extrarenal deposits are less common in patients with HCDD.

Hematologic Findings

Myeloma is diagnosed in about 50% of the patients with LCDD or LHCDD and in about 25% of those with HCDD. MIDD, as with AL amyloidosis, is often the presenting disease that leads to the discovery of myeloma at an early stage. MIDD may occasionally complicate Waldenström macroglobulinemia, chronic lymphocytic leukemia (CLL), and nodal marginal zone lymphoma. MIDD often occurs in the absence of a detectable malignant process, even after prolonged (>10 years) follow-up. A monoclonal bone marrow plasma cell population is then easily detectable on immunohistology.

Pathology

Light Microscopy

Because MIDD is not only a glomerular disease, tubular lesions may be more conspicuous than the glomerular damage. Tubular lesions are characterized by the deposition of a refractile, eosinophilic, periodic acid–Schiff (PAS)–positive, ribbon-like material along the outer part of the tubular basement membranes. The deposits predominate around the distal tubules, the loops of Henle, and, in some instances, the collecting ducts, whose epithelium is flattened and atrophied. Typical myeloma casts are only occasionally seen in pure forms of MIDD. In advanced stages, a marked interstitial fibrosis including refractile deposits is frequently associated with tubular lesions.

Glomerular lesions are heterogeneous. Nodular glomerulosclerosis is the most characteristic and is found in 30% to 100% of patients

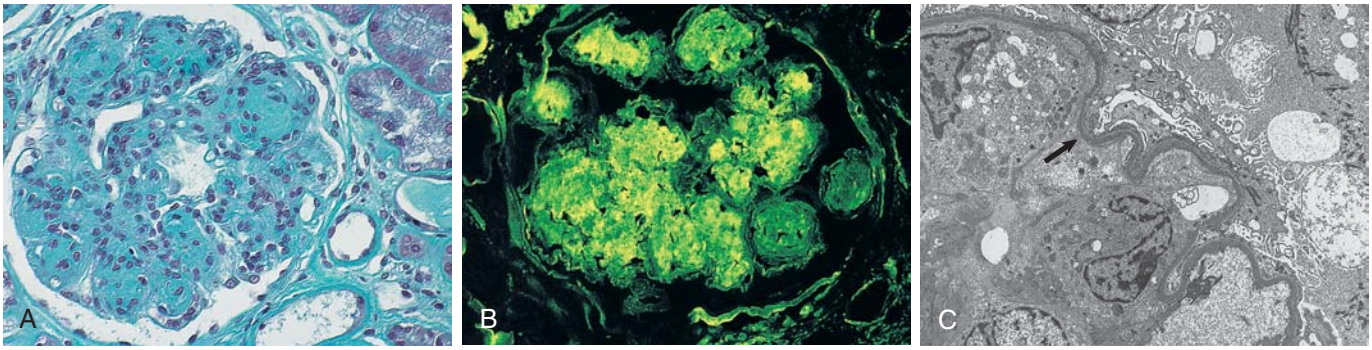

Figure 27-6 Light-chain deposition disease. A, Nodular glomerulosclerosis with mesangial matrix accumulation. (Masson trichrome stain; ×312.) **B,** Staining of mesangial nodules and tubular basement membranes with anti-κ antibody. with LCDD (Fig. 27-6, *A*). Expansion of the mesangial matrix with nodular glomerulosclerosis characterizes HCDD. Mesangial nodules are composed of PAS-positive, membrane-like material and are often accompanied by mild mesangial hypercellularity. Lesions resemble diabetic nodular glomerulosclerosis, with distinctive characteristics: the distribution of the nodules is fairly regular in a given glomerulus; the nodules are often poorly argyrophilic; and exudative lesions (e.g., fibrin caps and extensive hyalinosis of efferent arterioles) are not observed. In occasional cases with prominent endocapillary cellularity and mesangial interposition, the glomerular features mimic membranoproliferative glomerulonephritis (MPGN). Crescents are very uncommon except in α-HCDD.[48] Milder forms of LCDD show increased mesangial matrix or cells and a modest GBM thickening, with abnormal brightness and rigidity. Glomerular lesions may be detectable only by immunostaining or ultrastructural examination in early stages, or if they are induced by light chains with weak pathogenic potential.

Arteries, arterioles, and peritubular capillaries all may contain PAS-positive deposits in close contact with their GBM. Deposits do not show the staining characteristics of amyloid, but Congo red–positive amyloid deposits co-occur in approximately 10% of patients.[47]

Immunohistology

Immunohistology is central in the diagnosis of the various forms of MIDD. A criterion required for the diagnosis of MIDD is monotypic light-chain (mainly κ; Fig. 27-6, *B*) or heavy-chain fixation along tubular basement membranes. The tubular deposits stain strongly and predominate along the loops of Henle and the distal tubules, but also often are detected along the proximal tubules. In contrast, glomerular immunohistology patterns display marked heterogeneity. In patients with nodular glomerulosclerosis, deposits of monotypic immunoglobulin chains are usually found along the peripheral GBM and to a lesser extent in the nodules themselves (Fig. 27-6, *B*). Glomerular staining is typically weaker than that observed along the tubular basement membranes. This may not relate to the actual amount of deposited material because glomerular immunohistology may be negative despite prominent granular glomerular deposits observed by EM. Local modifications of deposited light chains thus might change their antigenicity. In patients without nodular lesions, glomerular staining occurs along the GBM and less frequently in the mesangium. A linear staining usually decorates Bowman capsule. Deposits are common in vascular walls and interstitium.

In patients with HCDD, immunohistology with anti–light-chain antibodies is negative despite typical nodular glomerulosclerosis. Monotypic deposits of γ, α, or μ heavy chains may be identified. Any γ subclass may be observed. Analysis of the kidney biopsy specimen with monoclonal antibodies specific for the constant domains of the γ heavy chain allowed identification of a deletion of the C_H1 domain in all tested cases. In most cases of HCDD, especially when a γ1 or γ3 chain is involved, complement components including C1 could be demonstrated in a granular or pseudolinear pattern. Complement deposits were often associated with signs of complement activation in serum.[49]

Recently, eculizumab treatment in dense deposit disease was shown to induce an HCDD-like pathology.[50]

Electron Microscopy

The most characteristic ultrastructural features on EM are finely to coarsely granular electron-dense deposits along the outer (interstitial) aspect of the tubular basement membranes. In the glomerulus, the deposits predominate in a subendothelial position along the GBM and are located mainly along and in the lamina rara interna (Fig. 27-6, *C*). Deposits can also be found in mesangial nodules, Bowman capsule, and the wall of small arteries between the myocytes. Nonamyloid fibrils have been reported in a few patients with LCDD or HCDD.

Diagnosis

The diagnosis of MIDD must be suspected in any patient with the nephrotic syndrome or rapidly progressive tubulointerstitial nephritis or with echocardiographic findings indicating diastolic dysfunction and the presence of a monoclonal immunoglobulin component in the serum or the urine (see Fig 27-5). The same combination is also seen in AL amyloidosis, but AL amyloidosis is more often associated with the λ light-chain isotype. Sensitive techniques such as urine immunofixation fail to identify a monoclonal immunoglobulin component in 10% to 20% of patients with LCDD or LHCDD and about 40% of those with HCDD (see Table 27-5), although the serum FLC ratio is consistently abnormal.[46] The kidney biopsy thus plays an essential role in the diagnosis of MIDD and of the associated dysproteinemia.

The definitive diagnosis is made by the immunohistologic analysis of tissue from an affected organ, in most cases the kidney, with use of a panel of immunoglobulin chain–specific antibodies, including anti-κ and anti-λ light-chain antibodies to stain the noncongophilic deposits. When the biopsy specimen stains for a single heavy-chain isotype and does not stain for light-chain isotypes, the diagnosis of HCDD should be suspected.

The diagnosis of the plasma cell dyscrasia relies on bone marrow aspiration and bone marrow biopsy with cell morphologic evaluation and, if necessary, immunophenotyping with anti-κ and anti-λ antisera to demonstrate monoclonality.

Outcome and Treatment

The outcome of MIDD remains uncertain, mainly because extrarenal deposits of light chains can be totally asymptomatic or cause severe organ damage leading to death. As in AL amyloidosis, treatment of patients with MIDD should be aimed at reducing immunoglobulin production. Nodular mesangial lesions and light-chain deposits may be reversible after effective chemotherapy. In the most recent series, 57% had stable or improved renal function, whereas 39% progressed to ESRD. The mean renal and patient survival rates were 64 and 90 months, respectively.[46] The only variable independently associated with renal survival was serum creatinine at biopsy, and the only predictor of death was the presence of lytic bone lesions.

Most patients treated with HDM/SCT achieve a hematologic and organ response with very low TRM.[51-53] The combination of bortezomib and dexamethasone may be used alone or as an induction in anticipation of HDM/SCT. To reduce the risk of disease recurrence on the graft, only patients who achieve a complete hematologic response should be candidates for renal transplantation.[54]

Monitoring of light-chain production should rely on serum FLC assay, particularly when a blood or urine monoclonal component cannot be detected by conventional methods.

Renal Diseases Associated with Monoclonal Immunoglobulin Deposition Disease

Myeloma Cast Nephropathy

The association of monoclonal light-chain deposits, mostly along renal tubular basement membranes, with typical myeloma cast nephropathy, occurs more frequently than reported initially. It was found in 11 of 34 patients with MIDD.[47] Nodular glomerulosclerosis, however, occurs infrequently (<10%), and some ribbon-like tubular basement membranes are seen in less than half the patients. In addition, one third of patients do not have granular dense deposits on EM.

AL Amyloidosis

Amyloid deposits are found in one or more organs in about 7% of LCDD patients. Because amyloid deposits are focal, their true incidence may be greatly underestimated. Although this association may result from peculiar light chains endowed with intrinsic properties that make them prone to form both fibrillar and nonfibrillar deposits, depending on the environment,[42] one cannot exclude the possibility that the coexisting diseases are induced by different variant clones.

NONAMYLOID FIBRILLARY AND IMMUNOTACTOID GLOMERULOPATHIES

Definition

Fibrillary and immunotactoid glomerulopathies are characterized, respectively, by fibrillar and microtubular deposits in the mesangium and the glomerular capillary loops (Table 27-6). These deposits do not have an amyloid-like cross-β structure and are readily distinguishable from amyloid by the larger thickness of fibrils and lack of Congo red staining. For other glomerulopathies, the distinction between nonamyloid fibrillary and immunotactoid glomerulopathy is of great clinical and pathophysiologic interest in patients with plasma cell dyscrasias. About 30% of immunotactoid glomerulopathies are associated with hematologic malignancies, mainly CLL, while this association is uncommon in fibrillary glomerulopathies.[55-57]

Epidemiology

The incidence of glomerulopathy with nonamyloid deposition of fibrillar or microtubular material in a nontransplant adult biopsy population is estimated at around 1%. It is most likely underestimated because of the insufficient attention given to atypical reactions with histochemical amyloid stains and the frequent lack of immunoultrastructural studies.

Immunologic and Clinical Characteristics of Fibrillary and Immunotactoid Glomerulopathies

Characteristics	Amyloidosis (AL Type)	Fibrillary Glomerulopathy	Immunotactoid Glomerulopathy
Congo red staining	Yes	No	No
Composition	Fibrils	Fibrils	Microtubules
Fibril or microtubule size	8-15 nm	12-22 nm	>30 nm*
Organization in tissues	Random (β-pleated sheet)	Random	Parallel arrays
Immunoglobulin deposition	Monoclonal LC (mostly λ)	Usually polyclonal (mostly IgG4), occasionally monoclonal (IgG1, IgG4)	Usually monoclonal (IgGκ or IgGλ)
Glomerular lesions	Deposits spreading from mesangium	MPGN, CGN, MP	Atypical MN, MPGN
Renal presentation	Severe NS, absence of hypertension and hematuria	NS with hematuria, hypertension; RPGN	NS with microhematuria and hypertension
Extrarenal manifestations (fibrillar deposits)	Systemic deposition disease	Pulmonary hemorrhage	Microtubular inclusions in leukemic lymphocytes
Association with LPD	Yes (myeloma)	Uncommon	Common (CLL, NHL, MGUS)
Treatment	Melphalan + dexamethasone; intensive therapy with blood stem cell autograft	Corticosteroids ± cyclophosphamide (crescentic GN)	Treatment of the associated LPD

Table 27-6 Immunologic and clinical characteristics of fibrillary and immunotactoid glomerulopathies. *Mean diameter of the substructures did not differ between fibrillary glomerulonephritis (15.8 ± 3.5 nm) and immunotactoid glomerulopathy (15.2 ± 7.3 nm) in the series of Bridoux and colleagues.[54] *CGN,* Crescentic glomerulonephritis; *CLL,* chronic lymphocytic leukemia; *GN,* glomerulonephritis; *LC,* light chain; *LPD,* lymphoproliferative disorder; *MGUS,* monoclonal gammopathy of undetermined significance; *MN,* membranous nephropathy; *MP,* mesangial proliferation; *MPGN,* membranoproliferative glomerulonephritis; *NHL,* non-Hodgkin lymphoma; *NS,* nephrotic syndrome; *RPGN,* rapidly progressive glomerulonephritis.

Clinical Manifestations

The characteristics of fibrillary and immunotactoid glomerulopathies are described in Table 27-6 in comparison to AL amyloidosis. Patients with immunotactoid and fibrillary glomerulopathies have a mean age of 55 to 60 years (extreme: 19 to 86 years). They usually present with the nephrotic syndrome, microscopic hematuria, and mild to severe CKD. Recent series show no significant difference between immunotactoid and fibrillary glomerulopathy patients in serum creatinine level, incidence of nephrotic syndrome, microscopic hematuria, hypertension, or CKD.[55,56] Extrarenal manifestations are uncommon and may involve the lung, skin, and peripheral nervous system.

Pathology

Immunotactoid Glomerulopathy

Renal biopsy shows membranous nephropathy (often associated with segmental mesangial proliferation; Fig. 27-7) or lobular MPGN. Granular deposits of IgG and C3 with activation of the classical and terminal pathway of complement are observed along capillary basement membranes and in mesangial areas.[57] In a series of 23 patients in whom diagnosis was based on ultrastructural appearance of the deposits, IgG deposits were monotypic in 13 of 14 patients with immunotactoid glomerulopathy (κ, seven cases; λ, six cases) and in only one of nine patients with fibrillary glomerulopathy.[55] A circulating monoclonal immunoglobulin was detected in only 6 of 14 patients with immunotactoid glomerulopathy. On EM, the distinguishing morphologic features of immunotactoid glomerulopathy are organized deposits of large, thick-walled microtubules (typically >30 nm in diameter), at times arranged in parallel arrays (Fig. 27-7, *C*).

Patients with immunotactoid glomerulopathy exhibit a high prevalence of CLL, lymphoplasmacytic lymphoma, and MGUS.[55,57] Intracytoplasmic crystal-like immunoglobulin inclusions were found in four patients with CLL and in the lymphoma patient.[55]

Fibrillary Glomerulopathy

Mesangial proliferation and aspects of MPGN are predominantly reported in series of fibrillary glomerulopathy. Glomerular crescents are present in about 30% of the biopsy specimens. Immunofluorescence studies mainly show IgG deposits of the IgG subclass with a predominant mesangial localization. Monotypic deposits containing mostly IgGκ are detected in no more than 15% of patients. On EM, fibrils are randomly arranged, and their diameter varies between 12 and 22 nm. The fibril size alone is not sufficient to distinguish nonamyloidotic fibrillary glomerulonephritis (GN) from amyloid.[55]

Diagnosis

Diagnosis of immunotactoid and fibrillary glomerulopathies relies on EM, which must be performed in patients with atypical membranous nephropathy or MPGN as well as in those with monotypic deposits in glomeruli. Renal biopsy specimens from such patients with glomerular disease should be routinely examined with anti-κ and anti-λ light-chain antibodies. In patients with immunotactoid glomerulopathy, lymphoproliferative disease should be sought. Association of immunotactoid and fibrillary glomerulopathy with hepatitis C virus or human immunodeficiency virus infection has also been reported.

Outcome and Treatment

Patients with fibrillary glomerulopathy usually respond poorly to corticosteroids and cytotoxic drugs, with an incidence of ESRD of about 50%.[55,57] Preliminary reports suggest that they may respond to rituximab.[58] The prognosis of immunotactoid glomerulopathy appears to be better than that of fibrillary glomerulonephritis. Therapy directed against the underlying hematologic malignancy usually leads to remission of the nephrotic syndrome.[55,59] Renal transplantation has been performed in a few patients. Disease recurred in several, especially in those with a persistent monoclonal gammopathy.[58]

GLOMERULAR LESIONS ASSOCIATED WITH WALDENSTRÖM MACROGLOBULINEMIA

Symptomatic renal disease is much less common in patients with Waldenström macroglobulinemia than in those with multiple myeloma. Glomerulonephritis with intracapillary thrombi of aggregated IgM (intracapillary monoclonal deposit disease) is the most characteristic renal morphologic finding, but it has become rare, probably because of increased efficacy of chemotherapy. This entity may also occur with other IgM-secreting monoclonal proliferations.[61] Waldenström macroglobulinemia is associated with variable degrees of proteinuria and altered renal function. It is characterized by PAS-positive, Congo red–negative intracapillary deposits, sometimes voluminous enough to occlude capillary lumina. On immunohistology, thrombi and deposits stain with anti-μ and with anti-κ. The deposits are electron dense and granular without microtubular organization. Some of these patients have strong activation of the classical complement pathway with or without cryoglobulinemia. Other patients have MPGN with a bright μ and κ staining along the glomerular capillaries, without cryoglobulinemia. Renal manifestations usually improve with chemotherapy. Renal amyloidosis (mostly

AL) is uncommon but should be suspected in patients presenting with massive proteinuria. Because renal biopsy may be hazardous in patients with Waldenström macroglobulinemia, who frequently have increased bleeding time, it is wise to search for amyloid deposits first by a less invasive tissue biopsy. Hematopoietic stem cell transplantation and purine analogues may represent the most effective therapies.[19]

OTHER TYPES OF GLOMERULONEPHRITIS

In some patients, glomerular deposition of monoclonal IgG can produce a proliferative GN that mimics immune complex GN on light and electron microscopy.[62] Proper recognition of this entity requires confirmation of monoclonality by immunostaining for the γ heavy-chain subclasses. Tissue fixation of complement was observed in 90% of cases, and 40% of patients had hypocomplementemia. Clinical presentation included CKD in 80%, proteinuria in 100%, nephrotic syndrome in 44%, and microhematuria in 60%. Minute amounts of a monoclonal serum protein with the same heavy- and light-chain isotype as that of the glomerular deposits was identified in 50% of cases. No patient had overt myeloma or lymphoma at presentation or during follow-up. Proliferative GN with monoclonal IgG deposits recurs in the allograft.[63]

Few cases of nonorganized MIDD with a membranous pattern have been reported. The majority of these patients have IgG1 deposits, and those with proliferative lesions have mainly IgG3 deposits.[64] A circulating monoclonal IgG could be detected in only one fourth of these patients.

Several cases of GN with isolated C3 deposits and monoclonal gammopathy have been reported. These may be related to complement activation through an autoantibody activity of the monoclonal IgG against a complement alternative pathway regulatory protein.[65]

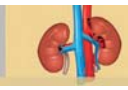
CHAPTER 28



Other Glomerular Disorders and the Antiphospholipid Syndrome

Richard J. Glassock

This chapter provides a description of several glomerular and vascular diseases, not necessarily related to each other. Each disorder must be recognized and differentiated from other, more common glomerular disorders to estimate the prognosis, to determine whether a familial disorder is present, to plan appropriate therapy, or to determine the risk of a recurrence in the transplanted kidney.

MESANGIAL PROLIFERATIVE GLOMERULONEPHRITIS WITHOUT IgA DEPOSITS

Mesangial proliferative glomerulonephritis (MesPGN) encompasses a heterogeneous collection of disorders having a diverse and largely unknown etiology and pathogenesis. The common feature that binds these various disorders is a histologic pattern on light microscopy of glomerular injury characterized by diffuse mesangial proliferation[1-3] (Fig. 28-1). Thus, MesPGN is noted for a diffuse and global increase in mesangial cells, often accompanied by an increase in mesangial matrix. Other cells (e.g., monocytes) may also contribute to the hypercellularity. As such, MesPGN is a glomerular lesion, not a specific disease entity.

For the purpose of this discussion, other forms of cellular proliferation that occur within the mesangial zones but are more focally and segmentally distributed are not included. These focal and segmental forms of proliferative glomerulonephritis (GN), often accompanied by areas of segmental necrosis of the glomerular tufts and very localized crescents, may be a part of the evolutionary stages of an initially pure MesPGN, but they often signify the presence of systemic disease processes, including systemic lupus, Henoch-Schönlein purpura and IgA nephropathy, infective endocarditis, microscopic polyangiitis, granulomatous polyangiitis (Wegener granulomatosis), Goodpasture disease, rheumatoid vasculitis, and mixed connective tissue disease. On occasion, a lesion of focal and segmental proliferative GN is discovered in the absence of any recognizable multisystem disease process and in the absence of IgA deposits (i.e., idiopathic focal and segmental proliferative GN). Such patients have a clinical presentation, course, and response to treatment that are similar to those described for pure MesPGN, but they are not discussed further in this section.

In "pure" MesPGN, the peripheral capillary walls are thin and delicate without obvious deposits, reduplication, focal disruptions, or cellular necrosis. The visceral and parietal epithelial cells, although occasionally enlarged, have not undergone proliferation. Crescents and segmental sclerosis should be absent in the "pure" form of the disorder. In addition, large deposits staining with periodic acid–Schiff or fuchsin in the mesangium should be absent, because these deposits suggest IgA nephropathy (see Chapter 23) or lupus nephritis (see Chapter 26). The tubulointerstitium and vasculature are usually normal, unless reduced renal function or hypertension is present or the patient is of advanced age.

On immunofluorescence (IF) microscopy, a wide variety of patterns of immunoglobulin and complement deposition are observed (Table 28-1). Most often, diffuse and global IgM and C3 deposits are found scattered throughout the mesangium in a granular pattern (so-called IgM nephropathy), but isolated C3, C1q, or even IgG deposits may also be seen.[4] If IgA is the predominant immunoglobulin deposited, the diagnosis is IgA nephropathy. In some cases, no immunoglobulin deposits are found at all. Prominent C3 deposition in the absence of immunoglobulin deposition should suggest a C3 glomerulopathy (see Chapter 22).[5] Extensive C1q deposits, with or without immunoglobulin deposits should suggest C1q nephropathy.[6]

On electron microscopy (EM), the number of mesangial cells is increased, with an occasional infiltrating monocyte or polymorphonuclear leukocyte. The amount of mesangial matrix is frequently but not invariably diffusely increased. Electron-dense deposits within the mesangium can be seen in many cases, particularly those with immunoglobulin (IgG or IgM) deposits on IF microscopy. Very large mesangial or paramesangial electron-dense deposits suggest IgA nephropathy even if IF microscopy is not available. Subendothelial, intramembranous, or subepithelial deposits are not seen. If present, these suggest a postinfectious etiology such as underlying lupus nephritis or a C3 glomerulopathy. Deposits of multiple immunoglobulin classes identified by immunohistology and large numbers of tubuloreticular inclusions on EM suggest underlying lupus nephritis.

The clinical presentation of MesPGN is quite varied, although persistent or recurring microscopic or macroscopic hematuria with mild proteinuria is most common. Nephrotic syndrome with heavy proteinuria is a less frequent initial presentation but is seen more often in association with diffuse mesangial IgM deposits (IgM nephropathy)[2] or C1q deposits (C1q nephropathy).[4,6] Pure MesPGN is a rather uncommon lesion (<5%) in patients diagnosed with idiopathic nephrotic syndrome.[2,3] Lesions of MesPGN have been observed in acute parvovirus B19 disease and in association with Castleman disease.[7,8]

Renal function and blood pressure are usually normal, at least initially. Serologic studies are generally unrewarding. Serum C3 and C4 complement components and hemolytic complement activity (CH50) are normal. A low C3 level suggests a C3 glomerulopathy. Assay results for antinuclear antibody (ANA), antineutrophil cytoplasmic autoantibody (ANCA), anti–glomerular basement membrane (anti-GBM) autoantibody, and cryoimmunoglobulins are negative. Nevertheless, these studies should be performed in most patients to exclude known causes. MesPGN can also be a finding in

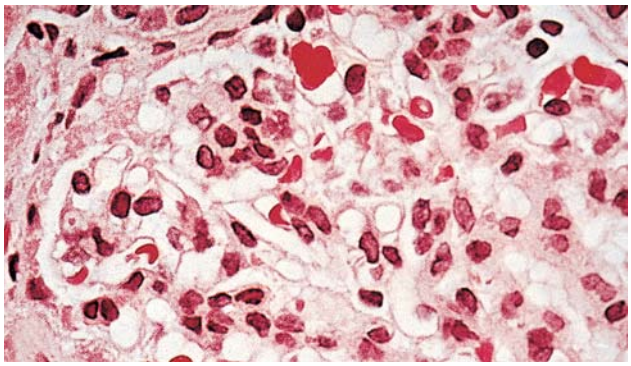


Figure 28-1 Pure mesangial proliferative glomerulonephritis (MesPGN). Note the increase in mesangial cellularity, the delicate peripheral capillary walls, and the absence of sclerosis or parietal epithelial cell proliferation. (Hematoxylin-eosin stain; magnification ×410.) *(Modified from reference 1.)*

Immunofluorescence Microscopy Patterns in MesPGN

Pattern	Associated Disorders
Predominantly mesangial IgA deposits	IgA nephropathy (± IgM, C3)
Predominantly mesangial IgG deposits	Often associated with systemic lupus (± IgM, C3)
Predominantly mesangial IgM deposits	IgM nephropathy (± C3)
Mesangial C1q deposits	C1q nephropathy (± IgG, IgM, C3)
Isolated mesangial C3 deposits	Often associated with resolving poststreptococcal GN
Negative for immunoglobulin or complement deposits	Idiopathic MesPGN

Table 28-1 Immunofluorescence microscopy patterns in mesangial proliferative glomerulonephritis (MesPGN).

resolving postinfectious (poststreptococcal) GN. Isolated C3 deposits with scanty, subendothelial or subepithelial (hump-like) deposits on EM may be seen in this situation. Urinary protein biomarkers may help to determine prognosis.[9]

IgM Nephropathy

IgM nephropathy[2] is characterized by diffuse and generalized glomerular deposits of IgM often accompanied by C3. Mesangial electron-dense deposits are also observed. On light microscopy, a picture of "pure" MesPGN is usually observed, sometimes with superimposed focal segmental glomerulosclerosis (FSGS).[10] It is an uncommon finding accounting for <5% of all renal biopsies.[10] Patients may present with recurring macroscopic hematuria and proteinuria, the latter in the nephrotic range in as many as 50% of patients. Persisting abnormalities and a poor response to corticosteroids or immunosuppressive therapy are often seen. As many as 50% of patients will eventually progress to typical FSGS and, if unresponsive to corticosteroids, will slowly develop chronic kidney disease (CKD) and end-stage renal disease (ESRD). Treatment of IgM nephropathy is highly uncertain, although steroid therapy may be associated with a complete or partial remission in as many as 50% of patients. The etiology and pathogenesis are unknown.

C1q Nephropathy

C1q nephropathy is characterized by diffuse deposits of C1q, often accompanied by IgG, IgM, or both.[4,6] C3 deposits are observed less frequently. These immunopathologic features resemble those seen in lupus nephritis; however, these patients have none of the clinical features of systemic lupus erythematosus (SLE) and do not develop SLE even after prolonged follow-up.[11] In addition to MesPGN, other morphologic lesions, including FSGS, are typically observed by light microscopy. Nephrotic-range proteinuria occurs, often with hematuria. Males predominate, and African Americans are often affected. Serum C3 components, ANA, and anti–double-stranded DNA (anti-dsDNA) antibodies are consistently normal or negative. The response to treatment is poor, and progression to ESRD may occur.

Mesangial Proliferative Glomerulonephritis Associated with Minimal Change Disease

MesPGN may also be a part of the spectrum of minimal change disease (MCD)–FSGS lesions (see also Chapters 17 to 19). Distinct mesangial hypercellularity superimposed on a lesion of MCD (diffuse foot process effacement seen on EM) may point to a greater likelihood for corticosteroid unresponsiveness and an eventual evolution to the FSGS lesion.

Natural History of Mesangial Proliferative Glomerulonephritis

The natural history of MesPGN varies, undoubtedly the result of etiologic and pathogenetic heterogeneity. In many patients, a benign course ensues, especially if hematuria and scant proteinuria (<1 g/day) are the principal features. Persisting nephrotic syndrome has a less favorable prognosis, and such patients may evolve into FSGS (see Chapters 18 and 19) and accompanying progressive CKD.[3,10]

Treatment of Mesangial Proliferative Glomerulonephritis

The treatment of "pure" MesPGN, unaccompanied by other underlying diseases or lesions such as SLE, C1q nephropathy, IgM nephropathy, MCD lesion, or IgA nephropathy, has not been well defined.[2,3] No prospective, randomized controlled trials (RCTs) have been performed because of the uncommon nature of the disorder. The prognosis for patients with isolated hematuria or hematuria combined with mild proteinuria (<500 mg/day) is generally benign, and thus no treatment other than management of hypertension is needed. For those patients with nephrotic syndrome, with or without impaired renal function, a more aggressive approach is often recommended, especially in the presence of diffuse IgM deposits, as discussed earlier, because many such patients will eventually progress to FSGS. Even in the absence of RCTs, an initial course of corticosteroid therapy may be justified in most patients with nephrotic-range proteinuria, such as prednisone, 60 mg/day or 120 mg every other day for 2 to 3 months, followed by lowered doses on alternate-day regimen for 2 to 3 additional months. About 50% of these patients experience a decrease in proteinuria to subnephrotic levels. Complete remissions occasionally occur. However, relapses of proteinuria are common when steroids are tapered or discontinued. Such relapsing, partially corticosteroid-responsive patients might benefit from the addition of cyclophosphamide, chlorambucil, or even cyclosporine or mycophenolate mofetil (MMF) to the regimen, although information on the therapeutic efficacy and safety of these agents in pure MesPGN is very limited.

Collagen Vascular (Rheumatic) Diseases Associated with Glomerular Lesions
Systemic lupus erythematosus (SLE; see Chapter 26)
Rheumatoid arthritis
Mixed connective tissue disease
Rheumatic fever
Ankylosing spondylitis
Reiter syndrome
Dermatomyositis/polymyositis
Scleroderma
Relapsing polychondritis
Systemic or renal-limited polyangiitis (see Chapter 25)

Box 28-1 Collagen vascular (rheumatic) diseases associated with glomerular lesions.

Patients with persistent treatment-unresponsive nephrotic syndrome will almost invariably progress to ESRD over several years. Whereas transplantation is not contraindicated, patients who do progress to ESRD rapidly and who develop superimposed FSGS may have a high risk of recurrence of proteinuria and FSGS in the transplanted kidney.

GLOMERULONEPHRITIS WITH RHEUMATIC DISEASE

Several so-called collagen vascular diseases other than SLE may be complicated by GN (Box 28-1). This section covers the glomerulonephritides that accompany rheumatoid arthritis,[11] mixed connective tissue disease,[12] polymyositis and dermatomyositis, acute rheumatic fever, scleroderma, and relapsing polychondritis. IgA nephropathy may also be seen in association with the seronegative spondyloarthropathies.

Rheumatoid Arthritis

A wide variety of glomerular, tubulointerstitial, and vascular lesions of the kidney may complicate rheumatoid arthritis (RA) (Box 28-2). Clinical abnormalities, including abnormal urinalyses (hematuria, leukocyturia, proteinuria), and reduced renal function are common in patients with RA, particularly those with severe or longstanding disease. Membranous nephropathy (MN) (see Chapter 20) is the most common glomerular lesion encountered, possibly because of the underlying disease itself or its therapy (parenteral or oral gold or penicillamine). The presence of HLA-DR3 increases the risk for development of MN in a patient with RA. The lesion is not associated with anti–phospholipase A_2 receptor (anti-PLA_2R) autoantibodies.

The course of MN in association with RA, in the absence of drugs, is similar to that of the idiopathic disease, although spontaneous remissions appear less likely to occur. By comparison, MN associated with drugs used to treat RA is most likely to remit after discontinuance of the drug therapy.[11] Such remissions may take many months to occur. Nevertheless, 60% to 80% of RA patients with drug-induced MN will remit within 1 year of stopping treatment.

Secondary (AA) amyloidosis (see Chapter 27) is found in 5% to 20% of patients with RA undergoing renal biopsy. Nephrotic syndrome and progressive renal failure are common.

The use of nonsteroidal anti-inflammatory drugs (NSAIDs) may also produce tubulointerstitial nephritis or MCD (see also Chapters 60 and 17).[13] A severe, necrotizing polyangiitis may complicate the course of longstanding RA (rheumatoid vasculitis).[14] These patients may have profound reduction in C3 levels, striking elevation of rheumatoid factors, and marked polyclonal hypergammaglobulinemia. Renal involvement in rheumatoid vasculitis is now relatively uncommon for poorly understood reasons. The use of TNF-α inhibitors for treatment of rheumatoid arthritis can evoke a picture resembling lupus nephritis (see Chapter 26).

Renal Disease in Rheumatoid Arthritis
Glomerular Lesions that May Be Direct Complications of the Disease
Membranous nephropathy (MN)
MesPGN (± IgA or IgM deposits)
Diffuse proliferative GN
Necrotizing and crescentic GN (rheumatoid vasculitis)
Amyloidosis (AA type)
Glomerular Lesions Associated with Agents Used in Treatment of Rheumatoid Arthritis
Gold: MN, MCD, acute tubular necrosis
Penicillamine: MN, crescentic GN, MCD
NSAIDs: acute tubulointerstitial nephritis (TIN) with MCD, acute tubular necrosis, MCD without TIN
Cyclosporine: chronic vasculopathy and TIN, focal and segmental glomerulosclerosis (?)
Azathioprine/6-mercaptopurine: TIN
Pamidronate: focal segmental glomerulosclerosis

Box 28-2 Renal disease in rheumatoid arthritis. *MCD,* Minimal change disease; *MesPGN,* mesangial proliferative glomerulonephritis; *NSAIDs,* nonsteroidal anti-inflammatory agents.

Mixed Connective Tissue Disease

Mixed connective tissue disease is characterized by features that overlap with those of SLE, scleroderma, and polymyositis.[12] Typically, the serum of such patients contains high-titer autoantibodies to extractable nuclear antigens (ribonucleoprotein-extractable nuclear antigen, U1 ribonucleoprotein antigen). Low titers of anti-dsDNA antibody may also be found. Renal disease, originally thought to be quite rare, is found in 10% to 50% of patients, most frequently MN and MesPGN.[14] Treatment with steroids is generally effective, but some patients exhibit progressive CKD. Patients with severe GN may respond to treatment regimens similar to those used in the treatment of lupus nephritis (see Chapter 26).

Polymyositis and Dermatomyositis

The related collagen vascular diseases polymyositis and dermatomyositis are characterized by inflammatory lesions in muscle and variable skin lesions and often include Raynaud phenomenon.[15] On occasion, patients have proteinuria and hematuria secondary to MesPGN with IgM deposits. Acute kidney injury (AKI) may rarely supervene when severe muscle injury and myoglobinuria are present. Treatment with steroids may, at least in part, ameliorate the renal manifestations in concert with improvement in the muscle and skin manifestations.

Acute Rheumatic Fever

Acute rheumatic fever secondary to a pharyngeal (but not cutaneous) infection with a rheumatogenic strain of group A β-hemolytic

streptococci is seldom accompanied by renal disease[16] (see Chapter 57). Poststreptococcal GN and acute rheumatic fever almost never coexist because of the distinct difference between nephritogenic and rheumatogenic strains of streptococci. In addition, cutaneous streptococcal infections are never associated with acute rheumatic fever sequelae. Nevertheless, on rare occasions, MesPGN has been associated with acute rheumatic fever.[16] MesPGN usually manifests with hematuria with scant proteinuria and often resolves with appropriate treatment and control of acute rheumatic fever.

Ankylosing Spondylitis and Reiter Syndrome (Seronegative Spondyloarthropathies)

The seronegative spondyloarthropathies and oligoarticular arthropathies may be associated with mesangial IgA deposition or MesPGN in some patients. Clinical manifestations are usually mild and nonprogressive. AA amyloidosis may complicate longstanding ankylosing spondylitis.

Scleroderma (Systemic Sclerosis)

Scleroderma is a heterogeneous disorder of unknown etiology and pathogenesis characterized by uncontrolled expansion of connective tissue in the skin and other visceral organs. There is also a marked tendency to produce vascular thickening and narrowing. Clinical manifestations vary from increased connective tissue in localized patches of skin (morphea) to diffuse and generalized disease (systemic sclerosis). The latter pattern leads to thickening of the skin of the face and hands, telangiectasia, Raynaud phenomenon, tendon friction rubs, and sclerodactyly. A characteristic pattern of blood vessel abnormalities is seen in the nail beds. Visceral involvement in the systemic form causes interstitial pulmonary fibrosis, loss of esophageal and other gastrointestinal motility, restrictive cardiomyopathy, and renal disease. Limited forms of the disease (CREST syndrome: calcinosis, Raynaud phenomenon, esophageal dysmotility, sclerodactyly, and telangiectasia) also occur but are seldom associated with renal disease. The disorder is seen more frequently in females, with an onset usually in young adults. Approximately 90% of patients will have a speckled pattern of fluorescent ANA; 20% will have detectable antibody to topoisomerase I (Scl-70). Anticentromere antibody is strongly associated with the CREST syndrome. Anti-DNA polymerase is associated with a poor prognosis and a high prevalence of renal involvement. Rarely, the visceral abnormalities may occur in the absence of cutaneous lesions (scleroderma sine scleroderma).

Renal involvement in scleroderma can be quite varied, from a low-grade proteinuria and slight impairment of glomerular filtration rate (GFR), to a more marked reduction in renal blood flow leading to a greatly elevated filtration fraction due to a mild MesPGN, to severe AKI. The last is referred to as *scleroderma renal crisis* and consists of severe (hyperreninemic) hypertension, encephalopathy, systolic and diastolic congestive heart failure, and AKI. There is often an accompanying microangiopathic hemolytic anemia with schistocytes in the peripheral blood film and greatly elevated serum lactate dehydrogenase levels. On occasion, AKI may develop in the absence of hypertension. AKI results from primary involvement of the arcuate and interlobular arteries (Fig. 28-2). It may be superimposed on lesions of hypertensive emergencies (malignant hypertension, such as fibrinoid necrosis of the afferent arterioles) and ischemic glomerular changes, such as wrinkling of the capillary wall and thickening of the basal lamina.

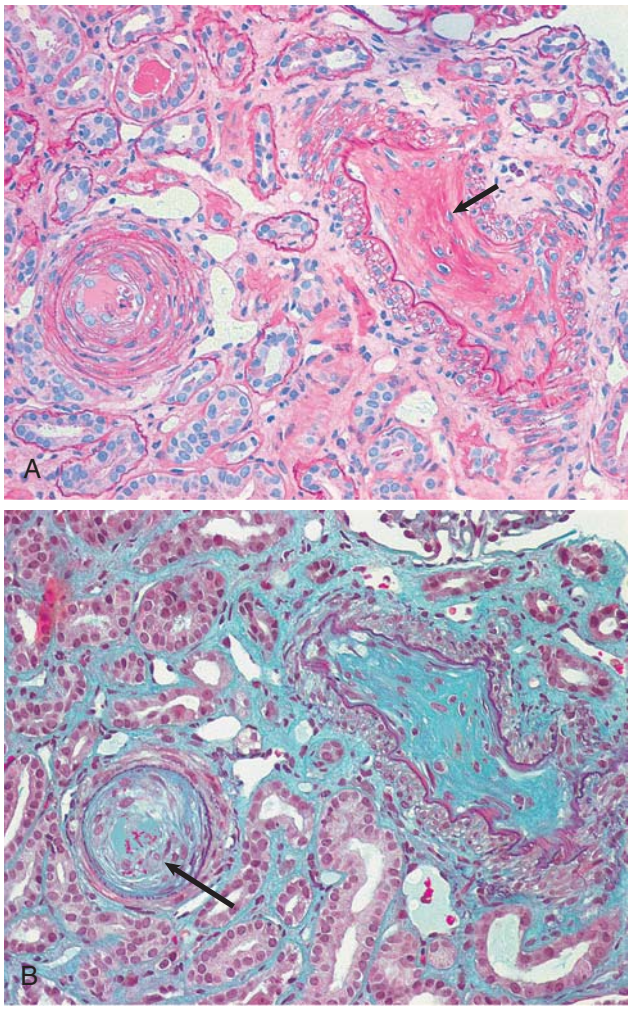

Figure 28-2 Scleroderma. A, Two interlobular arteries, one transversely and one tangentially cut, show a pronounced subendothelial thickening with weakly periodic acid–Schiff–positive mucinous material and myofibroblasts *(arrow)*. **B,** Fragmented erythrocytes (schistocytes) can be seen in the Goldner elastica stain in *red (arrow)*. The process is limited to the intima as the lamina elastica interna is preserved. Surrounding tubules are collapsed and have atrophic epithelia due to postarteriolar ischemia. *(Courtesy H. J. Groene, Heidelberg, Germany.)*

The prognosis of patients with scleroderma crisis has remarkably improved with the use of angiotensin-converting enzyme (ACE) inhibitors. In one study, ACE inhibitor treatment was associated with better patient survival at 1 year (75% vs. 15%) and with significant preservation or recovery of renal function.[17] Transplantation may be a reasonable treatment option, but progression of disease in other visceral organs may limit life expectancy.

Relapsing Polychondritis

Polychondritis is a chronic relapsing disorder characterized by destructive inflammation of cartilage (ear, nose, trachea, costal cartilage) and may be associated with crescentic GN, MesPGN, or MN. Lesions of cartilage may lead to deformities (saddle nose, floppy ears, tracheal collapse or stenosis), and the renal disease may be severe and progressive, leading to renal failure. Aggressive management of progressive disease with corticosteroids and cytotoxic agents (cyclophosphamide) is indicated to control both the systemic and renal manifestations.

ANTIPHOSPHOLIPID ANTIBODY SYNDROME

The antiphospholipid antibody syndrome (aPLA syndrome, APS) is a prothrombotic disorder characterized by venous and arterial thrombosis and by the presence of circulating autoantibodies to phospholipid-protein complexes, including those of the coagulation cascade.[18-20] The syndrome was first recognized by Graham Hughes in 1983 and in the succeeding three decades has been described to have protean manifestations ranging from migraine headaches to multiple thrombosis and multiorgan failure ("catastrophic" aPLA syndrome).[19] The clinical features are quite varied, and a high degree of clinical suspicion is required for early diagnosis. Neurologic symptoms and signs are common, including transient cerebral ischemic attacks (TIAs), strokes, migraine, seizures, myelitis, and balance and sensory disturbances (often resembling multiple sclerosis). Cardiovascular problems, such as pulmonary hypertension, premature atheromatous disease, renal artery stenosis, and myocardial infarction, are common. Livedo reticularis is an important diagnostic clue (Fig. 28-3). Adrenal infarction or hepatic venous thrombosis may lead to acute adrenal insufficiency or Budd-Chiari syndrome, respectively. Visual loss, field defects, anosmia, aseptic bone necrosis, fracture, spinal claudication, and autonomic dystrophy are other, less well-described complications. Pulmonary hemorrhage or fibrosing alveolitis can be a presenting feature.[21] Repeated pregnancy loss (two or more) is observed often. The kidneys are frequently involved with a form of thrombotic microangiopathy (see Chapter 29).

The aPLA syndrome may occur as a "primary" form without any known systemic disease or may accompany SLE (see also Chapter 26). The aPLA syndrome (primary or SLE related) should always be suspected whenever a history of migraine, headache, TIA or stroke, multiple pregnancy loss, or arterial or venous thrombosis or a family history of autoimmune disease is elicited. In 2006, the criteria for the definite diagnosis of APS were revised and updated.[22] These include the presence of at least both one clinical criteria plus one laboratory criteria: Clinical- i) thrombosis (arterial or venous); ii) Pregnancy morbidity (spontaneous abortions, still births). Laboratory (two or more occasions at least 12 weeks apart):- i) Lupus anticoagulant; ii) anticardiolipin antibody; iii) anti-β_2 glycoprotein-I antibody.

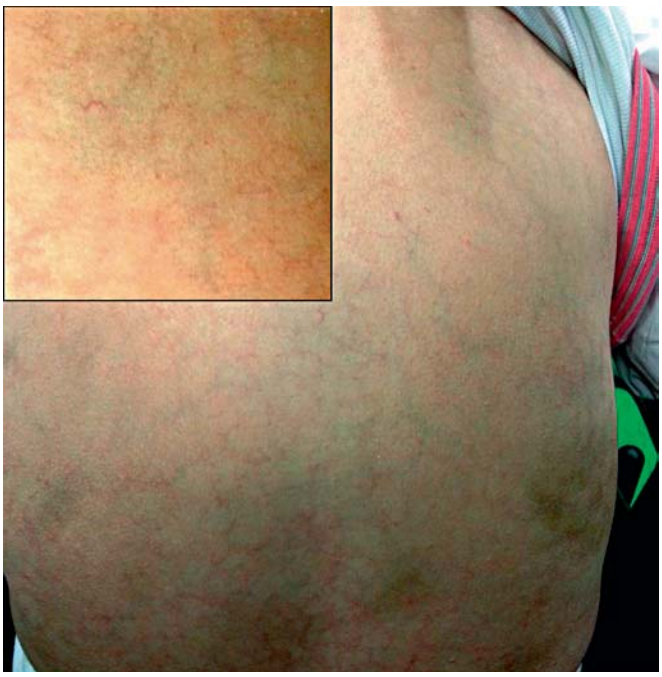

Figure 28-3 Livedo racemosa (livedo reticularis) in patient with antiphospholipid antibody syndrome. Note reticulated skin changes (*insert,* higher magnification) on the patient's back in addition to some hematomas related to her warfarin therapy. *(Courtesy J. Floege, Aachen, Germany.)*

The pathogenesis of APS is quite complex and probably multifactorial. The thrombotic state seems to involve generation of reactive oxygen species leading to alterations in β_2-glycoprotein-1 function, impaired function of endothelial nitric oxide synthase, activation of prothombotic receptors by autoantibodies, increased expression/activation of tissue factor, increased modified forms of prothrombotic factor XI, disruption of annexin A5 shield, and antibody-mediated activation of C3 and/or C5.[23]

Laboratory testing will usually reveal an autoantibody to phospholipids (anticardiolipin, anti–β_2-glycoprotein 1, or prothrombin), but "antibody-negative" aPLA syndrome has been described.[24,25] False-positive test results for syphilis and a "lupus anticoagulant" are common.[24,25] A prolonged prothrombin or partial thromboplastin time that does not correct when plasma is diluted 1:1 with normal plasma is found in such circumstances. Antiphospholipid antibodies may also cross-react with platelet factor 4–heparin complex and thus may be associated with a "false positive" for antibody in heparin-induced thrombocytopenia, giving rise to significant clinical confusion. Mild thrombocytopenia is common (platelet counts about 100,000/mm^3, but usually not less than 80,000/mm^3). Thrombocytopenia may be an *in vitro* phenomenon related to the effect of the aPLA antibody on platelet membrane biology. A mild hemolytic anemia (Coombs negative or positive) may coexist, giving rise to confusion with thrombotic thrombocytopenic purpura, hemolytic uremic syndrome, and Evans syndrome. A frank microangiopathic hemolytic anemia is relatively uncommon.

In the primary aPLA syndrome, overt renal manifestations are generally mild (proteinuria, hematuria, hypertension, reduced renal function) and are frequently absent. Nephrotic syndrome is relatively rare. In APS associated with SLE, the renal manifestations are determined largely by the severity of the underlying glomerular lesions, but the coexistence of APS adds a dimension of vascular disease (microangiopathy) that contributes to a worsened prognosis and to a multiplicity of extrarenal manifestations (neurologic, cardiovascular, osseous, ophthalmologic, pulmonary, hepatic, visceral, and obstetric) (see also Chapter 26). A strong association of aPLA with alveolar hemorrhage exists in SLE.[21]

The therapy for primary aPLA syndrome and that accompanying SLE is difficult and controversial. Immunosuppressive agents, such as steroids or cytotoxic agents, even when they are used to control SLE, have yielded disappointing results. Symptomatic patients are best treated with anticoagulation. Aspirin (or clopidogrel) can be used routinely in mild cases. Combinations of aspirin and low-dose warfarin might be effective, but the risk of bleeding may be increased. Warfarin is the mainstay of treatment in severe cases, with the international normalized ratio (INR) adjusted to a level depending on symptoms; INR between 2.0 and 3.5 may be required. Low-molecular-weight heparin (subcutaneous or intravenous) is the treatment of choice for pregnancy complicated by aPLA syndrome and is also useful in alleviating migraine headache. Aspirin therapy in pregnancy with an aPLA-like syndrome does not appear to be effective.[26] High-dose intravenous IgG can have dramatic beneficial effects, especially in acutely evolving disease associated with SLE. The benefits of newer immunomodulating agents such as rituximab have not been adequately evaluated in APS, but preliminary reports are encouraging when used with intensive plasma exchange.[27] Intensive plasma exchange (plus immunosuppression) may rarely be effective in pregnancy, but this therapy has been used in other

circumstances, such as in APS associated with SLE, with variable degrees of success.[28] Recently, a monoclonal antibody to C5 (eculizumab) has been used to treat catastrophic aPLA syndrome with success, but further evaluation is required before this becomes acceptable treatment.[29]

The previously posited pathogenetic mechanisms lend credence to some suggested novel therapeutic approaches to the aPLA syndrome, such as hydroxychloroquine, coenzyme Q10, statins, *N*-acetylcysteine, phosphodiesterase inhibitors, factor XI inhibitors, and eculizumab (anti-C5 monoclonal antibody). None of these has yet been thoroughly tested for safety and efficacy in RCTs.

GLOMERULONEPHRITIS ASSOCIATED WITH MALIGNANT DISEASE

Many malignant disorders and their treatment may be complicated by the development of glomerular lesions.[30] Furthermore, the treatment of glomerular disease with certain agents may give rise to neoplasia. Malignant neoplasms may also be associated with a wide variety of fluid, electrolyte, acid-base, divalent ion, tubulointerstitial, and vascular disorders, including direct invasion of the renal parenchyma by neoplastic cells.

Table 28-2 lists the glomerular lesions frequently observed in association with neoplastic processes. Membranous nephropathy is the most common lesion (see also Chapter 20). Approximately 7% to 20% of patients with MN will be found to have an underlying malignant neoplasm. Most patients are adults older than 50 years; however, despite the increasing frequency of malignant disease with age in the general population, epidemiologic studies support that the prevalence of malignant disease is higher in patients with MN than in age-matched controls.[31] In addition, remissions (although temporary) can be achieved by surgical removal or chemotherapy of the neoplastic disease, and relapses may develop with recurrence of tumor. Furthermore, tumor neoantigens or antibodies have been detected within the glomerular deposits, suggesting an immune complex pathogenesis. In about one third of patients, the neoplastic disorder is already evident before the development of glomerular lesions; in about one third it is discovered concomitantly with the onset of glomerular disease; and in about one third the neoplastic process is detected after the diagnosis of glomerular disease. MN occurring with an underlying malignant neoplasm can closely resemble the idiopathic disease both clinically and morphologically, so it is prudent to undertake an exploration for possible malignant disease in any patient older than 50 years who presents with an apparent "idiopathic" MN. This can consist of a careful physical examination, several stool specimens for occult blood, colonoscopy, computed tomographic (CT) scan of the chest (especially in smokers), mammography in women, and prostate-specific antigen determination in men. Some studies have also suggested that prominent IgG1 and IgG2 instead of IgG4 deposits in the glomeruli are suggestive of a malignant cause or underlying lupus nephritis. In MN, positive anti-PLA_2R autoantibodies in the circulation or PLA_2R antigens in the glomerular deposits strongly indicate an idiopathic form of MN.[32]

Major Cancers That Can Be Associated with Specific Glomerular Lesions

Glomerular Disease	Most Commonly Associated Malignancy
MN	Colon, breast, stomach, and lung cancer
MCD	Hodgkin lymphoma, pancreatic cancer, mesothelioma, prostate cancer
FSGS	Leukemia, lymphoma
MPGN	Chronic lymphocytic leukemia, lymphoma (some associated with HCV)
IgA nephropathy	Lung carcinoma
Crescentic GN, systemic vasculitis	Lung carcinoma
Systemic amyloidosis AL type	Multiple myeloma, Waldenström macroglobulinemia
Systemic amyloidosis AA type	Carcinoma (especially renal)
Cryoglobulinemic GN	Chronic lymphocytic leukemia (often hepatitis C associated)
Light-chain nephropathy	Lymphoma, myeloma
Fibrillary (immunotactoid) GN	Lymphoma
Hemolytic-uremic syndrome	Gastric cancer, mucin-producing cancer

Table 28-2 Major glomerular lesions associated with neoplastic disease. *MN,* Membranous nephropathy; *MCD,* minimal change disease; *FSGS,* focal segmental glomerulosclerosis; *MPGN,* membranoproliferative glomerulonephritis; *HCV,* hepatitis C virus; *GN,* glomerulonephritis.

Less frequent lesions observed in patients with neoplasia include MCD, FSGS, proliferative GN (including crescentic GN), thrombotic microangiopathy, monoclonal immunoglobulin deposition diseases (MIDD), and amyloidosis. MCD may be associated with lymphoma (particularly Hodgkin) and certain other cancers (pancreas, mesothelioma, prostate). Membranoproliferative GN (MPGN) may be associated with chronic lymphocytic leukemia (CLL) and lymphoma. FSGS may also occasionally be encountered in patients with underlying malignant disease, including CLL and lymphoma. IgA nephropathy and crescentic GN may be associated with lung cancer. Vasculitis accompanied by crescentic GN, often resembling Henoch-Schönlein purpura, has been reported with several malignant neoplasms, most notably lung cancer.

Systemic amyloidosis (AL type) may affect the kidney and produce nephrotic syndrome and renal failure in 10% to 15% of patients with multiple myeloma and rarely in association with Waldenström macroglobulinemia (see Chapter 27). Carcinomas, including renal cell carcinoma, are also rarely complicated by amyloidosis, which is usually of the AA variety. MIDD may accompany lymphomas and leukemias (Chapter 27). Light-chain nephropathy, in which deposits of either κ or γ light chain are found in the glomerular capillaries and tubular basement membranes, may occur in association with a variety of neoplastic lymphoproliferative states (Chapter 27).

Thrombotic microangiopathy, producing renal cortical necrosis or glomerular lesions resembling MPGN, may be seen in association with disseminated cancer (carcinoma of stomach) and other mucin-producing carcinomas. It may also appear secondary to treatment with certain antineoplastic agents, especially mitomycin C.

Interferon (IFN) treatment, used in the management of certain malignant neoplasms, may cause MCD, often in association with interstitial nephritis, and IFN therapy may also be associated with development of FSGS (see Chapters 17 to 19).

OTHER UNCOMMON DISORDERS

Lipoprotein Glomerulopathy

Lipoprotein glomerulopathy is believed to be caused by an abnormality in lipoprotein metabolism[33,34] (see also Chapter 19), It is

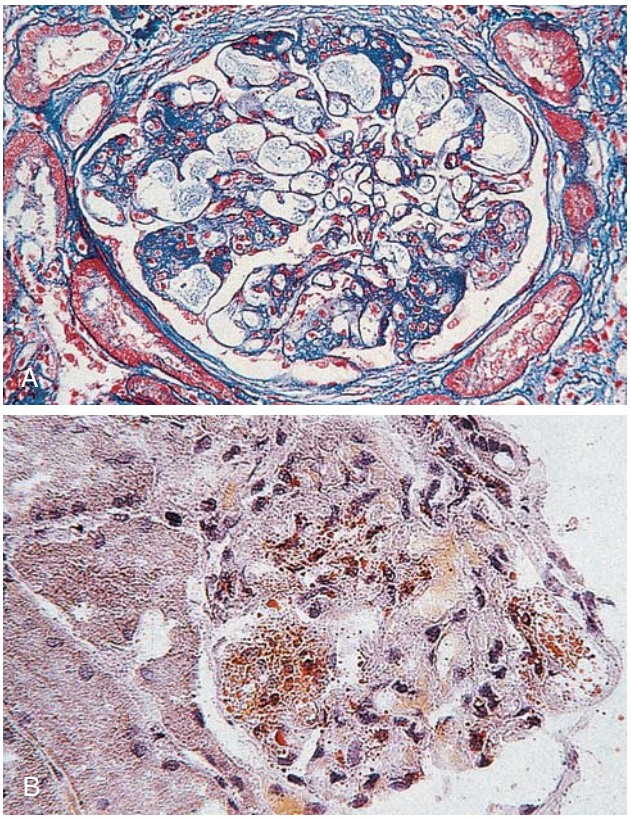

Figure 28-4 Lipoprotein glomerulopathy. A, Dilated capillary lumina containing a pale, trichrome-stained, mesh-like or granular substance. (×260.) **B,** The granules stain positively with oil red O and antilipoprotein E antisera. (×260.) *(Modified from reference 1.)*

characterized by extensive deposits of apolipoproteins A, B, and E in the glomeruli (mostly apoE), leading to greatly expanded capillaries filled with a pale-staining, mesh-like substance having the appearance of lipid "thrombi" (Fig 28-4). Clinically, there may be heavy proteinuria with nephrotic syndrome. Apolipoprotein B and E levels are increased in plasma in association with a type III hyperlipoproteinemia. The apoE usually shows a heterozygous E2/E3 or E2/E4 phenotype, but homozygosity for apolipoprotein E2 or E3 has also been observed. Homozygous apolipoprotein E2 is also seen in familial type III hyperlipoproteinemia. Decreased low-density lipoprotein (LDL) receptor binding and increased heparin affinity may explain some of the pathogenetic processes in lipoprotein glomerulopathy. The disease may be associated with psoriasis.[35] Otherwise, there are no distinctive clinical features. Familial cases have strongly suggested a hereditary abnormality. Lipoprotein glomerulopathy may recur in the renal transplant. Treatment with bezafibrate or fenofibrate may be effective.[36,37] Treatment with Heparin-induced Extracorporeal Lipoprotein Precipitation–apheresis systems (HELP-apheresis) can achieve a complete remission in some patients.[38]

Lecithin–Cholesterol Acyltransferase Deficiency

Lecithin–cholesterol acyltransferase (LCAT) deficiency is an autosomal recessive disorder associated with a very low high-density lipoprotein HDL cholesterol but a remarkably variable and often low frequency of cardiovascular disease in carriers[39-41] (see also Chapter 19). The clinical characteristics include corneal opacities (misty deposits, also known as "fish eye"), normocytic normochromic anemia

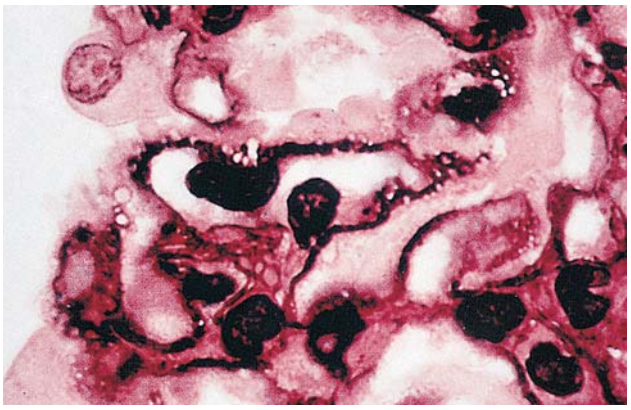

Figure 28-5 Lecithin–cholesterol acyltransferase deficiency. Note the irregular, thickened glomerular capillary walls containing clear vacuoles, which are characteristic of the LCAT lesion. (Periodic acid–Schiff reaction; ×1000.) *(Modified from reference 1.)*

(with target cells), low HDL and α-lipoprotein levels, and elevated LDL level. Proteinuria, including the nephrotic syndrome, as well as hypertension and progressive renal failure are the main renal manifestations. On light microscopy, the glomeruli reveal foam cells, intimal hyperplasia, and thickening of the glomerular basement membrane (GBM) with effacement of the foot processes (Fig. 28-5). Progressive renal failure is the rule; however, it is of slow and insidious onset and is usually first detected in the fourth decade of life. Treatment is generally ineffective, but theoretically, an inhibitor of hepatic acyl coenzyme A–cholesterol acyltransferase activity might be of benefit.[42] A case report of beneficial effects of steroid therapy recently appeared, but this approach is of unconfirmed value.[43] The disease can recur in the renal allograft.[44]

Collagen III Glomerulopathy

Collagen III glomerulopathy, also known as *collagenofibrotic glomerulopathy,* is an autosomal recessive systemic disorder with prominent renal manifestations that may be a *forme fruste* of nail-patella syndrome (see Chapter 48) because the glomerular abnormalities are similar.[45-47] Nevertheless, patients with collagen III glomerulopathy lack the typical skeletal abnormalities observed in the nail-patella syndrome. Clinically, patients present with proteinuria and slowly progressive renal failure. Patients may be of any age, and males predominate. On light microscopy, the glomeruli are enlarged with a marked expansion of the mesangial matrix by material weakly positive for periodic acid–Schiff (PAS) reaction (Fig. 28-6). Conventional IF microscopy is usually negative, but rarely will show "full-house" immunoglobulin and complement deposition.[48] However, antisera to collagen type III will strongly react with the glomerular deposits. EM shows bundles spirally arranged and frayed fibrillar deposits (Congo red negative) with periodicity characteristic of collagen. Similar deposits may be found in the spleen, liver, myocardium, and thyroid in fatal cases. No treatment is known to be effective, and there are no data yet on recurrent disease after renal transplantation, but because of the systemic nature of collagen III (collagenofibrotic) glomerulopathy, such recurrences would be likely.

Fibronectin Glomerulopathy

Fibronectin glomerulopathy is a rare, autosomal dominant, nonamyloid, fibrillary glomerular disease with onset usually in early adolescence with proteinuria, microhematuria, hypertension, distal (type

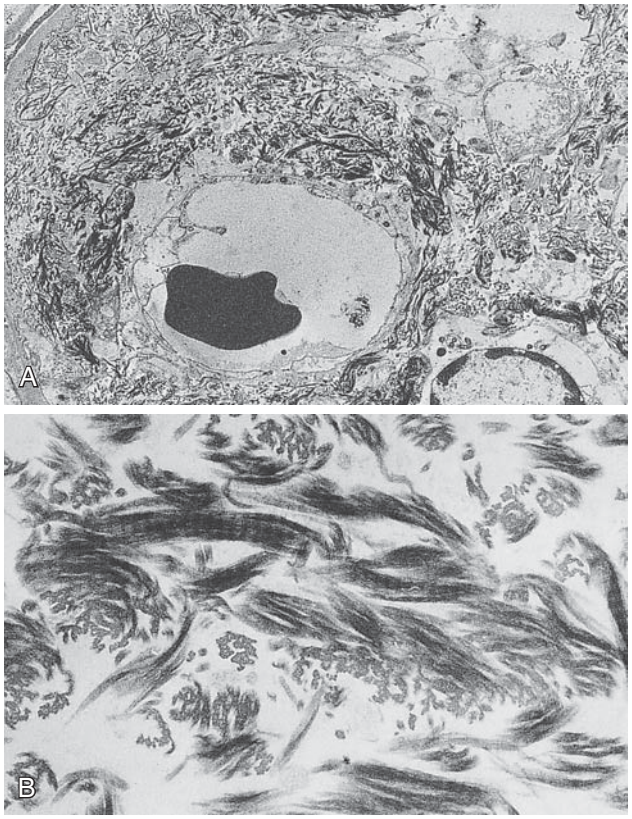

Figure 28-6 Electron microscopy of collagen III (collagenofibrotic) glomerulopathy. A, Fine fibrils occur in the mesangial and subendothelial areas. (×3000.) **B,** These fibrils are randomly oriented with typical periodicity and average 30 nm in diameter. The fibrils are strongly positive for periodic acid–Schiff reaction with anti–collagen type III antibodies. (×15,000.) *(Modified from reference 1.)*

4) renal tubular acidosis, and slowly progressive renal failure.[49,50] The gene *(FN1)* responsible for the disorder maps to chromosome 2q32.[51] Most patients reach ESRD between the second and sixth decade of life. The renal pathology usually reveals enlarged, hyperlobular, and normocellular glomeruli with a homogeneous or fibrillar material (on PAS staining) in the mesangium and subendothelium. These fibrils are Congo red negative. EM shows randomly oriented fibrils (12 to 16 nm wide and 120 to 170 nm long). IF is negative for antibody and complement components but will stain brightly with use of an antifibronectin antibody. The pathogenesis of the disease is unknown, although mice "knocked out" for uteroglobin develop a similar lesion. However, studies in humans have not documented any linkage to genes for uteroglobin or fibronectin. The differential diagnosis includes other disorders associated with fibril deposition (see Chapter 27). There is no known effective treatment of fibronectin glomerulopathy. The disease can recur in renal allografts.[52]

Nephropathic Cystinosis

Late-onset adult cystinosis is a variant of typical pediatric cystinosis in which the mutations in the *CTNS* gene result in a milder phenotype. These patients may present with glomerular disease during the teenage years. Nephrotic syndrome may occur, and the glomerular lesions resemble FSGS except that crystals of cystine are found in glomerular and tubular epithelial cells.[53] Patients with cystinosis may also have blond hair, photophobia, hypothyroidism, corneal deposits, rickets, and Fanconi syndrome with tubular proteinuria (see Chapter 50).

Miscellaneous Storage Diseases and Other Unusual Glomerular Lesions

A variety of diseases associated with storage of abdominal lipids or carbohydrates in tissue may provoke glomerular lesions. These include Hurler syndrome (type I mucopolysaccharidoses), von Gierke disease (glycogen storage disease), Gaucher disease, Refsum disease, nephrosialidosis, and I cell disease (mucolipidosis type II). Juvenile malabsorption of vitamin B_{12} with megaloblastic anemia (Imerslund syndrome; cubulin deficiency) can be associated with prolonged glomerular proteinuria (albuminuria), but progressive renal disease does not develop. Asphyxiating thoracic dystrophy (Jeune syndrome) is associated with glomerular, tubular, and interstitial abnormalities. Hereditary osteolysis causing arthralgias and deformities of wrists and ankles can be accompanied by chronic GN. The nail-patella syndrome and Fabry disease are discussed in Chapter 48.

"Idiopathic" Nodular Glomerulosclerosis

An intercapillary nodular expansion of the mesangium encroaching on the glomerular capillary lumina is characteristically called the *Kimmelstiel-Wilson* lesion and is most commonly associated with diabetes mellitus and proliferative diabetic retinopathy (see Chapter 30). However, in recent years, a small group of patients have been described in whom a similar or identical lesion is seen in the absence of any overt features of diabetes mellitus or disordered glucose metabolism or other known causes of a similar lesion, such as κ light-chain nephropathy (see Chapter 27), chronic thrombotic microangiopathy, MIDD, fibrillary GN, and fibronectin glomerulopathy. Thus, idiopathic nodular glomerulosclerosis is a diagnosis of exclusion.

The first examples of this new disorder were recognized in 1989,[54] and approximately 65 additional cases have subsequently been reported.[55-58] Whereas some of these patients may have had intermittent manifestation of diabetes or only mild abnormalities of glucose homeostasis, such as an abnormal glucose tolerance test result, most have not had features conventionally used to define the presence of diabetes mellitus (i.e., normal fasting blood glucose concentration and hemoglobin A_{1c} measurements). Thus, the intercapillary nodular lesion does not appear to require prolonged abnormal glucose homeostasis for its generation.

The clinical features are nonspecific and nondiagnostic. Patients with idiopathic nodular glomerulosclerosis are usually older (average age of about 70 years), and female gender and nephrotic syndrome are a common presentation. A heavy smoking history, obesity, and longstanding hypertension are frequently present, but the role of these abnormalities in the pathogenesis of the lesion is unknown.

The pathology includes typical intercapillary nodular glomerulosclerosis with thickening of the GBM and varying degrees of arteriolonephrosclerosis and hyalinosis identical to the diabetes-associated Kimmelstiel-Wilson lesions. No electron-dense or organized deposits are seen on EM. The GBM and tubular basement membrane may "stain" with IgG and albumin on IF. Neovascularization can be seen within the nodules.

The prognosis is poor and relates to the persistence of nephrotic-range proteinuria. Most patients with idiopathic nodular glomerulosclerosis will progress to ESRD, sometimes quite rapidly. The 50% renal survival point in those who continue to smoke heavily is about 1 year after diagnosis. There is no known effective therapy, other than angiotensin inhibition to reduce the proteinuria. Stopping smoking may be beneficial and should be urged for all patients with this diagnosis.

CHAPTER 29

Thrombotic Microangiopathies, Including Hemolytic Uremic Syndrome

Marina Noris, Piero L. Ruggenenti, and Giuseppe Remuzzi

DEFINITIONS

Thrombotic microangiopathy (TMA) is a lesion of arteriolar and capillary vessel wall thickening with intraluminal platelet thrombosis and a partial or complete obstruction of the vessel lumina. Laboratory features of thrombocytopenia and microangiopathic hemolytic anemia are almost invariably present in patients with TMA lesions and reflect the consumption and disruption of platelets and erythrocytes in the microvasculature. Depending on whether renal or brain lesions prevail, two pathologically indistinguishable but somehow clinically different entities have been described: the hemolytic uremic syndrome (HUS) and thrombotic thrombocytopenic purpura (TTP). Because HUS can involve extrarenal manifestations and TTP may be associated with severe renal disease, the two can be difficult to distinguish on clinical grounds only.[1] Newly identified pathophysiologic mechanisms, however, have allowed for the differentiation of the two syndromes on a molecular basis (Table 29-1). These new data also show, that, for example, pregnancy-associated HUS is genetically determined (Table 29-1) with pregnancy or transplantation acting as a trigger of TMA in a genetically predisposed individual.

The term *hemolytic uremic syndrome* was introduced in 1955 by Gasser and coworkers[2] in their description of an acute fatal syndrome in children characterized by hemolytic anemia, thrombocytopenia, and severe renal failure. HUS occurs most frequently in children younger than 5 years, in whom the incidence is 5 to 6 children per 100,000 children population per year, compared with an overall incidence of 0.5 to 1/100,000/yr. Most cases (>90% of pediatric cases) are associated with infection by Shiga-like toxin (Stx)–producing *Escherichia coli* (STEC). STEC-HUS occurs primarily in children, except in epidemics, when it may occur in patients with a wider age range. For example, from May to July 2011, several European countries, particularly northern Germany, experienced one of the largest STEC-HUS outbreaks ever reported, with 3816 patients who had *E. coli* O104:H4 infection, with 845 cases. Almost 90% of affected patients were adults and, compared to previous STEC epidemics, there was a higher prevalence of affected young and middle-aged women.[3] *Streptococcus pneumoniae* causes a distinctive form of HUS, accounting for 40% of cases not associated with Stx-producing bacteria.[4]

Approximately 10% of HUS cases are classified as "atypical," caused neither by Stx-producing bacteria (STEC or *Shigella dysenteriae*) nor by *Streptococcus*.[5] Atypical HUS is significantly less common than STEC-HUS, with an incidence of 0.5 to 2 per 1 million population per year.[4] It occurs at any age. Patients with atypical HUS have a poor outcome; 50% progress to end-stage renal disease (ESRD), and 25% may die in the acute phase.[4,6] Neurologic symptoms and fever can occur in 30% of patients. Pulmonary, cardiac, and gastrointestinal manifestations can also occur.[4,6]

Thrombotic thrombocytopenic purpura was first described in 1925 by Moschcowitz[7] in a 16-year-old female patient with a fulminant febrile attack, hemolytic anemia, bleeding, renal failure, and neurologic involvement. Pathologic changes were characterized by widespread hyaline thrombosis of small vessels. TTP is a rare disease, with an incidence of approximately 2 to 4 cases per 1 million persons per year. TTP can affect any age group. TTP classically presents with the pentad of thrombocytopenia, microangiopathic hemolytic anemia, fever, and neurologic and renal dysfunction.[7] Neurologic symptoms can be seen in more than 90% of patients over the course of the disease. Central nervous system (CNS) involvement mainly represents thrombo-occlusive disease of the gray matter, but can also include headache, cranial nerve palsies, confusion, stupor, and coma. Up to half of patients who present with neurologic involvement may be left with sequelae. Chronic kidney disease (CKD) may occur. One group has reported 25% of patients with creatinine clearance less than 40 ml/min receiving long-term follow-up. Cardiac involvement may be common in TTP patients.[8]

LABORATORY SIGNS

Laboratory features of thrombocytopenia and microangiopathic hemolytic anemia are almost invariably present in patients with TMA lesions and reflect consumption and disruption of platelets and erythrocytes in the microvasculature.[5] Hemoglobin levels are low, less than 10 g/dl in more than 90% of patients. Reticulocyte counts are uniformly elevated. The peripheral smear reveals increased schistocyte numbers, with polychromasia and often nucleated red blood cells (RBCs) (Fig. 29-1). Detection of fragmented erythrocytes is crucial to confirm the microangiopathic nature of the hemolytic anemia, provided that heart valvular disease and other anatomic arterial abnormalities that may cause erythrocyte fragmentation are excluded. Other indicators of intravascular hemolysis include elevated lactate dehydrogenase (LDH), increased indirect bilirubin, and low haptoglobin level.[5] The Coombs test is negative. Moderate leukocytosis may accompany the hemolytic anemia. Thrombocytopenia is uniformly present in HUS and TTP. It may be severe but is usually less so in patients with predominant renal involvement.[9] The presence of giant platelets in the peripheral smear or reduced platelet survival time (or both) is consistent with peripheral consumption. In children with STEC-HUS, the duration of thrombocytopenia is variable and does not correlate with the course of renal disease. Bone marrow biopsy specimens usually show erythroid hyperplasia and an increased number of megakaryocytes.

Classification of Hemolytic Uremic Syndrome and Thrombotic Thrombocytopenic Purpura

Clinical Presentation	Etiology
Hemolytic Uremic Syndrome	
Stx associated	Infections by Shiga toxin (Stx)–producing bacteria
Neuraminidase associated	Infections by *Streptococcus pneumoniae*
Atypical Hemolytic Uremic Syndrome	
Familial	Mutations: *CFH*, 40%-45%; *CFI*, 5%-10%; *C3*, 8%-10%; *MCP*, 7%-15%; *THBD*, 9%; *CFB*, 1%-2%
Sporadic	
Idiopathic	Mutations: *CFH*, 15%-20%; *CFI*, 3%-6%; *C3*, 4%-6%; *MCP*, 6%-10%; *THBD*, 2%; *CFB*, <1% Anti-CFH antibodies: 6%-10%
Pregnancy associated	Mutations: *CFH*, 40%-50%; *CFI*, 10%-20%; *MCP*, 10%; *C3*, 14%
HELLP syndrome	Mutations: *CFH*, 10%; *CFI*, 20%; *MCP*, 10%
Transplantation (*de novo* atypical HUS)	Mutations: *CFH*, 15%; *CFI*, 16%
Thrombotic Thrombocytopenic Purpura	
Congenital	Homozygous or compound heterozygous mutations in *ADAMTS13* gene
Idiopathic	Anti-ADAMTS13 autoantibodies
Secondary	
Ticlopidine, clopidogrel	Anti-ADAMTS13 autoantibodies (ticlopidine, 80%-90%, clopidogrel, 30%)
HSC transplantation	Unknown; rarely, low ADAMTS13 levels
Malignancies	Unknown; rarely, low ADAMTS13 levels
HIV	HIV; rarely, low ADAMTS13 levels
SLE, APS, and other autoimmune disease	Depends on the specific primary disease

Table 29-1 Classification of hemolytic uremic syndrome (HUS) and thrombotic thrombocytopenic purpura (TTP) according to clinical presentation and underlying etiology. *HELLP,* Hemolytic anemia, elevated liver enzymes, and low platelet count; *HSC,* hematopoietic stem cell; *SLE,* systemic lupus erythematosus; *APS,* antiphospholipid syndrome. For all other abbreviations, refer to Table 29-3.

Prothrombin time, partial thromboplastin time, fibrinogen level, and coagulation factors are normal, thus differentiating HUS and TTP from disseminated intravascular coagulation (DIC). Mild fibrinolysis with minimal elevation in fibrin degradation products, however, may be observed. Evidence of renal involvement is present in all patients with HUS (by definition) and in about 25% of patients with TTP.[1,10] Microscopic hematuria and subnephrotic proteinuria are the most consistent findings. STEC-HUS in 90% of patients is preceded by diarrhea, often bloody.

PATHOLOGY

The diagnostic histologic lesions of TMA consist of widening of the subendothelial space and microvascular thrombosis. Electron microscopy best identifies the characteristic lesions of swelling and detachment of the endothelial cells from the glomerular basement membrane and the accumulation of fluffy material in the subendothelium, intraluminal platelet thrombi, and partial or complete obstruction of vessel lumina[11] (Figs. 29-2 and 29-3). These lesions

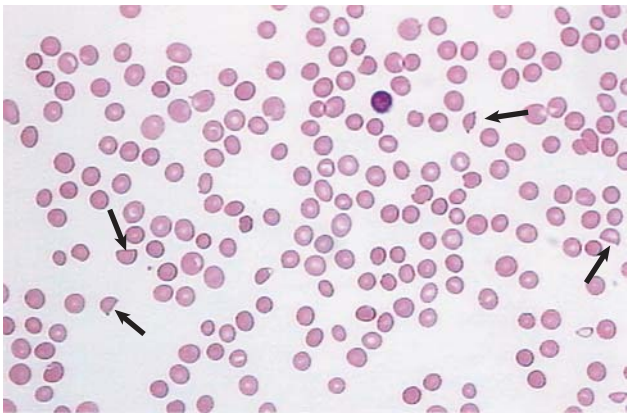

Figure 29-1 Peripheral blood smear from patient with hemolytic uremic syndrome. The presence of fragmented red blood cells with the appearance of a helmet *(arrows)* is pathognomonic for microangiopathic hemolysis in patients with no evidence of heart valvular disease.

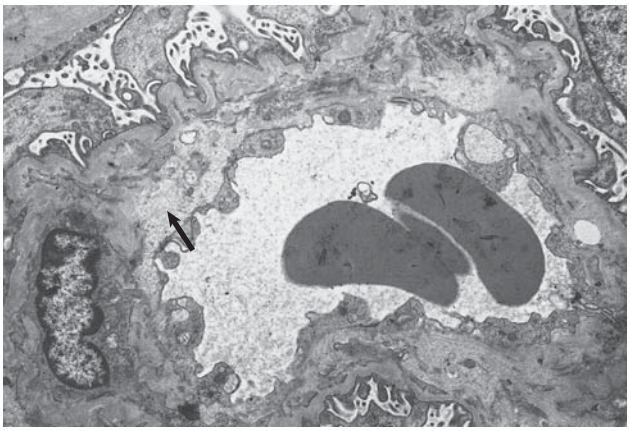

Figure 29-2 Electron micrograph of glomerular capillary in hemolytic uremic syndrome. The endothelium is detached from the glomerular basement membrane (GBM); the subendothelial space is widened and occupied by electron-lucent fluffy material and cell debris *(arrow).* Beneath the endothelium is a thin layer of newly formed GBM.

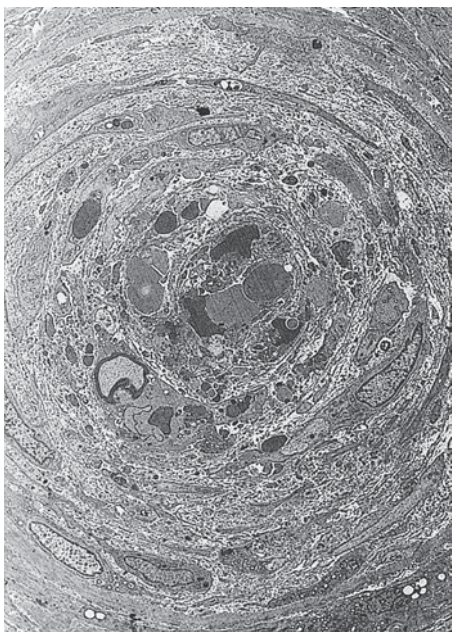

Figure 29-3 Electron micrograph of renal arteriole in hemolytic uremic syndrome. The vascular lumen is completely occluded by thrombi. There is marked intimal edema with consequent separation of myointimal cells.

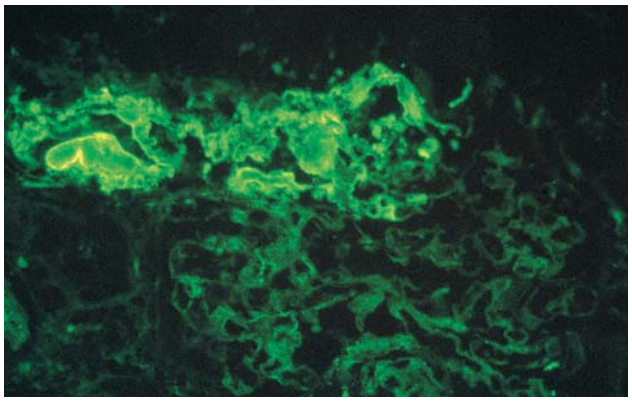

Figure 29-4 Glomerulus with its vascular pole from patient with STEC-associated hemolytic uremic syndrome. Strong staining with immunofluorescence-labeled antifibrinogen antibody occurs in the glomerulus and in the arteriolar wall. *STEC,* Shiga toxin-producing *E. coli*.

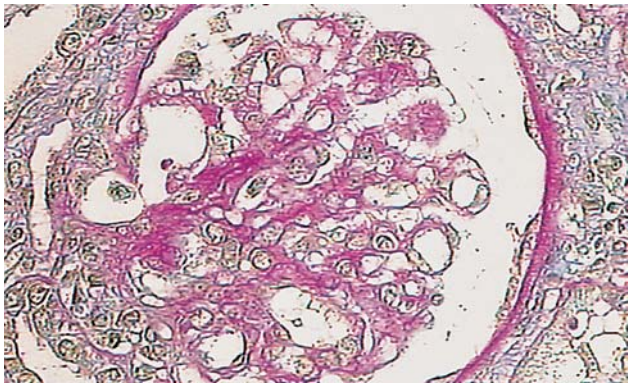

Figure 29-5 Glomerulus from patient with STEC-associated hemolytic uremic syndrome. Marked thickening of the glomerular capillary wall occurs, with many double contours. *STEC,* Shiga toxin-producing *E. coli*.

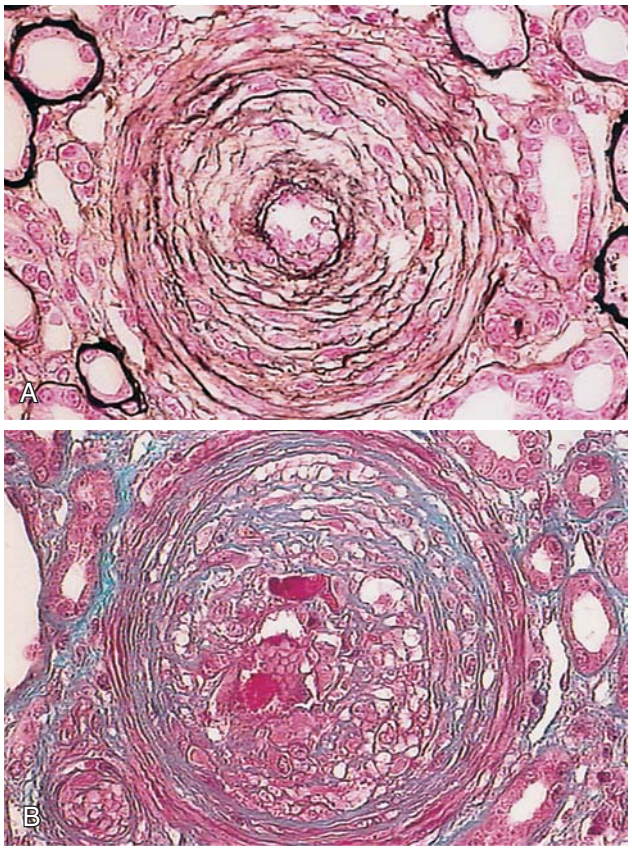

Figure 29-6 Interlobular artery in hemolytic uremic syndrome with severe vascular involvement. A, The vascular lumen is almost completely occluded. Changes include myointimal proliferation and reduplication of the lamina elastica. **B,** Thrombotic material and erythrocytes can be seen in the lumen and within the vascular wall.

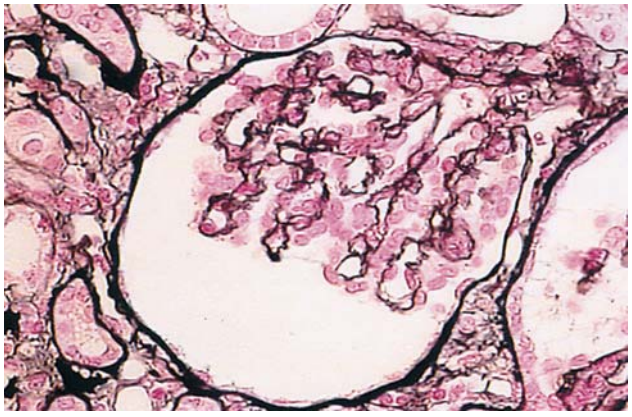

Figure 29-7 Glomerulus from patient with atypical hemolytic uremic syndrome with predominant vascular involvement. Severe ischemic changes have occurred. Note the shrinkage of the glomerular tuft and marked thickening and wrinkling of the capillary wall.

are similar to those seen in other renal diseases, such as scleroderma, malignant nephrosclerosis, chronic transplant rejection, and calcineurin inhibitor nephrotoxicity. In HUS, microthrombi are present primarily in the kidneys; in TTP, they mainly involve the brain. In pediatric patients, particularly those younger than 2, and in those with STEC-HUS, the glomerular injury is predominant[11] (Figs. 29-4 and 29-5). Thrombi and infiltration by leukocytes are common in the early phases of HUS and usually resolve after 2 to 3 weeks. Patchy cortical necrosis may be present in severe cases; crescent formation is uncommon. In idiopathic and familial forms and in adults, the injury mostly involves arteries and arterioles, with thrombosis and intimal thickening (Fig. 29-6; see also Fig. 29-3), and secondary glomerular ischemia and retraction of the glomerular tuft (Fig. 29-7). Focal segmental glomerulosclerosis may be a long-term sequela of acute cases of HUS and is usually seen in children with long-lasting hypertension and progressive deterioration in renal function.

The typical pathologic changes of TTP are the thrombi that occlude capillaries and arterioles in many organs and tissues. These thrombi consist of fibrin and platelets, and their distribution is widespread. Thrombi are most frequently detected in kidneys, pancreas, heart, adrenals, and brain. Compared with HUS, pathologic changes of TTP are more extensively distributed, probably reflecting the more systemic nature of the disease.

MECHANISMS, CLINICAL FEATURES, AND MANAGEMENT OF SPECIFIC FORMS OF THROMBOTIC MICROANGIOPATHY

Shiga Toxin–Producing *Escherichia coli*–Associated Hemolytic Uremic Syndrome

Mechanisms

Shiga toxin–producing *E. coli*–associated HUS may follow gastrointestinal (GI) infection by certain strains of *E. coli or S. dysenteriae*

that produce powerful exotoxins (Shiga toxins, Stx).[12] Most patients present with bloody diarrhea that may still be active or that may resolve at presentation of HUS. Several strains of *E. coli* were found to produce Stx (STEC), mostly the serotype O157:H7, but also other serotypes, such as O111:H8, O103:H2, O123, O26, O145, and the O104:H4 strain of the recent German outbreak,[3] isolated from patients with diarrhea. After food (beef, vegetables, fruit) or water contaminated by STEC or *S. dysenteriae* is ingested, the toxin is released into the gut and may cause watery or most often bloody diarrhea because of a direct effect on the intestinal mucosa. Stx-producing *E. coli* closely adhere to the epithelial cells of the GI mucosa, causing destruction of brush border villi. Shiga toxins are transported to the intracellular space of polarized GI cells via transcellular pathways and then translocated into the circulation. Circulating human blood cells (e.g., erythrocytes, platelets, monocytes) express Stx receptors on their surface and could serve as Stx carriers from the intestine to the kidney and other target organs.

In the kidney, Shiga toxins bind mainly to glomerular endothelial cells, but also to podocytes, mesangial cells, and proximal tubules. After binding to cell receptors, the toxin is internalized in the cytosol within 2 hours and inhibits protein synthesis. Treatment of endothelial cells with sublethal doses of Stx, exerting minimal influence on protein synthesis, leads to increased messenger RNA levels and protein expression of chemokines and cell adhesion molecules. By altering endothelial cell adhesion properties and metabolism, Shiga toxins favor leukocyte-dependent inflammation and induce loss of thromboresistance in endothelial cells, leading to microvascular thrombosis.[13]

Evidence is also emerging that complement activation at the renal endothelial level may contribute to microangiopathic lesions in STEC-HUS. High plasma levels of complement activation products Bb and C5b-9 were measured in children with STEC-HUS, indicating complement activation by the alternative pathway. Stx induced the expression of P-selectin on cultured human microvascular endothelial cell, and P-selectin bound and activated C3 via the alternative pathway, leading to thrombus formation under flow conditions.[14] In a murine model of HUS induced by Stx/lipopolysaccharide (LPS), factor B–deficient mice, which cannot activate the alternative pathway of complement, exhibited less thrombocytopenia and were protected against glomerular abnormalities and renal function impairment.[14]

In vitro, tubular epithelial and mesangial cells are as susceptible to the cytotoxic effects of Shiga toxins as endothelial cells. The tubular damage caused by Stx can lead to a reduction in the renal water-handling capacity. The toxins inhibit water absorption across human renal tubular epithelial cell monolayers, which may contribute to the early events in the pathogenesis of renal dysfunction in STEC-HUS.

Diagnosis

Diagnosis depends on the detection of *E. coli* O157:H7 and other STEC and their products in stool cultures. When infection with STEC is suspected, physicians should ensure that stool specimens are collected promptly and specifically cultured for STEC.[12] Unlike most other *E. coli*, serotype O157:H7 does not ferment sorbitol rapidly and thus forms colorless colonies on sorbitol-containing MacConkey agar (SMAC). The use of SMAC provides a simple, inexpensive, and generally reliable method of screening stools for *E. coli* O157. Suspect colonies can be assayed for the O157 antigen with commercially available antiserum or latex agglutination kits. The use of tests that identify Shiga toxins or the genes encoding them (by polymerase chain reaction) is helpful for diagnosis. Convalescent-phase serum samples can be assayed for antibodies to O157 or other specific strain-derived LPS. However, results may be biased by false-positives caused by antibodies preformed during antecedent STEC exposure.[12]

E. coli O157:H7 and other STEC have been responsible for multiple outbreaks throughout the world, becoming a public health problem in both developed and developing countries.[12] Contaminated undercooked ground beef, meat patties, raw vegetables, fruit, milk, and recreational or drinking water have all been implicated in the transmission of STEC; healthy cattle are a major reservoir for human infection. The large 2011 outbreak of HUS in Germany was caused by ingestion of sprouts contaminated by an unusual STEC strain O104:H4. The chain of transmission appeared to have started in Egypt with fecal contamination of fenugreek seeds by either humans or farm animals. The higher prevalence of women in this outbreak may reflect a gender-specific dietary preference.[3]

Clinical Course

After exposure to STEC, 38% to 61% of individuals develop hemorrhagic colitis, and 3% to 9% (in sporadic infections) to 20% (in epidemic forms) progress to overt HUS[12] (Fig. 29-8). STEC-induced hemorrhagic colitis not complicated by HUS is self-limiting and is not associated with an increased long-term risk of high blood pressure or renal dysfunction. STEC-HUS is characterized by prodromal diarrhea followed by acute kidney injury (AKI). The average interval between *E. coli* exposure and illness is 3 days. Illness typically begins with abdominal cramps and nonbloody diarrhea; diarrhea may become hemorrhagic in 70% of patients, usually within 1 or 2 days.[12] Vomiting occurs in 30% to 60% and fever in 30%. Leukocyte count is usually elevated. HUS is usually diagnosed 6 to 10 days after onset of diarrhea. In patients who develop HUS, 70% require RBC transfusions, and 40% to 50% need dialysis for an average 10 days, whereas the remainder have milder renal involvement without the need for dialysis.[12,15] About 25% of STEC-HUS patients have neurologic involvement, including lethargy, apnea, cortical blindness, hemiparesis, stroke, seizures, and coma. Rare complications include pancreatitis, diabetes mellitus, and pleural or pericardial effusions. From 1% to 2% of patients die during the acute phase of STEC-HUS. More than 90% of children with STEC-HUS fully recover from the acute disease. However, a meta-analysis of 49 published studies (3476

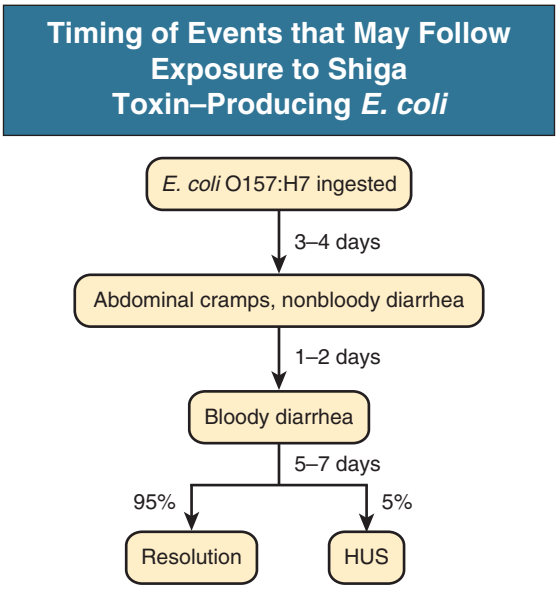

Figure 29-8 Timing of events that may follow exposure to Shiga toxin–producing *E. coli*. *HUS,* Hemolytic uremic syndrome.

patients, including children and adults, mean follow-up of 4.4 years) describing the long-term prognosis of patients who survived an episode of STEC-HUS reported death or permanent ESRD in 12% and glomerular filtration rate (GFR) less than 80 ml/min/1.73 m^2 in 25% of patients.[15]

Disease presentation and outcome were particularly severe during the STEC O104:H4 German outbreak, in which 53 of the 855 patients with HUS died.[3] Compared with previous STEC epidemics, there was a higher incidence of dialysis-dependent AKI patients (20% vs. 6%) and mortality (6% vs. 1%).[3] Almost half the patients presented with neurologic symptoms, and 20% had seizures. The severe clinical phenotype was explained by the lack of previous immunity to this novel STEC strain and its exceptional virulence. *E. coli* O104:H4 not only produces the same Stx as STEC enterohemorrhagic strains, but also has 93% of the genomic sequence of enteroaggregative *E. coli* strains that form fimbriae, which facilitate adhesion to the intestinal wall. The evolution of *E. coli* O104:H4 is likely the result of the acquisition by an enteroaggregative strain of *E. coli* of a Stx-encoding phage from a Stx-producing enterohemorrhagic strain of *E. coli*. The combination of these two virulence factors would lead to increased gut colonization and thus the release of increased quantities of toxin into the circulation. Moreover, whereas enterohemorrhagic *E. coli* bacteria are found in the GI tract of ruminants, enteroaggregative *E. coli* appear to have their reservoir in humans. This might explain why *E. coli* O104:H4 strain has acquired new resistances to the most common antibiotics used in human disease.

Therapy

Typical pediatric STEC-HUS treatment relies on supportive management of anemia, renal failure, hypertension, and electrolyte and water imbalance. Initiating intravenous isotonic volume expansion as soon as an *E. coli* O157:H7 infection is suspected, that is, within the first 4 days of illness, even before culture results are available, may limit the severity of AKI and the need for renal replacement therapy.[16] Up to 80% of patients receive packed RBCs for symptomatic anemia. Patients with severe STEC-HUS require careful monitoring, including urine output, weight, volume status, cardiovascular/respiratory function, and early signs of CNS or other organ involvement. Bowel rest is important for the enterohemorrhagic colitis associated with STEC-HUS. Antimotility agents should be avoided because these may prolong the persistence of *E. coli* in the intestinal lumen, increasing patient exposure to its toxin. The use of antibiotics should be restricted to the very limited number of patients presenting with bacteremia. In children with gastroenteritis, antibiotics may increase the risk of HUS 17-fold;[17] possibly because antibiotic-induced injury to the bacterial membrane might favor the acute release of large amounts of preformed toxin. Alternatively, antibiotic therapy might give *E. coli* O157:H7 a selective advantage if these organisms are not as readily eliminated from the bowel as are the normal intestinal flora. Moreover, several antimicrobial drugs, particularly the quinolones, trimethoprim, and furazolidone, are potent inducers of Stx gene expression and may increase the level of toxin in the intestine. An interesting exception may be azithromycin; its use appeared to have some benefit on the duration of bacterial shedding in adult patients from the German O104:H4 epidemic.[18] In contrast to *E. coli*–associated HUS, hemorrhagic colitis and HUS caused by *Shigella* dysentery type 1 should be treated with antibiotics. Treatment shortens the duration of diarrhea, decreases the incidence of complications, and reduces the risk of transmission by shortening the duration of bacterial shedding.

Careful blood pressure control and renin-angiotensin system (RAS) blockade may be particularly beneficial in the long term for those patients who have CKD after an episode of STEC-HUS. Thus, 8 to 15 years of treatment with angiotensin-converting enzyme (ACE) inhibitors after severe STEC-HUS normalized blood pressure, reduced proteinuria, and improved GFR.[19]

Among newer treatments for Stx-HUS, Stx-neutralizing monoclonal antibodies are the most advanced, including dual antibodies against Stx 1 and 2 (SHIGATEC) given at the time of GI infection; results of a completed Phase 2 clinical trial are forthcoming. Peptides impairing the ability of enterohemorrhagic *E. coli* to survive under the acidic conditions of the gastric system could halt the disease process at even earlier stages by preventing bacterial intrusion into the gut. Heparin and antithrombotic agents may increase the risk of bleeding and should be avoided.

The efficacy of specific treatments in adult patients is difficult to evaluate because most information is derived from uncontrolled series that also may include atypical HUS cases. In particular, no prospective, randomized controlled trials (RCTs) are available to establish definitely whether plasma infusion or exchange offers specific benefit compared with supportive treatment alone (Table 29-2). However, comparative analyses of two large series of patients treated[20] or not treated[21] with plasma suggest that plasma therapy may dramatically decrease overall mortality of STEC O157:H7–associated HUS. Plasma infusion or exchange should therefore be considered in adult patients with severe AKI and CNS involvement.

Kidney transplantation is effective and safe for children who progress to ESRD. Recurrence rates range from 0% to 10% (due to potential coincident genetic complement abnormalities), and graft survival at 10 years is even better than in control children with other diseases.

Evidence that uncontrolled complement activation may contribute to microangiopathic lesions of STEC-HUS[14] led to complement inhibitor therapy in three children with severe STEC-HUS who fully recovered with the humanized anti-C5 monoclonal antibody eculizumab.[22] Eculizumab therapy in HUS patients of the STEC O104:H4 outbreak in Germany showed no significant difference in outcome between patients who received eculizumab together with plasma exchange and those who received plasma exchange alone[23] (Table 29-2). However, these data are retrospectively collected. Moreover, patients given eculizumab also had the most severe disease. Whether eculizumab is a useful adjunct to treating the most severe forms of STEC-HUS needs to be clarified by prospective RCTs.

Neuraminidase-Associated Hemolytic Uremic Syndrome

Mechanisms

Neuraminidase-associated HUS is a rare but potentially fatal disease that may complicate pneumonia, or less frequently, meningitis caused by *S. pneumoniae*[24] (see Table 29-1). Neuraminidase produced by *S. pneumoniae* cleaves *N*-acetylneuraminic acid from the glycoproteins on the cell membrane of erythrocytes, platelets, and glomerular cells. This exposes the normally hidden Thomsen-Friedenreich antigen (T antigen), which can then react with anti-T IgM antibody naturally present in human plasma. This antigen-antibody reaction occurs more frequently in infants and children and causes polyagglutination of RBCs *in vitro*. Therefore, unlike in other forms of HUS, in neuraminidase-associated HUS there is a positive Coombs test.

Clinical Course and Therapy

Patients with neuraminidase HUS are usually less than 2 years old and present with severe microangiopathic hemolytic anemia. The clinical picture is severe, with respiratory distress, neurologic involvement, and coma. The acute mortality is about 25%. The outcome

Specific Therapies Used in HUS and TTP: Dosing and Efficacy		
Therapy	**Dosing**	**Efficacy**
Immunosuppressive Agents		
Prednisone	200 mg tapered to 60 mg/day, then 5 mg reduction per week	Probably effective in addition to plasma exchange in patients with TTP and anti-ADAMST13 autoantibodies or in aHUS with anti–factor H autoantibodies and in forms associated with autoimmune diseases Lack of evidence from controlled trials in immune-mediated HUS or TTP
Prednisolone	200 mg tapered to 60 mg/day, then 5 mg reduction per week	
Immunoglobulins	400 mg/kg/day	
CD20 Cell-Depleting Agent		
Rituximab	375 mg/m^2/week, up to CD20 depletion	Effective in treatment or prevention of TTP associated with immune-mediated ADAMTS13 deficiency resistant to or relapsing after immunosuppressive therapy
Fresh-Frozen Plasma		
Exchange	1-2 plasma volumes/day	First-line therapy for aHUS and TTP Unproven efficacy in childhood STEC-HUS
Infusion	20-30 ml/kg, followed by 10-20 ml/kg/day	To be considered if plasma exchange not available
Cryosupernatant	See Exchange, Infusion	To replace whole plasma in the event of plasma resistance or sensitization
Solvent-detergent–treated plasma	See Exchange, Infusion	To limit risk of infections
Liver-Kidney Transplant		
		To prevent CFH-associated HUS recurrence post-transplant; about 30% mortality risk
Complement Inhibition		
Eculizumab	900 mg weekly for first 4 weeks 1200 mg every 14 days, thereafter	Reported efficacy in aHUS

Table 29-2 Dosing and effectiveness of specific therapies for patients with hemolytic uremic syndrome or thrombotic thrombocytopenic purpura. *aHUS,* Atypical hemolytic uremic syndrome; *STEC,* Shiga toxin–producing *E. coli.*

strongly depends on the effectiveness of antibiotic therapy. In theory, plasma infused or exchanged is contraindicated because adult plasma contains antibodies against the Thomsen-Friedenreich antigen, which may accelerate polyagglutination and hemolysis. Thus, patients should be treated only with antibiotics and washed RBCs. In some cases, however, plasma therapy, occasionally in combination with steroids, has been associated with recovery.

Atypical Hemolytic Uremic Syndrome

Atypical HUS (aHUS) includes a number of associations and presentations.[5] Atypical HUS is usually sporadic, and fewer than 20% of cases are familial. Although some are in siblings, suggesting autosomal recessive transmission, others occur across two to three generations, indicating an autosomal dominant mode. Incomplete penetrance of the disease in mutation carriers is a common feature, which confounds the interpretation of inheritance. Indeed, many individuals with sporadic cases of aHUS were found to have inherited the disease-associated genetic defect from an unaffected parent.

Various precipitants of aHUS have been described in complement gene mutation carriers, including nonenteric bacterial and viral infections,[5] immunotherapeutic agents (e.g., cyclosporine, tacrolimus), malignant hypertension, transplantation, and pregnancy.[5] *De novo* post-transplant HUS has been reported in patients receiving renal transplants or other organs, caused by calcineurin inhibitors (CNIs) or humoral rejection. HUS occurs in 5% to 10% of renal transplant patients who receive cyclosporine and approximately 1% of those given tacrolimus. In 20% of female patients, aHUS manifests during pregnancy, tending to occur at term or postpartum, within 3 months of delivery in most cases.[6] Pregnancy-associated increased concentrations of procoagulant factors, decreased fibrinolytic activity, and reduced expression of endothelial thrombomodulin may be predisposing factors. A severe form of pregnancy-associated TMA is the HELLP syndrome, in which microangiopathic hemolysis and liver injury accompany hypertension and renal dysfunction (see Chapter 44). About 50% of patients with sporadic aHUS show no clear trigger (idiopathic HUS) (see Table 29-1).

Mechanisms

Atypical HUS is linked to uncontrolled activation of the complement system[5] (Fig. 29-9). Reduced serum levels of C3 with normal C4 in aHUS patients were known since 1974. In cases of familial aHUS, serum C3 was low even during remission, suggesting genetic defects.[25] Low C3 reflected complement activation and consumption with high levels of activated products, C3b, C3c, and C3d (see Table 29-1).

The complement system is part of innate immunity and consists of several plasma and membrane-bound proteins protecting against invading organisms. Three activation pathways (classical, lectin, alternative) produce protease complexes, the C3 and C5 convertases, that cleave C3 and C5, respectively, eventually leading to the membrane attack complex (MAC, C5b-9) that causes cell lysis (Fig. 29-9). The alternative pathway is initiated spontaneously in plasma by C3 hydrolysis responsible for covalent deposition of a low amount of C3b onto practically all plasma-exposed surfaces (Fig. 29-10). On bacterial surfaces, C3b leads to opsonization for phagocytosis by neutrophils and macrophages. Without regulation, a small initiating stimulus is quickly amplified to a self-harming response until complement components are consumed. On host cells, such a dangerous cascade is controlled by membrane-anchored and fluid-phase regulators. Both favor the cleavage of C3b to inactive iC3b by the plasma serine-protease factor I (CFI, cofactor activity) and dissociate the

multicomponent C3 and C5 convertases (decay acceleration activity). Foreign targets and injured cells that either lack membrane-bound regulators or cannot bind soluble regulators are attacked by complement.

The C3 convertases of classic and lectin pathways are formed by C2 and C4 fragments, whereas the alternative pathway convertase requires cleavage of C3 only (Fig. 29-10). Thus, low serum C3 levels in aHUS with normal C4 indicate selective alternative pathway activation.[25]

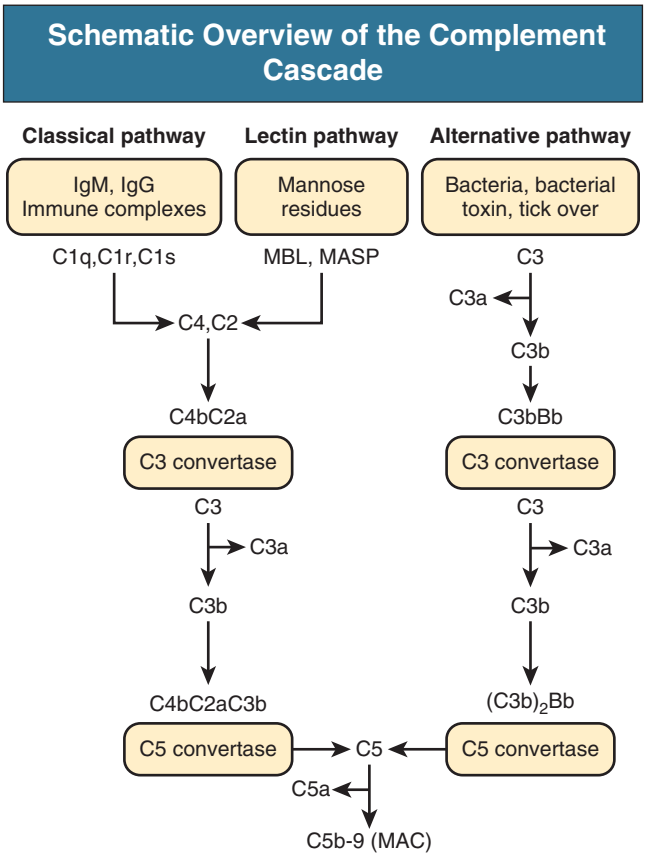

Figure 29-9 Schematic overview of complement cascade. The three activation pathways (classical, lectin, and alternative) and the membrane attack complex *(MAC)* are shown. *MBL,* Mannose-binding lectin; *MASP,* mannose-associated serine protease.

A variety of genetic abnormalities in members of the alternative pathway of complement have been described in aHUS, which account for about 60% of cases (see Table 29-1). Of note, different genetic abnormalities account for different patterns of dysfunction of the complement system with different outcome, response to therapy, and risk of recurrence after kidney transplantation (Table 29-3).

Complement Factor H Complement factor H (CFH) regulates the alternative pathway by competing with complement factor B (CFB) for C3b recognition, by acting as a cofactor for CFI, and by enhancing dissociation of C3 convertase (see Fig. 29-10). More than 100 *CFH* mutations have been identified in aHUS patients (mutation frequency ~30%)[26,27] (see http://www.FH-HUS.org). These mutations most often do not result in a quantitative deficiency in CFH, but instead result in normal levels of a protein that is unable to bind to and regulate complement on endothelial cells and platelets.[28] A high degree of sequence identity between *CFH* and the genes *CFHR1* to *CFHR5* for five factor H–related proteins (CFHR) located in tandem to *CFH* may predispose to nonallelic recombinations.[29] In 3% to 5% of patients with aHUS, a heterozygous hybrid gene deriving from an uneven crossover between *CFH* and *CFHR1* contained the first 21 *CFH* exons and the last two *CFHR1* exons,[29] resulting in a gene product with decreased complement regulatory activity on endothelial surfaces. Additional forms of CFH/CFHR hybrid genes have been recently described.

Acquired defects of CFH function are also seen in the form of inhibitory antibodies, reported in 5% to 10% of aHUS patients.[30] Analogous to the genetic defect seen in CFH, these autoantibodies also predominantly target the C-terminal end of the protein, thereby impairing complement regulation on host cell surfaces. The development of CFH autoantibodies in aHUS has a genetic predisposition, being strongly associated with a deletion of the *CFHR1* and *CFHR3* genes.

Membrane Cofactor Protein Membrane cofactor protein (MCP) is a transmembrane complement regulator widely expressed on the surface of all cells except erythrocytes. MCP serves as a cofactor for CFI to cleave C3b and C4b on cell surfaces (see Fig. 29-10). *MCP* mutations account for 10% to 15% of aHUS cases.[27,31,32] Most are heterozygous (see http://www.FH-HUS.org). The majority cluster in critical extracellular modules for regulation. Expression on blood

Outcome of Atypical Hemolytic Uremic Syndrome According to Associated Genetic Abnormality

Affected Gene	Affected Protein (Main Effect)	Frequency in aHUS (%)	Rate of Remission with Plasma Exchange* (%)	Mortality (5-10 yr) or ESRD (%)	Rate of Recurrence After Kidney Transplant (%)
CFH	Factor H (no binding to endothelium)	30	60 (dose and timing dependent)	70-80	60-70
CFHL1, CFHL3	Factor HR1, R3 (anti–factor H antibodies)	5-10	70-80 (combined with immunosuppression)	30-40	40
MCP	Membrane cofactor protein (no surface expression)	10-15	No indication to plasma exchange	<20	15-20
CFI	Factor I (low levels/low cofactor action)	4-10	30-40	60-70	70-80
CFB	Factor B (C3 convertase stabilization)	1-2	30	70	One case reported
C3	Complement C3 (resistance to C3b inactivation)	8-10	40-50	60	40-50
THBD	Thrombomodulin (reduced C3b inactivation)	4-5	60	60	One case reported

Table 29-3 Outcome of atypical hemolytic uremic syndrome (aHUS) according to the associated genetic abnormality. *Complete remission or hematologic remission with renal sequelae.

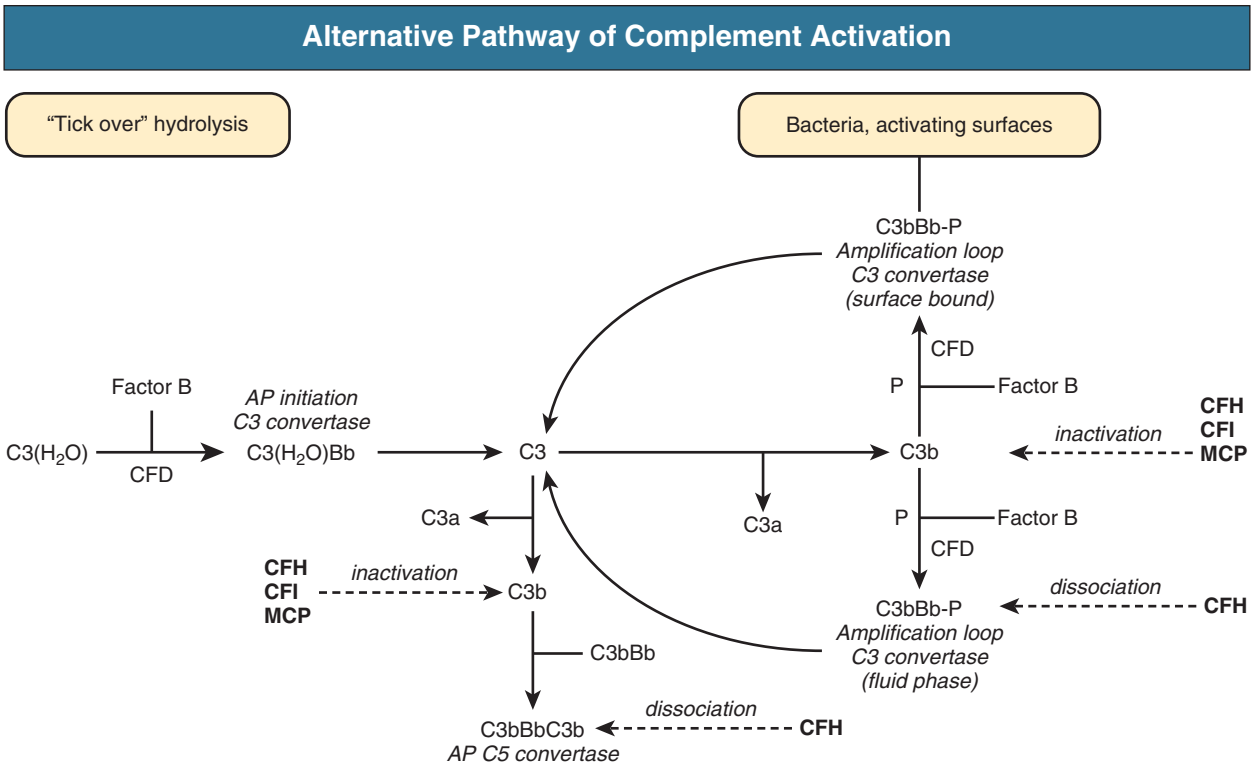

Figure 29-10 Alternative pathway of complement activation. The alternative pathway *(AP)* is continuously activated in plasma by low-grade hydrolysis of C3 (a process called tick over), which binds factor B to form a $C3(H_2O)B$ complex. Factor D *(CFD)* cleaves factor B to form the AP-initiating C3 convertase that cleaves C3 to C3b. The activation is then amplified by the covalent binding of a small amount of C3b to hydroxyl groups on cell surface carbohydrates and proteins of target cells (e.g., bacterial cells). This C3b binds factor B to form the amplification loop C3 convertase C3bBb. The binding of properdin *(P)* stabilizes this enzyme. C3 convertase enzymes cleave many molecules of C3, resulting in a positive-feedback amplification loop. C3b also binds to the C3 convertase, forming the C5 convertase enzyme $C3b_2Bb$. The AP is highly regulated to prevent nonspecific damage to host cells and limit the deposition of complement to the surface of pathogens. This fine regulation occurs through a number of membrane-anchored and fluid-phase regulators. *CFI,* Complement factor I (degrades C3b and C4b); *CFH,* complement factor H (acts as cofactor for factor I for C3b cleavage and favors decay of C3 convertase of AP); *MCP,* membrane cofactor protein (binds C3b and C4b and has cofactor activity for both classical and alternative pathways).

leukocytes was reduced for about 75% of mutants, causing quantitative defect. Others instead have low C3b-binding capability and decreased cofactor activity.[27]

Complement Factor I The plasma serine-protease CFI regulates the three complement pathways by cleaving C3b and C4b in the presence of cofactor proteins (see Figs. 29-9 and 29-10). *CFI* mutations affect 4% to 10% of aHUS patients.[27,33] All mutations are heterozygous, and 80% cluster in the serine-protease domain. Approximately 50% of mutations result in low CFI levels. Some mutants are secreted but have impaired proteolytic activity.[27,33]

Complement Factor B and C3 Gain-of-function mutations can affect genes encoding the alternative pathway C3 convertase components, CFB and C3.[34,35] *CFB* mutations are rare in aHUS (1% to 2%).[35] CFB mutants have excess C3b affinity and form a hyperactive C3 convertase resistant to dissociation.[35] About 10% of aHUS patients have heterozygous mutations in *C3,* usually with low C3 levels.[34] Most mutations reduce C3b binding to complement regulators, severely impairing degradation of mutant C3b.[34]

Thrombomodulin Heterozygous mutations in the gene *THBD* encoding thrombomodulin, a membrane-bound glycoprotein with anticoagulant properties that modulates complement activation on cell surfaces, have been found in 3% to 4% of patients with aHUS.[36] Cells expressing these variants inactivate C3b less efficiently than cells expressing wild-type thrombomodulin. These data document a functional link between complement and coagulation.

Diacylglycerol Kinase Epsilon Homozygous or compound heterozygous mutations in the diacylglycerol kinase ε *(DGKE)* gene cosegregated with aHUS in nine unrelated kindreds with autosomal recessive inheritance.[37] Mutation carriers presented with aHUS before age 1 year; had persistent hypertension, hematuria, and proteinuria; and developed CKD with age. *DGKE* is expressed in endothelium, platelets, and podocytes. *DGKE* is apparently unrelated to the complement cascade, and the mechanism by which *DGKE* mutations cause aHUS remains to be elucidated.

Determinants of Disease Penetrance Two other factors are thought to determine the development of aHUS. First, in most patients there is a *trigger;* infection and pregnancy are most often described.[38] Second, a further genetic variant *(modifier)* can increase the risk of developing the disease. This trigger can be in the form of either an additional mutation in one of the aforementioned genes or the presence of a common at-risk genetic variant. It is now recognized that about 10% of aHUS patients will have mutations in more than one gene.[39] Common at-risk genetic variants (single-nucleotide polymorphisms and haplotype blocks) in *CFH*, MCP and *CFHR1* have been shown to act as susceptibility factors for the development of HUS.[39]

Diagnosis and Screening

Differential diagnosis of aHUS is made on exclusion of infections by STEC or neuraminidase-producing *S. pneumoniae,* of ADAMTS13 deficiency, and systemic-associated diseases. Full analysis of disease-associated genes and screening for anti-CFH antibodies is recommended, in particular in the perspective of kidney transplantation for patients who progress to ESRD. Reference laboratories in several

countries are equipped for genetic and antibody screening. Although new sequencing techniques are reducing cost and timing, a complete screening still requires several days of work. Treatment of acute episodes (plasma exchange or eculizumab, if available and affordable; see later) should be started quickly after clinical diagnosis, without waiting for results of genetic and anti-CFH antibody tests.

Clinical Course

Regardless of mutation type, 60% of aHUS patients are affected during childhood,[27] and almost all patients with anti-CFH antibodies developed the disease before 16 years of age.[30] Acute episodes manifest with severe hemolytic anemia, thrombocytopenia, and AKI. Extrarenal involvement (CNS or multivisceral) occurs in 20% of patients.[5,27,38] Short-term and long-term outcomes vary according to the underlying complement abnormality (see Table 29-3). About 60% to 70% of patients with *CFH, CFI,* or *C3* mutations and 40% of children with anti-CFH autoantibodies lose renal function or die during the presenting episode, or they develop ESRD after relapse.[5,27] *CFB* mutations are associated with poor renal outcome (renal function loss in 7 of 8 patients).[35] Chronic complement dysregulation may lead to atheroma-like lesions with cardiovascular complications and excess mortality. In *MCP* mutation carriers, recurrences are common but long-term outcome is good; 80% of patients remain dialysis free.[5,27] However, rare patients with *MCP* mutations had severe disease, immediate ESRD, intractable hypertension, and coma, possibly because of concurrent genetic abnormalities.[39]

Therapy

Fresh-Frozen Plasma Guidelines suggest that plasma therapy (plasma exchange, 1 to 2 plasma volumes/day; plasma infusion, 20 to 30 ml/kg/day) should be started within 24 hours of diagnosis of aHUS.[5] Plasma exchange allows supplying larger amounts of plasma than would be possible with infusion while avoiding fluid overload (see Table 29-2). Trials of plasma therapy in HUS are scanty and not current. CFH is a plasma protein, so plasma infusion or exchange provides normal CFH to patients carrying *CFH* mutations[27,38] (see Table 29-3). Long-term treatment may fail, however, with development of plasma resistance.[40] Heterozygous *CFH* mutation carriers usually have normal levels of CFH, half of which is dysfunctional. The beneficial effect of plasma depends greatly on the amount, frequency, and modality of administration, with plasma exchange being superior to plasma infusion for remission and prevention of recurrences, by removal of mutant *CFH* that could antagonize the normal protein. Plasma exchange is used to remove anti-CFH antibodies,[30] but the effect is usually transient. Immunosuppressants (corticosteroids and azathioprine or mycophenolate mofetil) combined with plasma exchange allowed long-term dialysis-free survival in 60% to 70% of patients.[41] Data on the effect of rituximab, an anti-CD20 antibody, in such patients are scanty and inconsistent; of five patients treated with rituximab alone or with plasma exchange, only two showed disappearance of anti-CFH antibodies.[41] Thus, until better evidence is available, starting with plasma exchange plus steroids remains the treatment of choice for aHUS associated with anti-CFH antibodies.

Patients with *CFI* mutations show a partial response to plasma.[5,27,38] From 30% to 40% of patients with *CFB* mutations and 50% of those with *C3* mutations respond to plasma infusion or exchange.[5,34,35] These patients may need abundant and frequent plasma exchanges to clear the hyperfunctioning mutant *CFB* and *C3*.[5] Because MCP is a cell-associated protein, effects of plasma are unlikely in patients with *MCP* mutations. Indeed, 80% of patients with *MCP* mutation undergo remission independent of plasma treatment[5,27,38] (see Table 29-3).

Transplantation Disease recurs in 50% to 80% of transplanted patients with *CFH, CFI, CFB,* and *C3* mutations, and graft failure occurred in 80% to 90% (see Chapter 108).[34,35,42] Living related donation is contraindicated given the high risk of recurrence, and it may be risky to donors because uninephrectomy may precipitate aHUS in complement gene mutation carriers. For example, a male with a heterozygous *CFH* mutation developed *de novo* HUS after donating a kidney to his child. Most studies have shown that plasma exchange therapy fails to prevent graft loss in patients with recurrent post-transplant HUS.[42] A preemptive plasma infusion or exchange strategy has been successful in preventing recurrent aHUS in eight renal transplant recipients. In some of the patients, however, delayed recurrence occurred when plasma therapy was tapered.[43]

Simultaneous kidney and liver transplant was performed in two children with aHUS and *CFH* mutations, to correct the genetic complement abnormality defect.[44] However, both cases were complicated by premature liver failure. The first child recovered after a second liver transplantation. It was thought that the surgical stress with ischemia and reperfusion induced complement activation in a liver that could not be regulated because of functional CFH deficiency. A modified approach to the combined transplant was applied to eight patients,[45] including extensive plasma exchange before surgery to provide timely normal CFH until the liver graft recovered synthetic functions. This procedure was successful in seven patients. However, another child developed severe hepatic thrombosis and fatal encephalopathy. The risks of kidney and liver transplantation require a careful assessment of benefits for candidate patients.

The risk of post-transplant aHUS recurrence in patients with anti-CFH autoantibodies is not well known; available reports describe only 12 renal transplants in eight patients.[41] A reduction in autoantibody levels with plasma exchange, steroids, and rituximab enabled successful renal transplantation in few patients.[41]

The outcome of kidney transplant is favorable in patients with *MCP* mutations. About 80% did not experience HUS recurrence, with long-term graft survival comparable to patients transplanted for other causes.[5,38,42] MCP is a transmembrane protein highly expressed in kidney. Not surprisingly, a kidney graft corrects the defect of *MCP*-mutated recipients. However, about 20% of patients with *MCP* mutations also carry a mutation in another complement gene. Such patients have a worse graft outcome, with higher incidence of recurrences than patients with an isolated *MCP* mutation.[39]

Screening for mutations on all disease-associated genes should allow patients and clinicians to make informed decisions regarding listing for transplantation based on risk of recurrence.

Complement Inhibitors Identifying complement genetic abnormalities has paved the way for tailored treatments aimed at specifically downregulating complement activation. In particular, eculizumab will radically change short-term and long-term prognosis of aHUS. More than 35 aHUS patients treated with eculizumab have been reported in the literature thus far.[46] Some were treated for aHUS affecting the native kidneys; others received eculizumab to treat or to prevent post-transplant aHUS recurrence. Most patients treated during acute episodes achieved remission with eculizumab, including dramatic cases with severe neurologic involvement or with peripheral gangrene. The efficacy of eculizumab in aHUS has been definitely proved in two open-label controlled trials of adult and adolescent patients with plasma therapy–sensitive or plasma therapy–resistant aHUS[47,48] (see ClinicalTrials.gov Identifier: NCT1410916). Based on these results, in late 2011, eculizumab received approval for the treatment of atypical HUS in the United States and Europe.

Duration of eculizumab therapy and ideal treatment regimen remain to be established. Conceivably, lifetime treatment with

eculizumab at doses that can persistently block the complement cascade might be indicated to prevent disease recurrence in genetic forms. However, whether and to which extent this applies to all patients with aHUS and complement intrinsic abnormalities is unknown. Reasonably, different underlying genetic defects, different clinical courses before eculizumab therapy, and different residual complement activity while receiving eculizumab should be considered when planning strategies for long-term eculizumab therapy. Findings suggest that chronic treatment with regimens able to inhibit persistently the complement system may be required at least in some patients. On the other hand, the risk of sensitization associated with chronic drug exposure or with eculizumab deposition in tissues (see also Chapter 22), as well as the enormous costs in resource-limited settings, suggests that careful treatment, tapering up to withdrawal whenever possible, should be attempted in most aHUS patients under tight control of disease and complement activity.

Thrombotic Thrombocytopenic Purpura

In the microvasculature of patients with TTP, systemic platelet thrombi develop, mainly formed by platelets and von Willebrand factor (vWF). This protein plays a major role in primary hemostasis by forming platelet plugs at sites of vascular injury under high shear stress. The vWF is a large glycoprotein synthesized in vascular endothelial cells and megakaryocytes as a high-molecular-weight polymer.[49] Secretion of vWF occurs primarily through the Weibel-Palade bodies. Exocytosis of vWF from the storage granules may be swiftly increased by exposing endothelial cells to secretagogues such as histamine, thrombin, phorbolmyristate acetate, or calcium ionophores. On stimulation, vWF is secreted by endothelial cells as ultralarge (UL) multimers that form string-like structures attached to the endothelial cells, possibly through interaction with P-selectin. Under fluid shear stress, ULvWF strings are cleaved to generate the range of vWF multimer sizes that normally circulate in the blood.[50] The proteolytic cleavage of vWF multimers appears to be critical to prevent thrombosis in the microvasculature.

ADAMTS13 is the protease responsible for cleaving vWF, creating 140-kd and 176-kd fragments (Fig. 29-11). It derives primarily from the stellate cells of the liver. ADAMTS13 is also expressed, although at lower levels, in other types of cells, such as renal podocytes and tubular cells, vascular endothelial cells, and platelets. The plasma concentration of ADAMTS13 is approximately 1 µg/ml, or 5 nmol/L. The elimination half-life of ADAMTS13 is 1 to 2 days in the circulation.

Mechanisms

In the majority of patients with primary TTP, ADAMTS13 is deficient, leading to accumulation of ULvWF multimers that are highly reactive with platelets.[51,52] Exposure of ULvWF multimers and platelets to shear stress leads to platelet aggregation. The levels of shear stress necessary for inducing platelet aggregation is in the range found in normal arteriolar and capillary circulation. Therefore, vWF and platelets have a propensity to form aggregates in normal arterioles and capillaries that needs to be constantly regulated. By cleaving ULvWF multimers before they are activated by shear stress to cause platelet aggregation, ADAMTS13 prevents spontaneous microvascular thrombosis in the normal circulation (see Fig. 29-11). The platelet aggregation observed in patients with TTP and ADAMTS13 deficiency is thus a direct consequence of the accumulation of ULvWF multimers. Consequently, microvascular thrombi occur in almost all organ vessels, resulting in diffuse organ ischemia and thrombocytopenia secondary to platelet consumption. Microangiopathic

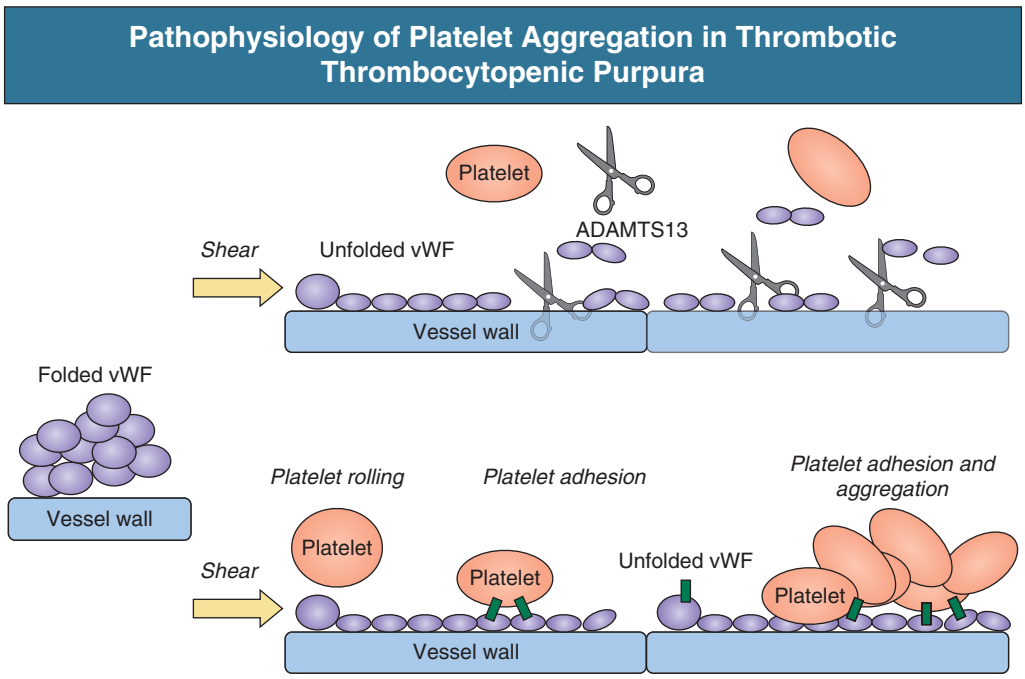

Figure 29-11 Pathophysiology of platelet aggregation in thrombotic thrombocytopenic purpura. Von Willebrand factor *(vWF)* is synthesized and stored as ultralarge (UL) multimers in endothelial cells and megakaryocytes. On stimulation, ULvWF multimers are secreted by endothelial cells into the circulation in a folded structure. On exposure to enhanced shear stress, UL multimers form string-like structures that adhere to endothelial cells. *Upper panel,* Normally, ULvWF strings are cleaved by ADAMTS13 to generate vWF multimers from 500 kDa to 20 million Da and prevent thrombosis in the microvasculature. *Lower panel,* When the ADAMTS13 proteolytic activity is defective because of the inhibitory effect of anti-ADAMTS13 autoantibodies or congenital defective synthesis of the protease, ULvWF multimers accumulate and interact with activated platelets to facilitate platelet adhesion and aggregation, with thrombi formation and occlusion of the vascular lumen.

hemolysis is caused by the passage of blood through the damaged capillaries and arterioles occluded by thrombi.

Two mechanisms for deficiency of the ADAMTS13 activity have been identified in patients with primary TTP: an acquired deficiency, caused by formation of anti-ADAMTS13 autoantibodies (acquired TTP), and a genetic deficiency, caused by homozygous or compound heterozygous mutations in *ADAMTS13* (congenital TTP) (see Table 29-1).

Associated with Immune-Mediated Deficiency of ADAMTS13 This acquired form of TTP accounts for the majority of acute primary cases (60% to 90%). The disease is characterized by severe deficiency of ADAMTS13,[52] the activity of which is inhibited by specific autoantibodies that develop transiently and tend to disappear during remission.[52] Patients with TTP secondary to hematopoietic stem cell transplantation, malignancies, or human immunodeficiency virus (HIV) infection rarely have severe ADAMTS13 deficiency and inhibitory IgG antibodies.[53] Severe ADAMTS13 deficiency and ADAMTS13 inhibitory antibodies were detected in 80% to 90% of patients with ticlopidine-associated TTP and in a few patients with clopidogrel-induced TTP. The deficiency resolved after the drugs were discontinued. ADAMTS13 inhibitors have not been described in other drug-associated TTP. TTP diagnosed during pregnancy accounts for about 7% of all TTP cases. The majority of these women have acquired ADAMTS13 deficiency, but pregnancy has also been reported as a triggering event in patients with genetic ADAMTS13 deficiency, as discussed later.

The pathogenicity of TTP-associated anti-ADAMTS13 autoantibodies is evidenced by their usual disappearance from the circulation when remission is achieved after effective treatment, which occurs in parallel with normalization of ADAMTS13 activity.

Associated with Congenital Deficiency of ADAMTS13 This rare inherited form of TTP is associated with a genetic defect of *ADAMTS13* and accounts for about 5% of all of cases of TTP (see Table 29-1). TTP associated with congenital ADAMTS13 deficiency can present both with and without a family history of the disease.[51,54] In both cases the disease is inherited as a recessive trait. To date, more than 120 *ADAMTS13* mutations have been identified in patients with TTP.[55] Studies on secretion and activity of the mutated forms showed that most led to impaired secretion of the protease from the cells, and when the mutated protein is secreted, the proteolytic activity is greatly reduced.

Most patients are carriers of compound heterozygous mutations; only 20% of mutations have been observed in homozygous form.

Clinical Course

Compared with patients who have nonsevere ADAMTS13 deficiency, severely deficient patients experience higher rates of therapy-induced remissions (82% to 88% vs. 20% to 75%) and lower mortality (8% to 18% vs. 18% to 80%).[53,56] The high mortality in non–severely deficient patients may be caused by the higher proportion of secondary causes and death from underlying diseases, such as patients with hematologic malignancies.

Among patients who have a severe ADAMTS13 deficiency, patients with inhibitory antibodies experience a more severe manifestation of the disease, take substantially longer time to achieve clinical remission, and require a higher plasma volume than patients with congenital ADAMTS13 deficiency. In patients with inhibitory antibodies, risk as high as 50% to develop relapses has been reported, and undetectable ADAMTS13 activity and persistence of anti-ADAMTS13 inhibitors during remission predict recurrences.

Thrombotic thrombocytopenic purpura has been reported in one of every 1600 to 5000 patients treated with ticlopidine, with 11 cases reported during clopidogrel therapy. The overall survival rate is 67% and is improved by early treatment withdrawal and plasma therapy.

Approximately 60% of patients with congenital deficiency of ADAMTS13 experience their first acute episode of disease in the neonatal period or during infancy, but a second group (10% to 20%) manifests the disease after the third decade of life. TTP recurrences occur in 80% of patients,[55] but their frequency varies widely. Whereas some patients with congenital ADAMTS13 deficiency depend on frequent chronic plasma infusions to prevent recurrences, others who achieved clinical remission after plasma treatment remain disease free for long periods after plasma discontinuation. The type and location of *ADAMTS13* mutations may influence the age of onset of TTP and the penetrance of the disease in mutation carriers. Patients carrying mutations associated with some residual ADAMTS13 activity in blood had a longer disease-free survival compared with patients with completely absent protease activity.[57]

Environmental factors may contribute to induce full-blown manifestation of the disease. According to this "two-hit model," deficiency of ADAMTS13 predisposes to microvascular thrombosis, and thrombotic microangiopathy supervenes after a triggering event that activates microvascular endothelial cells and causes the secretion of ULvWF multimers and P-selectin expression. Again, potential triggers of these phenomena are infections and pregnancy.

Therapy

Plasma is the cornerstone of therapy in an acute episode in TTP patients because it replaces defective protease activity. In patients with anti-ADAMTS13 antibodies and compared with infusion, plasma exchange may offer the advantage of also rapidly removing anti-ADAMTS13 antibodies[8] (see Table 29-2).

Because of the potential for sudden clinical deterioration, treatment should be initiated as soon as possible after diagnosis of TTP. The treatment approach consists of a daily 1 to 2 plasma volume exchange with plasma until clinical symptoms have resolved and the platelet count has reached a normal level (≥150,000/μl). Fresh-frozen plasma (FFP) and cryosupernatant plasma are considered equivalent because of comparable levels of ADAMTS13.

Corticosteroids, given in combination with plasma therapy, may be of benefit in autoimmune forms of TTP by inhibiting the synthesis of anti-ADAMTS13 autoantibodies. The rationale of combined treatment is that plasma exchange will have only a temporary effect on the presumed autoimmune basis of the disease, and additional immunosuppressive treatment may cause a more durable response (see Table 29-2).

Prospective studies have successfully and safely used rituximab, an anti-CD20 monoclonal antibody depleting B lymphocytes, in patients who failed to respond to standard daily plasma exchange and methylprednisolone, as well as in patients with relapsed acute TTP who had previously demonstrated antibodies to ADAMTS13. Treatment was associated with clinical remission in all patients, disappearance of anti-ADAMTS13 antibodies, and increased ADAMTS13 activity to levels greater than 10%.[58] Of the about 100 rituximab-treated patients reported, normalization of platelets and LDH has been noted in about 95%, although time to remission has been variable, from 1 to 4 weeks after the first dose. The duration of remission ranged from 9 months to 4 years, with relapses reported in approximately 10%. Rituximab has been also used electively to prevent relapses in patients with autoantibodies and recurrent disease.[59] Longitudinal evaluation of ADAMTS13 activity and autoantibody levels may help in monitoring patient response to treatment. Repeat treatment with rituximab should be considered when ADAMTS13 activity decreases and inhibitors reappear into the circulation, to prevent a relapse.

In patients who have TTP associated with congenital ADAMTS13 deficiency, ADAMTS13 is constitutively lacking and can be replaced by plasma infusions. During acute episodes, patients often require plasma exchange to restore a stable clinical and laboratory state. Providing enough ADAMTS13 to achieve 5% normal enzymatic activity may be sufficient to degrade large vWF multimers, which may be relevant to induce remission of the microangiopathic process, and this effect is sustained over time. Infused ADAMTS13 has a plasma half-life of 2 to 3 days *in vivo*,[60] and although plasma levels fall below 5% within 3 to 7 days after plasma administration, the effect of plasma on platelet count and clinical parameters may last up to 3 weeks, suggesting that ADAMTS13 remains available (e.g., on platelets and endothelial cells). Patients with congenital ADAMTS13 deficiency tend to relapse. Patients with frequent relapses, a severe clinical course with neurologic sequelae, or renal insufficiency, as well as patients who have siblings who died of TTP, should receive regular prophylactic plasma infusions every 2 to 3 weeks, a regimen shown to be effective in preventing acute TTP episodes and maintaining the patients in good health for years.

Other Forms of Thrombotic Microangiopathy, Associated with Systemic Disease or Drugs

Antiphospholipid Syndrome, Scleroderma, and Hypertensive Emergencies

Plasma therapy has often been attempted in patients with thrombotic microangiopathy associated with systemic diseases, even though its efficacy is poorly defined.[5] In the antiphospholipid syndrome, oral anticoagulation remains the only treatment of proven efficacy to prevent and to treat microvascular and macrovascular thrombosis, even if concomitant thrombocytopenia may increase the risk of bleeding. Preliminary reports suggest a potential efficacy of rituximab therapy, but further controlled studies are needed.[61]

Blood pressure control is fundamental in patients with TMA associated with scleroderma crisis and hypertensive emergencies.

Human Immunodeficiency Virus

Hemolytic uremic syndrome and thrombotic thrombocytopenic purpura are both possible complications of acquired immunodeficiency syndrome (AIDS), which may account for as many as 30% of hospitalized TMA patients in cities where AIDS is epidemic. Plasma therapy is the only feasible approach in these forms, although the prognosis is poor.[5]

Malignant Diseases

Spontaneous TMA complicates almost 6% of cases of metastatic gastric carcinoma, which in turn accounts for about 50% of all malignant disease–associated TMA. The prognosis is extremely poor. Therapy is minimally effective.[5]

Drugs

More often resembling HUS, TMA is described in 2% to 10% of cancer patients treated with mitomycin C.[62] Patients who develop mitomycin C–associated TMA are usually in remission from their malignant disease. Mortality is about 70%, and median time to death is about 4 weeks. Patients surviving the acute phase often continue to receive dialysis or die later of tumor recurrence or metastasis. The suggestion to administer corticosteroids during mitomycin treatment to prevent disease needs to be confirmed. Plasma exchange is usually attempted, but its effectiveness is unproved.

Platinum- and bleomycin-containing combinations have also been reported to induce HUS.[62]

Quinine is one of the most common drugs associated with TMA. It is generally used to treat muscle cramps but is also contained in beverages and nutrition health products (e.g., tonic water, herbal preparations). Quinine-dependent platelet, erythrocyte, granulocyte, lymphocyte, and endothelial antibodies may contribute to the pathogenesis. Severe renal impairment is frequent, and hemodialysis is required in most cases. High mortality and chronic renal failure have been reported.[62] Quinine cessation and plasma therapy should be initiated rapidly.

Thrombotic microangiopathy associated with interferon alfa is characterized predominantly by renal impairment. Patients typically recover with early discontinuation of the drug and prompt supportive therapy. However, kidney prognosis is usually poor, with ESRD in about 42% of patients.

SECTION V

Diabetic Nephropathy

CHAPTER 30

Pathogenesis, Clinical Manifestations, and Natural History of Diabetic Nephropathy

Gunter Wolf and Kumar Sharma

DEFINITIONS

Diabetic nephropathy (DN) is the leading cause of end-stage renal disease (ESRD) in most Western societies. It can develop in the course of both type 1 and type 2 diabetes and as a consequence of other forms of diabetes mellitus (DM). *Type 1 diabetes* is an autoimmune disease characterized by antibody-mediated and cell-mediated destruction of pancreatic islets. Type 1 diabetes may occur at any age but is common in childhood, usually presenting before age 30 years. *Type 2 diabetes* is characterized by a combination of insulin resistance and insulin deficiency. The *metabolic syndrome* (insulin resistance, visceral obesity, hypertension, hyperuricemia, and dyslipidemia with high triglyceride levels and low amounts of high-density lipoprotein) is often followed by type 2 diabetes. For a long period, insulin resistance is compensated by increased insulin secretion, but a gradual decline in pancreatic β-cell function finally culminates in hyperglycemia, and type 2 diabetic patients require treatment with insulin. Type 2 diabetes was typically a disease of mostly elderly adults, but recently it is increasingly seen in adolescents and even in children. In addition, other types of DM include maturity-onset diabetes of the young, gestational diabetes, and diabetes secondary to various metabolic disorders or the result of corticosteroid treatment.

PATHOGENESIS OF DIABETIC NEPHROPATHY

Genetic and Environmental Factors

The risk of nephropathy is strongly determined by polygenetic factors. The risk for development of DN is equal in type 1 and type 2 diabetes, and only 30% to 40% of patients with type 1 or type 2 diabetes will ultimately develop nephropathy. The prevalence of nephropathy in diabetic patients varies among different racial and ethnic groups such that it is relatively increased in African Americans, Native Americans, Mexican Americans, Polynesians, Australian aborigines, and urbanized South Asian immigrants in the United Kingdom compared with Caucasians. Although barriers to care seem likely to account for some of these interpopulation differences, genetic factors may also contribute.

Familial clustering of DN has been reported in both type 1 and type 2 diabetes and in both Caucasian and non-Caucasian populations. In a type 1 diabetic patient who has a first-degree relative with diabetes and nephropathy, the risk for development of DN is 83%. The frequency is only 17% if there is a first-degree relative with diabetes but without nephropathy.[1] In type 2 diabetes, familial clustering has been well documented in Pima Indians,[2] and a familial determinant is also suggested by the observation that albumin excretion rates are higher in offspring of type 2 diabetic patients with nephropathy. The risk is particularly high in the offspring if the mother had been hyperglycemic during pregnancy, perhaps because this causes reduced formation of nephrons ("nephron underdosing") in the offspring,[3] as shown in experimental studies.[4] Low birth weight and nephron underdosing are also associated with hypertension, metabolic syndrome, and perhaps DN, although for DN the data are somewhat controversial. The hypothesis has been proposed that nephron underdosing[5] leads to compensatory glomerular hypertrophy and increased single-nephron glomerular filtration rate (GFR), thus aggravating glomerular injury if a renal insult such as diabetes occurs.

There is ongoing research to identify genetic loci for DN susceptibility through genomic screening and candidate gene approaches. However, risk for DN does not show simple mendelian inheritance, and multiple genes are presumably involved. Whole-genome scanning has identified several chromosomal regions that are linked with DN with susceptibility loci, for example, on chromosomes 3q, 7p, and 18q. At present, the pathophysiologic function of such genetic regions is mainly unknown. Gene polymorphisms may also contribute to familial clustering. A study suggested a genetic predisposition to DN caused by a polymorphism in the carnosinase gene, causing accumulation of carnosine with antioxidant properties.[6] Several studies also suggested some detrimental effect of the double-deletion (DD) polymorphism of the angiotensin-converting enzyme (ACE) genotype on disease progression,[7] although the finding has not been uniformly confirmed.[8,9]

Environmental factors, especially dietary factors, may also be involved in the pathogenesis of diabetes and DN. One of the strongest risk factors is the intake of soft drinks containing added sugars such as sucrose or high-fructose corn syrup. Added sugars contain fructose, which has been shown to induce features of metabolic syndrome in both humans and laboratory animals, and the mechanism may be mediated in part by the ability of fructose to increase uric acid level. In turn, an elevated serum uric acid level has been found to be a potent predictor for the development of type 2 diabetes as well as DN. The mechanism is linked to the ability of uric acid to induce oxidative stress and endothelial dysfunction. Recent studies suggest that one of the mechanisms by which low birth weight increases the risk for hypertension and diabetes later in life is because low birth weight results in an elevation of uric acid that persists from birth throughout childhood.

Hemodynamic Changes

Hyperfiltration is common in early diabetes but can be corrected with good glycemic control. Increased GFR involves glucose-dependent effects causing afferent arteriolar dilation, mediated by a range of vasoactive mediators, including insulin-like growth factor 1 (IGF-1), transforming growth factor β (TGF-β1), vascular endothelial growth factor (VEGF), nitric oxide (NO), prostaglandins, and

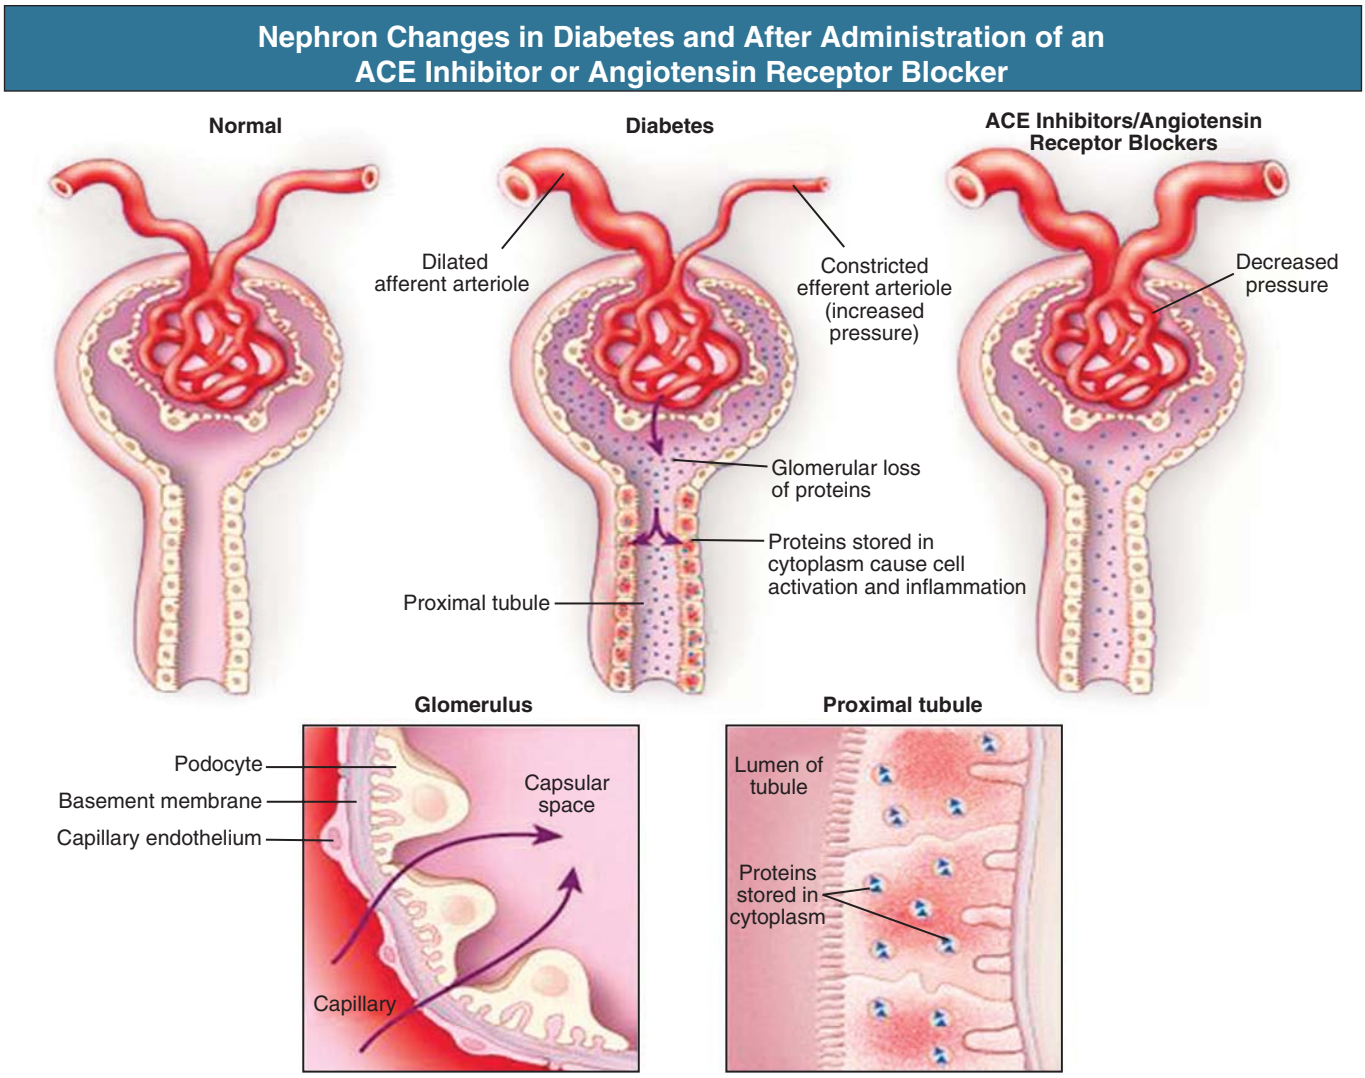

Figure 30-1 Schematic comparison of normal nephron, nephron in DN, and nephron in DN after ACE inhibitor/ARB administration. Note afferent vasodilation and efferent angiotensin II (Ang II)–mediated vasoconstriction in diabetic nephropathy (DN) causing glomerular hypertension, which is relieved by angiotensin-converting enzyme (ACE) inhibitor and angiotensin receptor blocker (ARB) therapy. Note also protein leakage into the filtrate and tubular loading, with endocytosed protein causing an inflammatory reaction that promotes interstitial fibrosis. This is reversed by ACE inhibitor/ARB treatment.

glucagon (Fig. 30-1). Over time, development of vascular disease of the afferent arteriole may result in permanent alterations in renal autoregulation that favor glomerular hypertension. Renal injury in DN is caused not only by hemodynamic disturbances (e.g., hyperfiltration, hyperperfusion) but also by disturbed glucose homeostasis, and the two pathways interact. For example, shear stress increases glucose transport into mesangial cells by upregulation of specific glucose transporters. Furthermore, shear stress and mechanical strain resulting from altered glomerular hemodynamics trigger autocrine and paracrine release of cytokines and growth factors in the glomerulus.

Diabetic nephropathy is also associated with tubular abnormalities (e.g., increased tubular reabsorption of sodium). Hyperfiltration increases the colloid osmotic pressure in postglomerular capillaries, facilitating reabsorption of sodium in the proximal tubule. In the presence of hyperglycemia, increased proximal sodium reabsorption may also result from increased activity of the glucose-sodium cotransporter. Angiotensin II (Ang II) also appears to have a role, causing hypertrophic proximal tubular growth and increased sodium reabsorption.[10]

Renal Hypertrophy

Renal growth is seen early after the onset of diabetes. The size of the kidney may increase by several centimeters. Glomerular enlargement is associated with an increase in the number of mesangial cells and of capillary loops, thus enhancing the filtration surface area. Enlargement of the glomeruli is the result of cellular hypertrophy, whereas the tubular epithelial cells undergo both proliferation and hypertrophy.

In animal experiments, avoidance of hyperglycemia prevents renal hypertrophy. Elevated serum glucose levels cause hypertrophy by stimulating growth factors in the kidney, including IGF-1, epidermal growth factor (EGF), platelet-derived growth factor (PDGF), VEGF, TGF-β, and Ang II. The molecular mechanisms involved in glycemia-induced hypertrophy include induction of cell cycle inhibitors such as $p27^{Kip1}$. TGF-β stimulates protein synthesis (hypertrophy) but prevents cell proliferation and division by induction of cell cycle inhibitors.[11,12] It is overexpressed in the glomeruli and the tubulointerstitium both in experimental and in human DN. Glucose as well as glucose-derived *advanced glycation end products* (AGEs) and Ang II stimulate the production of TGF-β in mesangial cells,

podocytes, and tubular epithelial cells. Hyperglycemia also induces the expression of thrombospondin, a potent activator of latent TGF-β. Treatment of diabetic mice with neutralizing anti–TGF-β antibodies attenuated diabetes-related renal hypertrophy and extracellular matrix (ECM) accumulation and preserved renal function, but had minimal influence on proteinuria. Similarly, inhibition of VEGF prevented glomerular hypertrophy in models of DN and also reduced albuminuria.[12]

Mesangial Expansion and Nodule Formation

The hallmarks of DN are mesangial expansion, nodular diabetic glomerulosclerosis (the acellular Kimmelstiel-Wilson lesion), and diffuse glomerulosclerosis. The early mesangial lesion is characterized by a variable increase in mesangial cell number and size associated with an increased ECM deposition. In later stages, a general loss of mesangial cells occurs. Increasing evidence suggests that local NO deficiency contributes to these histologic lesions, in particular nodule formation. Indeed, endothelial cell nitric oxide synthase (NOS)–deficient mice made diabetic with streptozotocin represent one of the most promising models for DN.

Mesangial expansion is mediated by both glucose and glucose-derived AGEs. In experimental models, mesangial changes can largely be prevented by tight glycemic control or the use of AGE inhibitors such as aminoguanidine. The effects are presumably mediated by TGF-β.

Inflammation and Diabetic Nephropathy

Inflammatory processes and immune cells are involved in the development and progression of DN.[11] Glomerular and interstitial infiltration by monocyte/macrophages and activated T lymphocytes is observed both in human biopsy specimens and in animal models of DN. An inflammatory state is also suggested by the frequent elevation of serum levels of acute-phase proteins and elevated neutrophil counts. Chemokines and their receptors, in particular monocyte chemotactic protein 1 (MCP-1/CCL2), as well as adhesion molecules seem to contribute to this.[11,13] Fractalkine/CX3CL1 may function as an arrest chemokine in monocyte/macrophage adhesion before migration into the kidney. T lymphocyte recruitment is the consequence of glomerular and tubulointerstitial upregulation of RANTES/CCL5 structures as well as tubulointerstitial upregulation of inducible protein 10 (IP-10/CXCL10) (Fig. 30-2). Bardoxolone methyl, as an inducer of the KEAP1-Nrf2 pathway, exhibits anti-inflammatory effects and showed initially promising results as a novel therapeutic agent in patients with type 2 diabetes. However, a large Phase III trial was stopped after an interim analysis revealed significantly more adverse effects and increased mortality in the intervention group (see Chapter 31).

Mechanisms Underlying Proteinuria

Widening of the glomerular basement membrane (GBM) is associated with accumulation of type IV collagen and net reduction in negatively charged heparin sulfate. However, heparin sulfate cannot be the key factor underlying proteinuria, because selective reduction of GBM proteoglycans unexpectedly reduced rather than increased proteinuria. This supports the podocyte being more important in the genesis of proteinuria. Biopsies in patients with DN documented a correlation between the degree of proteinuria and the width of podocyte foot processes. The expression of one permeability-controlling protein, nephrin, is abnormally low in DN.[12] The transcription of nephrin is suppressed by Ang II and restored by inhibitors of the renin-angiotensin system (RAS). In addition, in DN, apoptosis of podocytes is triggered by various factors, including Ang II and TGF-β, and adhesion of podocytes to the GBM is reduced by AGE-induced suppression of neuropilin-1. Furthermore, migration of podocytes is also attenuated by the reduction of neuropilin-1, thereby preventing surviving podocytes from covering denuded areas of GBM, and thus causing formation of synechiae and development of focal segmental glomerulosclerosis (FSGS).

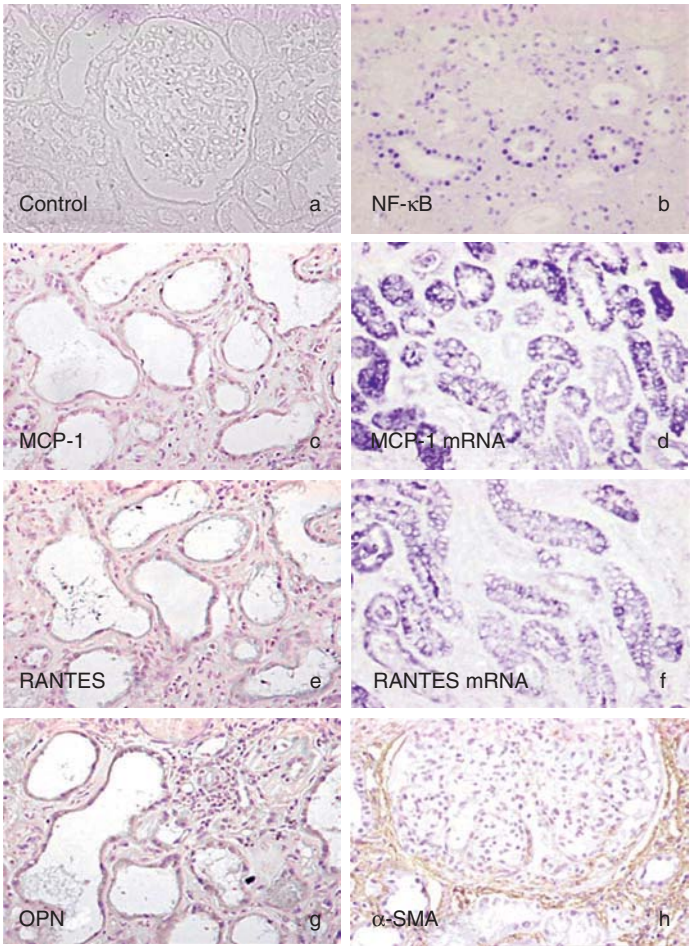

Figure 30-2 Activated nuclear factor (NF)-κB and overexpression of related chemokines in human diabetic nephropathy (DN). Overexpression of chemokines (MCP-1, RANTES), osteopontin *(OPN),* and activated NF-κB in human DN (**a,** normal, nondiabetic kidney; **b** to **h,** DN) indicating the inflammatory nature of DN. *MCP-1,* Monocyte chemotactic protein 1; *RANTES,* regulated on activation, normal T cell expressed and secreted (CCL5); *α-SMA,* α-smooth muscle actin. *(From reference 13.)*

Crosstalk between glomerular endothelial cells and podocytes involves activated protein C (APC). APC formation is regulated by endothelial thrombomodulin and is reduced in diabetic mice.[14] In DN, thrombomodulin-dependent APC formation inhibits podocyte apoptosis (Fig. 30-3).

In cultured podocytes, adiponectin administration reduced the permeability to albumin and caused podocyte dysfunction. Endothelial cell dysfunction associated with altered fenestrations and glycocalyx may also contribute to enhanced permeability. Because adiponectin levels are low in patients with the metabolic syndrome or type 2 diabetes, lack of adiponectin may further contribute to proteinuria.

In advanced stages of DN, high-molecular-weight serum proteins are able to escape across basal membranes with disrupted texture, gaps, and holes (nonselective proteinuria).

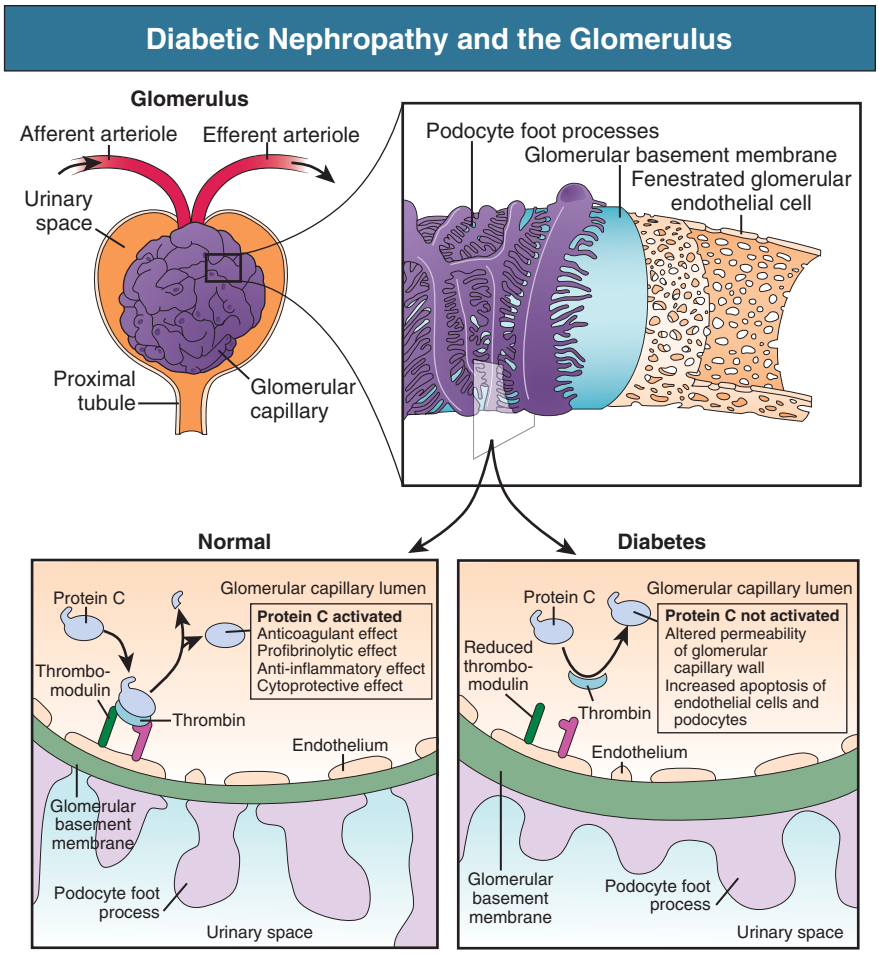

Figure 30-3 Crosstalk between endothelial cells and podocytes involving protein C. Under physiologic conditions, protein C is activated by the binding of thrombin to its receptor, called thrombomodulin, on glomerular endothelial cells. The formed complex catalyzes the conversion of protein C to its catalytically activated form, which has potent anticoagulant, profibrinolytic, anti-inflammatory, and cytoprotective effects. In diabetic nephropathy, the production of activated protein C in the glomerulus is reduced because of suppression of thrombomodulin expression. Decreased functional activity of activated protein C affects the permeability of the glomerular capillary wall and enhances apoptosis of glomerular endothelial cells and podocytes. *(From reference 69.)*

Tubulointerstitial Fibrosis and Tubular Atrophy

Tubulointerstitial pathology is seen early in DN and correlates with prognosis.[15] The pathogenic mechanisms underlying tubulointerstitial fibrosis and tubular atrophy are similar or identical to those in nondiabetic progressive renal disease (see Chapter 79): release of growth factors, in particular TGF-β, and other cytokines from the glomerulus and direct or indirect effects of proteinuria. Under the influence of mediators such as TGF-β and Ang II, tubular cells change their phenotype and become fibroblast-like.[15,16] High glucose concentration and AGEs further stimulate this process. One of the mechanisms by which glucose may promote tubular disease is by conversion through the polyol pathway to fructose, where it is degraded by local fructokinase to induce oxidative stress and local inflammation. Proapoptotic genes are expressed by tubular cells in DN, as promoted by Ang II.

Four different cell types may contribute to matrix accumulation along the glomerular and tubular basement membranes and within the interstitial space: glomerular cells, tubular epithelial cells, macrophages/lymphocytes, and fibroblasts/myofibroblasts. In renal fibrosis, the role of matrix-producing myofibroblasts, which contribute to the progression of fibrosis in DN by facilitating deposition of interstitial ECM, is widely accepted; however, their origin remains controversial. Up to 36% of all interstitial fibroblasts is derived from tubular epithelial cells by *epithelial-mesenchymal transition* (EMT).[16] In addition, endothelial cells and pericytes may also contribute to fibroblast-like transformation. EMT is a highly regulated process defined by four key events: (1) loss of epithelial cell adhesion (e.g., E-cadherin adhesion complex), (2) *de novo* α-smooth muscle actin (α-SMA) expression and actin reorganization, (3) disruption of tubular basement membrane, and (4) enhanced cell migration and invasion of the interstitium (Fig. 30-4). The third and fourth features are difficult to confirm in human disease. Several factors are known to be important in the induction of EMT and subsequently in tubulointerstitial fibrosis. Most important, the enhanced multifunctional cytokine TGF-β1 has been identified as a central mediator of the fibrotic response as a regulator for EMT. TGF-β1 is increased by hyperglycemia in glomeruli and tubulointerstitium of kidney specimens from patients with established DN, induces fibroblasts to synthesize ECM proteins, such as type I, III, and V collagen and fibronectin. We recently demonstrated that EMT in the diabetic kidney depends on the presence of collagen type VIII, a nonfibrillar collagen protein that exists as a heterodimer composed of two distinct polypeptide chains, α1(VIII) and α2(VIII).[17] However, recent findings render the contribution of EMT to renal fibrosis controversial (see Chapter 79).

Clinical studies showed that even mild anemia (hemoglobin level <12.5 g/dl for men, 11.5 g/dl for women) increases the risk of progression of DN. Treatment of anemia early in renal failure with erythropoietin (EPO) may slow the decline of renal dysfunction in DN. Anemia presumably causes renal hypoxia. Moreover, hypoxia is exacerbated by the progressive hyalinosis of the afferent and efferent arterioles and loss of peritubular capillaries. In experimental models of chronic renal injury, hypoxia is an important factor aggravating interstitial fibrosis, partly by the induction of factors such as TGF-β and VEGF. The transition of tubular epithelial cells into fibroblasts

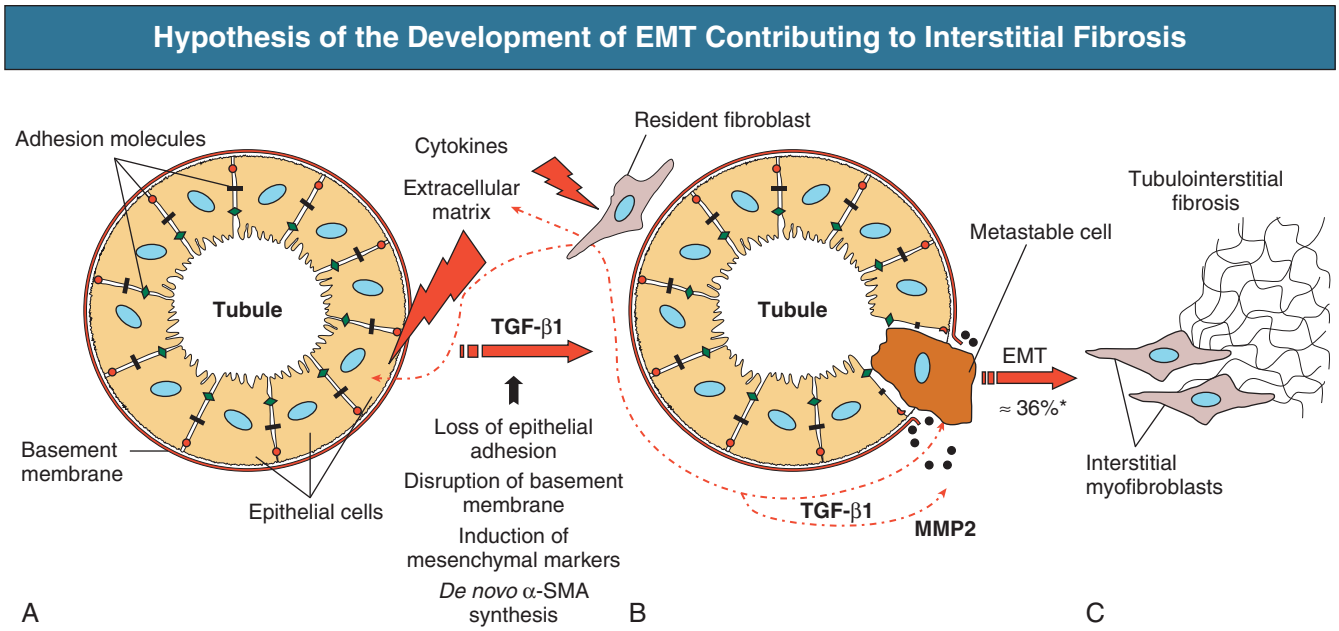

Figure 30-4 Hypothesis of the development of epithelial-mesenchymal transition (EMT) contributing to interstitial fibrosis. Initiated by external stimuli (e.g., cytokines), tubular cells lose their cell-cell contacts (e.g., E-cadherin) (**A**) and start to express mesenchymal markers (e.g., α-SMA, vimentin) (**B**). After disruption of tubular basement membrane (by MMP2) metastable cells disengage themselves from cell connective and transdifferentiate to interstitial myofibroblasts that synthesize extracellular matrix and contribute to fibrosis (**C**). *MMP,* Matrix metalloproteinase; *SMA,* smooth muscle actin; *TGF,* transforming growth factor. *Up to 36% of all interstitial myofibroblasts in diabetic nephropathy are thought to derive from EMT. *(Modified from reference 70.)*

is stimulated by cellular hypoxia.[18] The induction of growth factors and cytokines is mediated by hypoxia-inducing factor 1, which can be amplified by Ang II.

Hyperglycemia and Diabetic Nephropathy

Role of Glucose Control

Evidence of the role of tight glycemic control in retarding the development of DN includes the following:

- Studies suggest that with good glycemic control, as reflected by an average hemoglobin A_{1c} (HbA_{1c}) level of 7.0%, only 9% of type 1 diabetic patients will develop ESRD after 25 years, versus the historical prevalence of 40%.[19]
- Results from the Diabetes Control and Complications Trial (DCCT) showed a remarkable reduction in progression from normoalbuminuria to microalbuminuria and other microvascular complications, specifically retinopathy, in patients with type 1 diabetes with tight glycemic control.[20] At least for cardiovascular sequelae, the benefit of early aggressive reduction of glycemia persisted despite later deterioration of the glycemic control.[21]
- Euglycemia that followed isolated transplantation of the pancreas was associated with a regression of diabetic glomerulosclerosis after 10 years.[22]
- Evidence from the United Kingdom Prospective Diabetes Study (UKPDS) showed that reducing the HbA_{1c} level by approximately 0.9% in patients with type 2 diabetes reduces the risk for development of microvascular complications, including nephropathy.[23]
- The ADVANCE study randomly assigned 11,140 patients with type 2 diabetes to either intensive glucose control or standard glucose control. At the end of 5-year follow-up, HbA_{1c} level was 6.5% in the intensive group and 7.3% in the standard therapy group. Intensive glucose control was associated with a significant reduction in renal events and new-onset microalbuminuria. The trial did not show a significant effect of intensive control on major macrovascular events.[24]

The mechanisms by which hyperglycemia induces DN are complex and may involve not only effects of elevated glucose levels, but also the generation of AGEs and alcohol sugars (polyols) as a result of hyperglycemia.

Brownlee[25] proposed a unifying mechanism of how hyperglycemia leads to diabetic complications, including DN (Fig. 30-5). An increase in intracellular glucose concentrations stimulates glucose oxidation in the tricarboxylic acid cycle, pushing more electron donors (NADH, $FADH_2$) into the electron transport chain.[25,26] When a critical threshold is reached and electrons are donated to molecular oxygen, superoxide is generated. This mitochondrial overproduction of superoxide activates four major pathways that are involved in DN. Although this hypothesis is supported by studies in cell culture, validation in animal models remains inconclusive, partly because of the difficulty in measuring superoxide production accurately *in vivo.*

Protein Kinase C Pathway Many of the adverse effects of hyperglycemia have been attributed to activation of protein kinase C (PKC), a family of serine-threonine kinases that regulate diverse vascular functions. The activity of PKC, especially the membrane-bound form, is increased in the retina, aorta, heart, and glomeruli of diabetic animals. In short-term and long-term studies of diabetic rats, an orally effective PKC-β–selective inhibitor ameliorated glomerular hyperfiltration, albuminuria, and renal TGF-β overexpression as well as ECM accumulation.[12,26] PKC-α may represent an additional therapeutic target because albuminuria was virtually absent in diabetic PKC-α knockout mice.

Advanced Glycation End Products Pathway Chronic hyperglycemia can lead to nonenzymatic glycation of amino acids and proteins (Maillard or Browning reaction)[27] (Fig. 30-6). Over time, these products undergo rearrangement, including cross-linking, to become irreversible AGEs. Both circulating and tissue proteins as well as lipids and nucleic acids may thus be glycated. Although

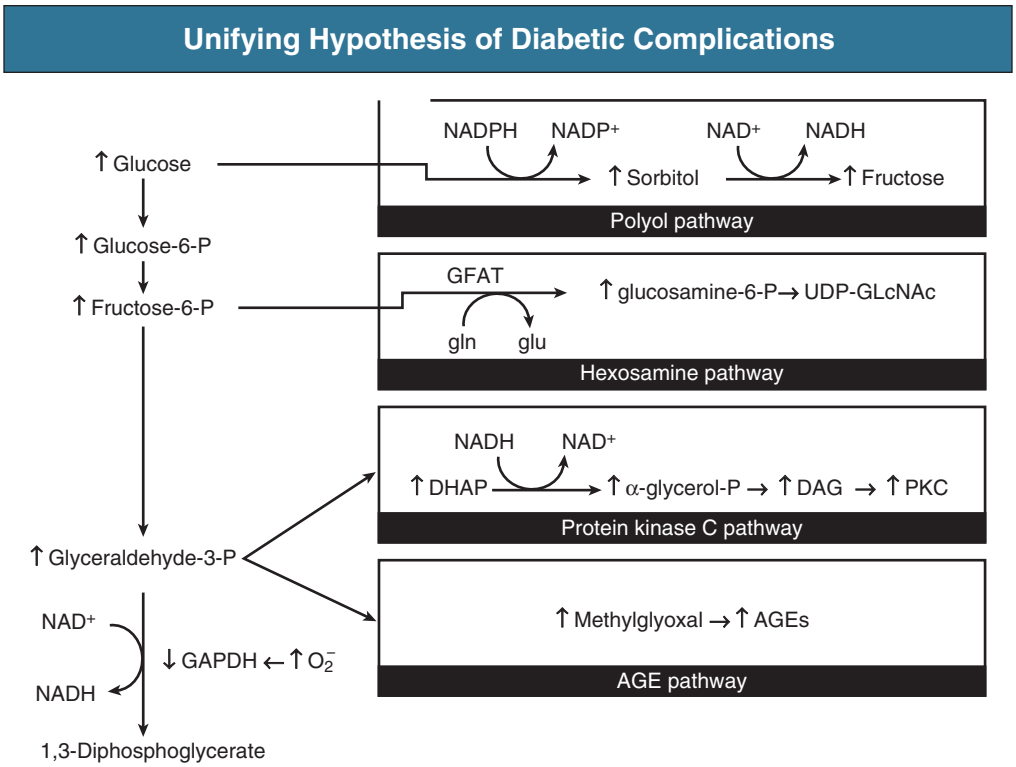

Figure 30-5 Unifying hypothesis of diabetic complications. Mitochondrial overproduction of superoxide activates four major pathways of hyperglycemic damage by inhibiting GAPDH. *DHAP,* Dihydroxyacetone phosphate; *DAG,* diacylglycerine (an activator of protein kinase C, *PKC,* and of triose phosphates to methylglyoxal), the main intracellular advanced glycation end products *(AGEs)* precursor. Increased flux of fructose-6-phosphate to UDP-*N*-acetylglucosamine increases modification of proteins by *O*-linked *N*-acetylglucosamine (GlcNAc) and increased glucose flux through the polyol pathway consumes nicotinamide adenine dinucleotide phosphate *(NADPH)* and depletes glutathione *(GSH). NAD,* Nicotinamide adenine dinucleotide; *UDP,* uridine diphosphate; *GAPDH,* glycerinaldehyde-3-phosphate-dehydrogenase; *GFAT,* glutamine fructose-6-phosphate amidotransferase; *gln,* glutamine; *glu,* glutaminic acid; *PARP,* poly [ADP-ribose] polymerase; *P,* phosphate. *(From reference 26.)*

primarily observed in diabetes, AGEs also accumulate in aging and in renal failure.[27]

The concentration of AGEs is increased in the serum of DN patients. AGEs have also been localized to diabetic glomeruli by immunohistochemistry. AGEs bind to a variety of cell types, including macrophages and mesangial cells, and mediate a variety of cellular actions, including expression of adhesion molecules, cell hypertrophy, ECM synthesis, EMT, and inhibition of NOS. AGEs injected *in vivo* induce albuminuria and glomerulosclerosis.[27] AGEs have profound effects on podocytes, including induction of hypertrophy, followed by apoptosis and suppression of nephrin synthesis. Among several binding sites, the most important is the putative receptor RAGE (receptor for AGE), a pattern recognition receptor. It is present in tubular cells and podocytes. Ang II stimulates upregulation of RAGE on podocytes.[28] This effect is mediated by angiotensin-2 (AT_2) receptors not blocked by sartanes.[28] One of the actions of RAGE is activation of nuclear factor-κB (NF-κB). sRAGE, the soluble extracellular domain of RAGE, acts as a decoy receptor and experimentally ameliorates the renal lesions in diabetes.[27]

Administration of aminoguanidine, an inhibitor of AGE formation, to diabetic animals reduces AGE deposition, mesangial matrix expansion, and albuminuria, but has inconsistent effects on GBM thickening. Preliminary clinical studies suggest beneficial effects on retinopathy, lipids, and proteinuria. The clinical experience with aminoguanidine has been disappointing and riddled with side effects. Newer, more specific agents have been developed that may be more potent blockers of AGE formation. For example, phenacylthiazolium bromide cleaves covalent, AGE-derived protein

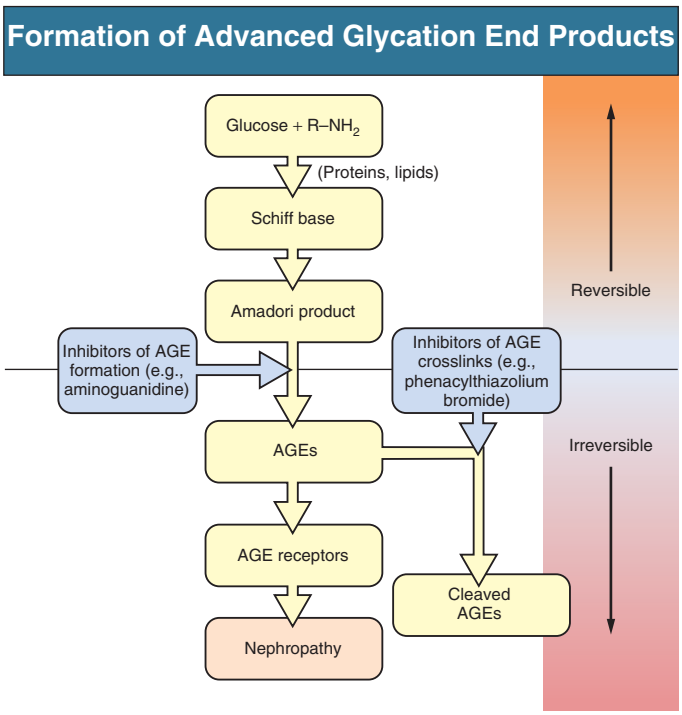

Figure 30-6 Mechanism of formation of advanced glycation end products (AGEs).

cross-links and provides a conceptual basis for the reversal of AGE-mediated tissue damage, which until now has been regarded as irreversible.

Polyol Pathway The polyol pathway involves the conversion of glucose to sorbitol and eventually fructose. The role of polyols in diabetic complications has been assessed with aldose reductase (AR) inhibitors such as sorbinil, tolrestat, and ponalrestat,[12] which have shown promise in preventing diabetic cataracts and improving or stabilizing DN. AR inhibitors also blunt hyperfiltration and have a mild effect on reducing albuminuria in both experimental and human diabetes. Overall, however, the experience with AR inhibitors in DN has been disappointing, and treatment was associated with hypersensitivity reactions and liver function abnormalities. More recently, laboratory studies have focused on blocking fructokinase, which is in the distal polyol pathway, with more promising results. However, fructokinase inhibitors have not yet been administered to humans.

Hexosamine Pathway Although most of the intracellular glucose is metabolized by the glycolytic pathway, some fructose-6-phosphate is diverted into the hexosamine pathway, increasing the concentrations of *N*-acetylglucosamine. This glucosamine modifies certain transcription factors, such as Sp1 activity, by post-translational *O*-linked glycosylation. In turn, Sp1 then leads to enhanced transcription of key mediators, such as TGF-β1 and plasminogen activator inhibitor 1. Glucosamine-mediated modification of the enzyme Akt/PKB reduces expression of endothelial NOS and promotes apoptosis of cells.

Adenosine Monophosphate–Activated Protein Kinase Pathway Recent studies suggest an alternative pathway that may also contribute to DN. The energy-sensing enzyme, 5′-adenosine monophosphate (AMP)–activated protein kinase (AMPK), appears to play an important role in many aspects of diabetic and obesity-related kidney disease.[29-31] Inhibition of AMPK in caloric-excess states has been linked to inflammation (NF-κB, NADPH oxidase, MCP-1 stimulation), vascular dysfunction (eNOS inhibition), stimulation of hypertrophy (mTOR activation), and profibrotic pathways (TGF-β signaling).[29-31]

Renin-Angiotensin-Aldosterone System and Diabetic Nephropathy

Studies in patients with type 1 and type 2 diabetes as well as in various animal models of diabetes suggest that ACE inhibitors or angiotensin receptor blockers (ARBs) retard progression of DN (see Chapter 31). Although plasma renin activity is low in DN, it is inappropriate in relation to increased extracellular volume and exchangeable sodium, suggesting activation of the RAS.[32] This has suggested that activation of the intrarenal RAS may play a critical role in the development of DN. In experimental diabetes, sites of local RAS activation have been identified in glomeruli (podocytes, mesangial/endothelial cells), renal vessels, and tubular cells.[32] High glucose concentration and AGEs stimulate angiotensinogen and renin expression in various renal cells, mainly through reactive oxygen species.[32] Proteinuria further activates the local RAS of tubular cells. A new mechanism of how high levels of glucose directly trigger the release of renin involves local accumulation of succinate and activation of the kidney-specific G protein–coupled metabolic receptor GPR91.[33] Adipocytes are another source of Ang II in obese patients.

In patients with DN, prorenin levels are elevated, possibly reflecting increased synthesis. Specific prorenin and renin receptors have been demonstrated in the kidney; ligand binding causes nonenzymatic activation of prorenin to yield renin activity and locally produced Ang II.[34] Moreover, prorenin as well as renin can directly bind to specific receptors on mesangial and tubular cells and induce proinflammatory and profibrogenic cytokines.[11] As a further complexity, in diabetes, chymase is strikingly expressed in the kidney; this enzyme generates Ang II but is not inhibited by ACE inhibitors.[35] On the other hand, the enzyme ACE2 generates peptides such as angiotensin 1-7, which antagonize the effects of Ang II.[35] ACE2 activity is reduced in DN, leading to a decrease in angiotensin 1-7 and further amplification of the effects of Ang II. Interestingly, 1,25-dihydroxyvitamin D_3 suppresses the RAS. Thus, in diabetic patients with advancing chronic kidney disease (CKD), decreasing calcitriol production further activates the RAS.

Ang II has many nonhemodynamic effects and mediates cell proliferation, hypertrophy, ECM expansion, and cytokine (TGF-β, VEGF) synthesis.[32] Therefore, ACE inhibitors and ARBs presumably act by hemodynamic as well as by nonhemodynamic actions.

Aldosterone accelerates progression in renal damage models independently of Ang II. In DN, aldosterone escape has been linked to progression of proteinuria (see Chapter 31). Aldosterone synthesis is stimulated in DN, and this steroid hormone stimulates the synthesis of other proinflammatory and profibrogenic cytokines (MCP-1, TGF-β).[12,35]

Other vasoactive agents may also be involved in the pathogenesis of DN, including alterations in systemic or intrarenal production of endothelin, NO, the kallikrein-kinin system, and natriuretic peptides.

Uric Acid and Fructose

As discussed earlier, there is also increasing evidence that uric acid may have a role in the pathogenesis of both diabetes and DN. Several studies have shown that an elevated uric acid level can predict the development of DN as well as diabetic CKD, and pilot studies have reported an early benefit of allopurinol therapy on diabetic albuminuria.[36]

Uric acid is generated during the metabolism of fructose, when it appears to induce oxidative stress in mitochondria. In addition to dietary sources of fructose from added sugars, there is increasing evidence that in diabetic patients, fructose is generated in the kidney, where it is metabolized to generate uric acid and oxidative stress that may mediate renal injury. Thus, both dietary fructose and endogenous production of fructose may be involved in the development of diabetes and its complications.[37]

EPIDEMIOLOGY

In most Western countries, diabetic nephropathy has become the leading cause of ESRD. According to the U.S. Renal Data System (www.USRDS.org), in 2006, DN was the most frequent primary diagnosis, with 159 cases per 1 million population per year. The proportion of diabetics among patients with ESRD varies considerably between countries but had consistently been on the rise in all countries until recently, when the incidence figures have stabilized. In patients starting renal replacement therapy (RRT), we found diabetes in 49%, but classic features of DN were observed in only 60% of these diabetic patients (i.e., normal kidney size despite ESRD; proteinuria > 1 g/24 h with or without retinopathy); 13% had an atypical presentation with ischemic nephropathy, and in 27%, a known primary renal disease coexisted with diabetes, including polycystic kidney disease (PKD), analgesic nephropathy, and glomerulonephritis (GN).[38] An important mode of presentation has become irreversible acute kidney injury (AKI), for example, after administration of radiocontrast media, cardiac events, and

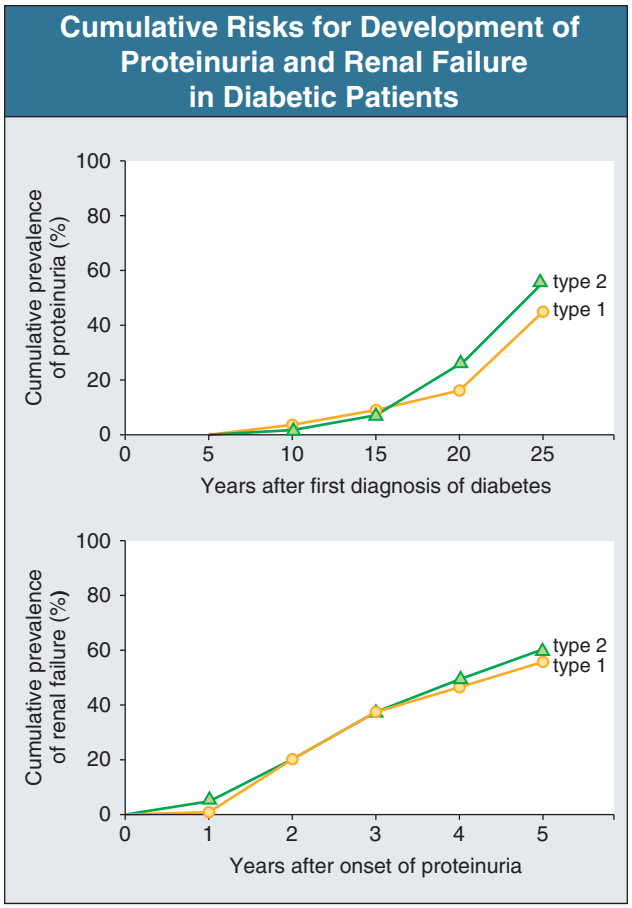

Figure 30-7 Cumulative risks for development of proteinuria and progression to renal failure in patients with type 1 and type 2 diabetes. *(From reference 38.)*

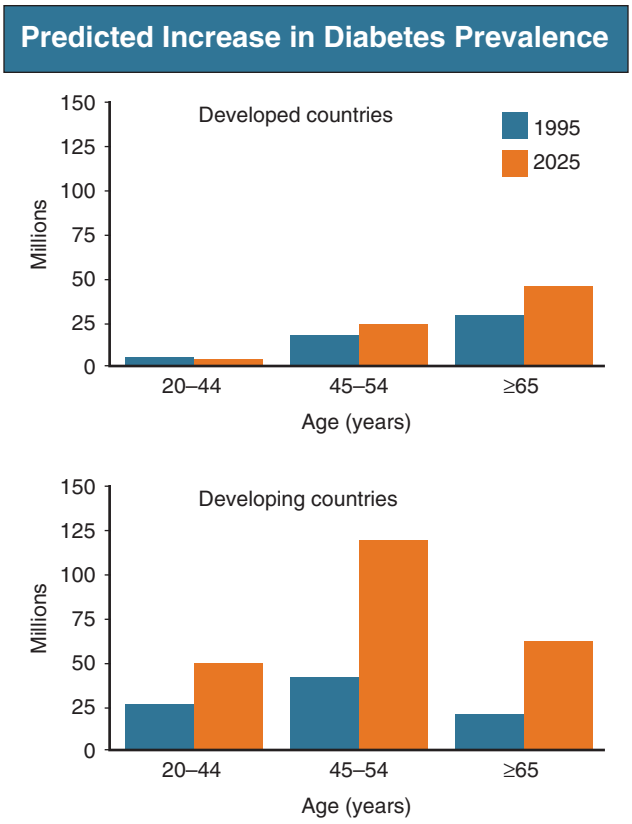

Figure 30-8 Predicted increase in diabetes prevalence. Number of patients by age group, region (developing versus developed countries), and year. *(From reference 42.)*

septicemia. Many patients also lose the clinical manifestations of overt diabetes (e.g., hyperglycemia) because of CKD-associated weight loss, impaired renal gluconeogenesis, or increased insulin half-life in CKD. This may explain why at least 5% of patients develop apparent *de novo* diabetes after the start of dialysis.

The great majority (in our experience >90%) of patients entering ESRD with diabetes as a comorbid condition have type 2 diabetes. In the past, few type 2 diabetic patients had a chance to live long enough to develop nephropathy.[38] Currently, with better treatment of hypertension and of coronary heart disease, an increasing proportion of type 2 diabetic patients survive and thus are exposed to the risk for development of DN and ESRD. The proportion of type 1 and type 2 diabetic patients who develop proteinuria and elevated serum creatinine concentration is related to the duration of diabetes. As shown in Figure 30-7, the cumulative risks for development of proteinuria and progression are practically superimposable on type 1 and type 2 diabetes.[38] Diabetes-related mortality (cardiovascular, related infections) amounted to almost 3 million, equivalent to 5% of worldwide all-cause mortality in 2000. There is a major increase in the prevalence of type 2 diabetes in the developing world compared with the developed world (Fig. 30-8). For example, in Asia, high mortality from diabetes is most prominent in patients age 50 to 60 years, which translates to a reduction in life expectancy of more than 1 decade. Up to 60% of Asian diabetic patients have microalbuminuria or macroalbuminuria, compared with 30% to 40% reported in Western diabetic populations in cross-sectional surveys.[39] Also, the incidence of diabetes-associated ESRD varies in Western countries, with very high numbers of patients in the United States. The reasons are complex and include genetic variability,[40] differences in lifestyle, and different national health care systems, with variable access to screening programs and early management for diabetes.[39] A targeted screening program may help in the early identification of individuals at high risk for DN.[41,42]

CLINICAL MANIFESTATIONS AND NATURAL HISTORY

Diabetic nephropathy is part of a generalized microvascular syndrome that is accompanied by macrovascular disease.

Obesity, Metabolic Syndrome, and Renal Disease

The metabolic syndrome—defined as having at least three of the five parameters of increased waist circumference, elevated triglycerides (TGs), decreased high-density lipoproteins (HDLs), elevated blood pressure (BP), and elevated fasting blood glucose concentration—is increasingly being recognized not only as a major contributor to cardiovascular diseases but also as a negative influence on renal function. The strong association of metabolic syndrome with kidney disease has been appreciated only relatively recently.[43,44] Obesity is often defined as body mass index (BMI) greater than 30, although different values define obesity in other countries (e.g. India, Japan). Obese individuals have large kidneys and glomerulomegaly, with increased renal blood flow, increased filtration fraction, and glomerular hyperfiltration.[45] Obese patients have microalbuminuria even in the absence of hypertension. The resemblance of obesity-related kidney disease to the early features of diabetic kidney disease

is striking. In addition, sleep apnea, which is common in obese individuals, leading to hypoxic episodes, may also contribute to kidney impairment. Visceral adipocytes are a potent source of deleterious factors[46] and could have an impact on renal function (Ang II, leptin, tumor necrosis factor α [TNF-α]). Thus, renal changes may occur years before the manifestation of type 2 diabetes during obesity and the development of the metabolic syndrome.

Evolution of Diabetic Nephropathy

One of the earliest changes of renal function in diabetes is an increase in GFR, or hyperfiltration, which is observed in patients with type 1 as well as many with type 2 diabetes and is accompanied by an increase in renal size. The next observable change is the development of albuminuria. Somewhat arbitrarily, albumin excretion rates between 0 and 30 mg/day are called *normo*albuminuria, and between 30 and 300 mg/day, *micro*albuminuria. Diabetic patients with persistent microalbuminuria are at greatly increased risk for development of overt DN, which is heralded by the development of proteinuria (albuminuria > 300 mg/day), on average 15 years after disease onset, with progressive increase in proteinuria and BP as well as development of progressive CKD.

Mogensen[47] proposed a scheme of the different stages of DN that is valid in type 1 diabetes but less reliable in type 2 diabetes (Fig. 30-9). In the later, CKD may occur in the absence of microalbuminuria, possibly as a result of macrovascular disease.

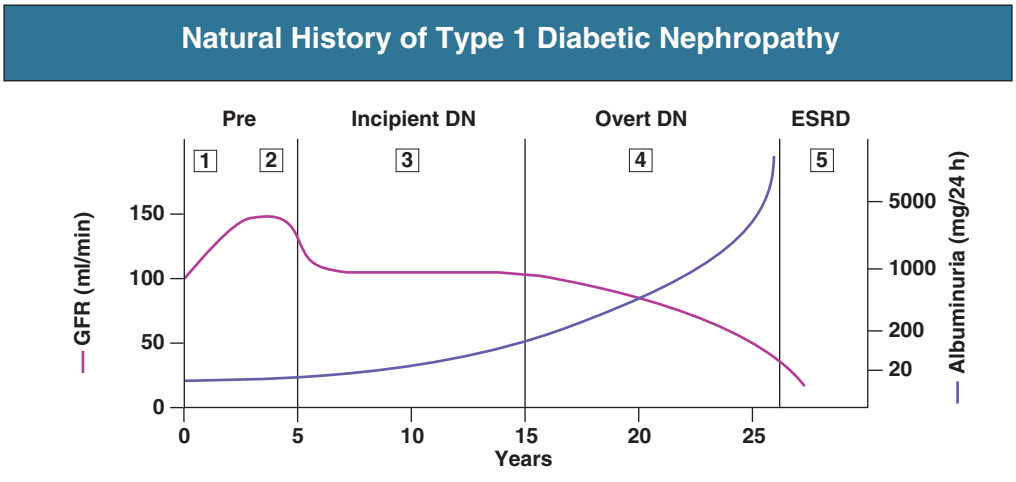
Hypertension and Diabetic Nephropathy

If hypertension develops in a patient with type 1 diabetes, it is almost always caused by renal parenchymal disease. At present, however, type 1 diabetic patients survive longer, and a minority of elderly type 1 patients develop primary hypertension with no evidence of nephropathy. In patients with type 2 diabetes, hypertension often precedes the onset of diabetes by many years and decades as a feature of the metabolic syndrome. At diagnosis of type 2 diabetes, an abnormal BP and an abnormal circadian BP profile are found in 80% of patients. Prediabetic hypertension increases the risk of onset and progression of DN. If patients with type 2 diabetes ultimately develop nephropathy, the prevalence of hypertension further increases, with greater BP elevation, but the relationship between hypertension and nephropathy is generally much less than in type 1 diabetes. The pathogenesis of hypertension in type 2 diabetes is complex and involves activation of the RAS, direct sympathetic nerve activation, and macrovascular changes.[48] Furthermore, there is evidence that genetic factors defining primary hypertension as well as diabetes are clustered (Fig. 30-10).

In DN, it has been well documented that the nocturnal BP decrease is frequently attenuated, or nondipping, which even precedes the onset of microalbuminuria.[48] Furthermore, the BP response to exercise tends to be exaggerated, even when the BP is normal under basal conditions. Diminished compliance of the central arteries with stiffening of the aorta increases the peak systolic pressure and decreases the diastolic pressure, resulting in increased BP amplitude. The great BP amplitude explains why isolated systolic hypertension is so common in patients with type 2 diabetes.[49] Low diastolic pressure increases the risk of coronary events because coronary perfusion occurs during diastole only.[50] Ambulatory pulse pressure and impaired nocturnal BP decline are independent predictors of nephropathy progression in type 2 diabetic patients (Fig. 30-11).

Associated Extrarenal Microvascular and Macrovascular Complications

Diabetic retinopathy is present in virtually all patients with type 1 diabetes and nephropathy. In contrast, only 50% to 60% of proteinuric patients with type 2 diabetes have retinopathy.[51,52] Consequently, the absence of retinopathy does not exclude the diagnosis of DN in patients with type 2 diabetes.[52] The risk of blindness because of



Stage	Pre	Incipient	Overt
Functional	GFR ↑ (25%–50%)	Microalbuminuria, hypertension	Proteinuria, nephrotic syndrome, GFR ↓
Structural	Renal hypertrophy	Mesangial expansion, GBM thickening, arteriolar hyalinosis	Mesangial nodules (Kimmelstiel-Wilson lesions) Tubulointerstitial fibrosis

Figure 30-9 Natural history of type 1 diabetic nephropathy (DN). Functional and structural manifestations of DN. Numbers *1* through *5* indicate the stages of nephropathy defined by Mogensen; *ESRD,* end-stage renal disease; *GBM,* glomerular basement membrane; *GFR,* glomerular filtration rate. *(From reference 47.)*

severe proliferative retinopathy is substantially higher in diabetic patients with nephropathy, but it has become rare today with better ophthalmologic care. In patients with DN, retinopathy tends to progress more rapidly so that yearly or half-yearly ophthalmologic examination is indicated.

Many patients with DN also have polyneuropathy. Sensory polyneuropathy is an important aspect of the "diabetic foot." There is a strong inverse correlation between the incidence of diabetic foot and renal function[53] (Fig. 30-12). Motor and sensory neuropathy may cause areflexia, wasting, and sensory disturbances such as paresthesia, anesthesia, and impaired perception of vibration and pain, but the most vexing clinical problems are the results of autonomic polyneuropathy. Because cardiac innervation is defective, pain and angina are frequently absent when the patient has coronary heart disease and myocardial infarction. Further consequences of autonomic polyneuropathy are gastroparesis (delayed emptying of gastric contents into the gut) and diarrhea or constipation (often alternating with each other). These problems are caused by impaired intestinal innervation, often complicated by intestinal bacterial overgrowth because of stasis. Also, urogenital abnormalities are common, including erectile impotence and detrusor paresis with delayed and incomplete emptying of the bladder.

The major macrovascular complications associated with DN are stroke, coronary heart disease, and peripheral vascular disease.[54,55] These complications occur up to five times more frequently in diabetic patients with than without DN.

Survival in Patients with Diabetic Nephropathy

The presence of DN greatly increases mortality in patients with both type 1 and type 2 diabetes. Compared with the background population, mortality in patients with type 1 diabetes and no proteinuria is elevated only twofold to threefold; in contrast, it is increased 20- to 200-fold in patients with proteinuria.[56,57]

The major increase in risk starts when microalbuminuria has developed (Fig. 30-13). An increased risk is found even in the upper-normal range of albuminuria (Fig. 30-14). Urinary albumin excretion is a good predictor of cardiovascular (CV) events the first 5 years after measurement, but repeating the measurement several years later also detects progression, which is also associated with increased CV risk.[57] The presence of albuminuria likely reflects generalized endothelial cell dysfunction, thus increasing the risk of atherosclerosis.[57] Albuminuria is also associated with many CV risk factors, such as elevated BP, dyslipoproteinemia, increased platelet aggregation, and increased C-reactive protein concentration. An added risk factor is presumably the association with autonomic polyneuropathy (as found in diabetic foot syndrome[58]), which is a predictor of death from myocardial infarction or arrhythmia.

RENAL PATHOLOGY

After the onset of diabetes, kidney weight increases by an average of 15%. Renal size remains increased until overt nephropathy is established. Most patients with type 1 diabetes have a sustained increase in glomerular volume and glomerular capillary luminal volume. Although atrophic ischemic glomeruli are present, some of the nonfunctioning glomeruli fill up with material staining with periodic acid–Schiff (PAS), thus preserving their increased dimensions. These changes are accompanied by hypertrophy of the interstitium.[59]

In patients with diabetes of more than 10 years' duration, whether or not nephropathy is present, GBM thickening up to three times the

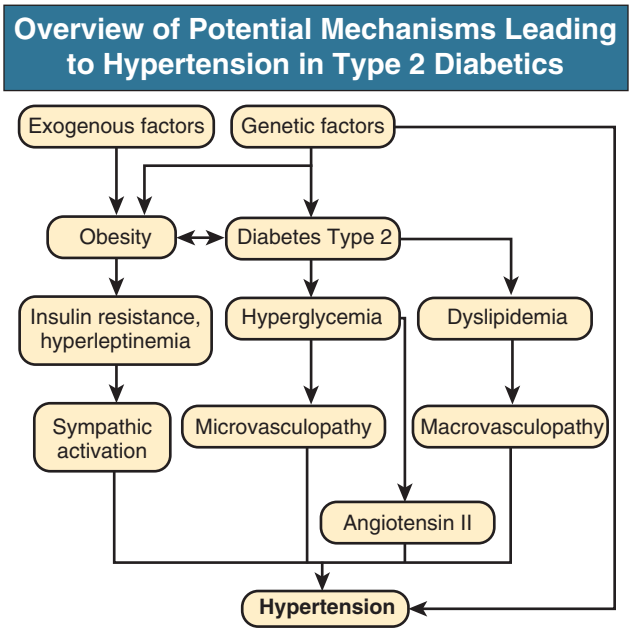


Figure 30-10 Overview of potential mechanisms leading to hypertension in type 2 diabetic patients. Genetic susceptibility factors for primary hypertension and diabetes may be clustered so that an individual patient may have a higher incidence of both diseases. Obesity and the metabolic syndrome lead to insulin resistance and hyperleptinemia associated with sympathic nerve activation. Hyperglycemia directly activates the renin-angiotensin system and, in addition, through renal microvasculopathy stimulates development of hypertension. Dyslipidemia leads through macrovasculopathic alteration to stiffness of vessels and hypertension.

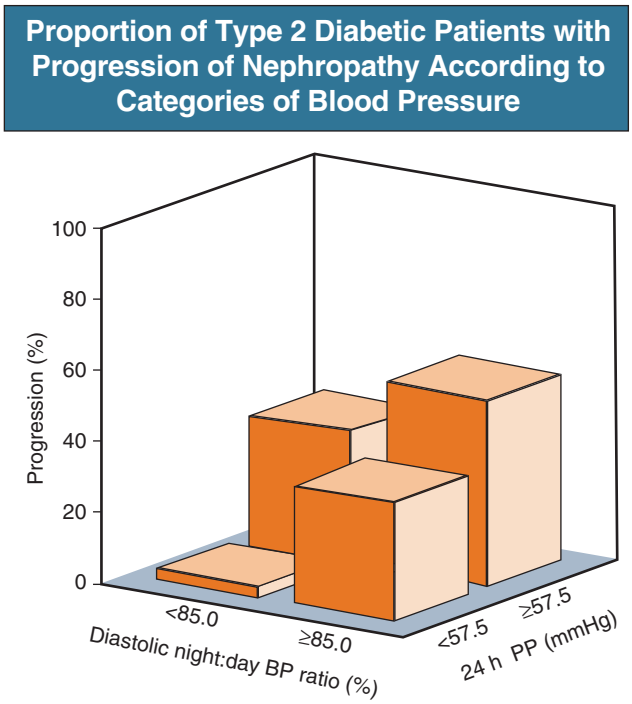

Figure 30-11 Proportion of type 2 diabetic patients with progression of nephropathy according to categories of blood pressure. Progression risk according to categories of night : day diastolic BP (median value < 85% or ≥ 85%), and 24 hour ambulatory pulse pressure *(PP)* (median value < 57.5% or ≥ 57.5%). *(From reference 54.)*

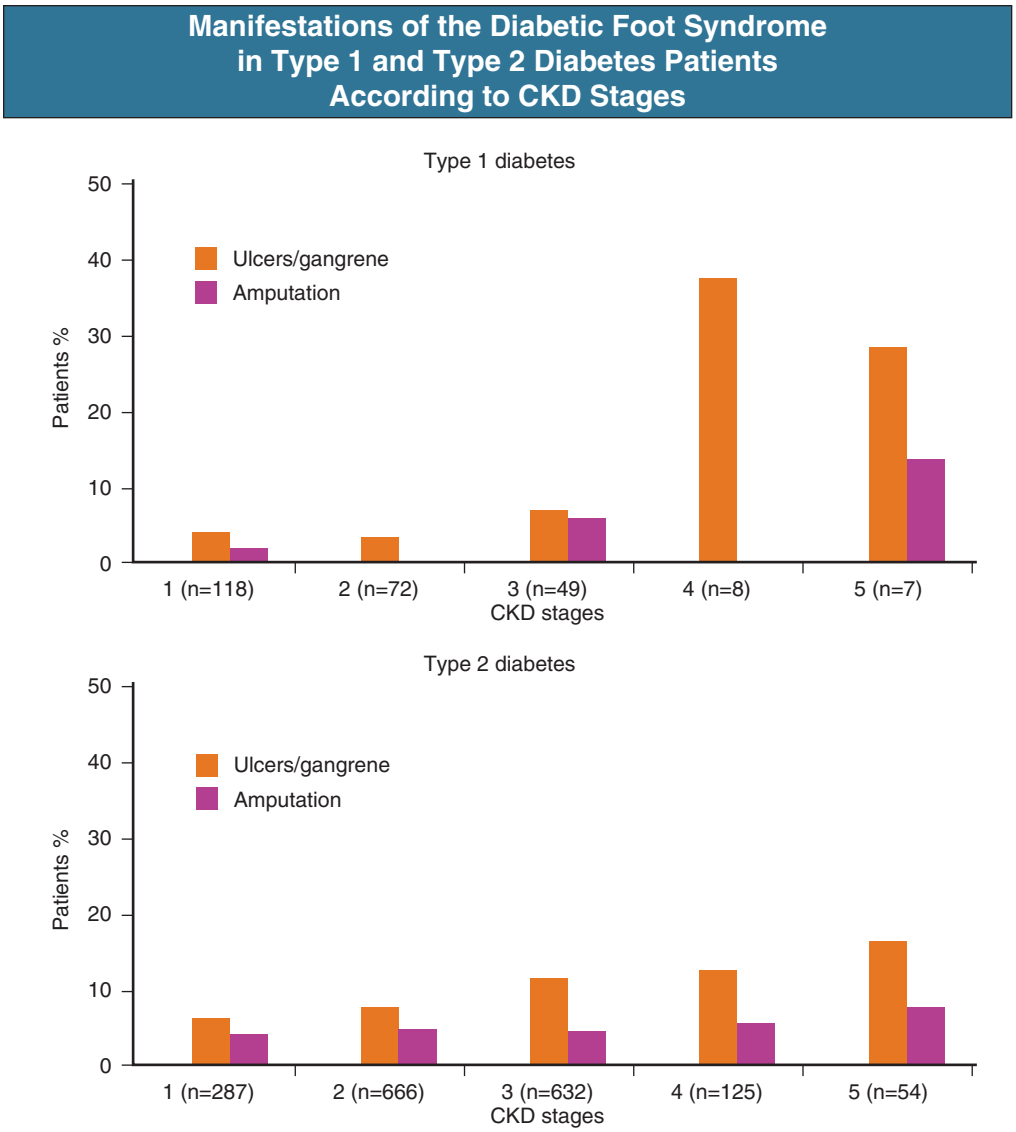

Figure 30-12 Association between manifestations of the DFS in type 1 and 2 diabetes patients classified according to CKD stages. Only patients with albuminuria were studied. All patients in a chronic kidney disease *(CKD)* stage were considered 100%. Diabetic foot syndrome *(DFS)* increases with higher CKD stages. *(From reference 58.)*

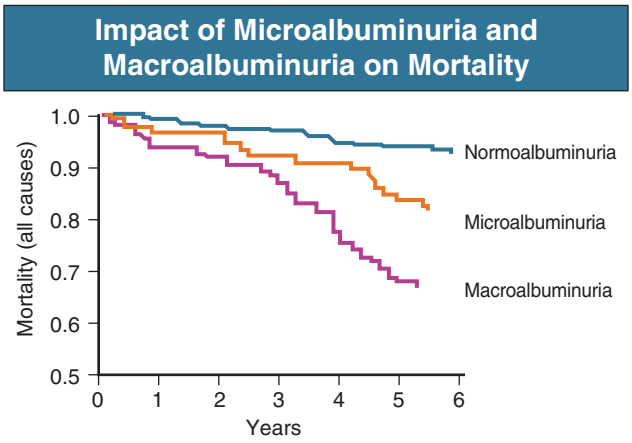

Figure 30-13 Impact of microalbuminuria and macroalbuminuria on mortality. The impact of microalbuminuria and macroalbuminuria on mortality was evaluated prospectively in 328 Caucasian patients with non–insulin-dependent diabetes mellitus (DM) observed for 5 years. Microalbuminuria and macroalbuminuria led to a significant increase in total mortality compared with patients who remained normoalbuminuric. *(From reference 56.)*

normal range of 270 to 359 nm is an almost universal feature (Fig. 30-15). In advancing DN, there is a consistent correlation between GBM thickness and fractional mesangial volumes with the urinary albumin excretion rate.

Nodular glomerular intercapillary lesions in advanced DN were described in 1936 by Kimmelstiel and Wilson (Fig. 30-16, *C*). The nodules are located in the central regions of peripheral glomerular lobules as well-demarcated eosinophilic and PAS-positive masses (Fig. 30-16, *C* and *D*). When they are not acellular, nodules contain pyknotic nuclei. It is suggested that nodules result from microaneurysmal dilation of the associated capillary followed by mesangiolysis and laminar organization of the mesangial debris with lysis of the center of the lobule. Foam cells often surround the nodules. These appearances are pathognomonic for diabetes but are reported in only 10% to 50% of biopsy specimens in both type 1 and type 2 diabetes. Nodules are also seen in membranoproliferative glomerulonephritis (MPGN) (see Chapter 21), in amyloidosis and light-chain deposition disease (see Chapter 27), and rarely, without diabetes (see Chapter 28); specific stains and immunofluorescence findings, respectively, will clarify the diagnosis. When no nodules are seen, specific staining should be used to exclude amyloid.

The diffuse glomerular lesion occurs more often than the nodular lesion, with an incidence of more than 90% in patients with type 1 diabetes longer than 10 years and an incidence of 25% to 50% in patients with type 2 diabetes. Diffuse glomerular lesions consist of an increase of mesangial matrix extending to involve the capillary loops (Fig. 30-16, *B*). In contrast to nodular lesions, which are of little functional significance, the degree of diffuse glomerulosclerosis correlates with the clinical manifestations of worsening renal function. Accumulation of mesangial matrix is the feature most consistently associated with progression.[60] In more severe disease, the capillary wall thickening and mesangial expansion lead to capillary narrowing (see Fig. 30-15, *B*) and hyalinization, with accompanying periglomerular fibrosis.

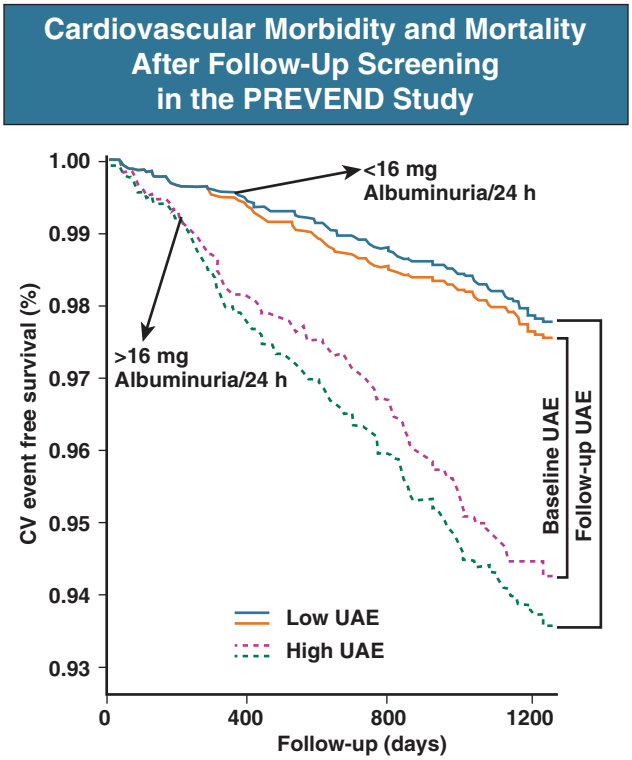

Figure 30-14 Event-free survival for cardiovascular (CV) morbidity and mortality after follow-up screening in the PREVEND study. Individuals are stratified according to the presence of a high or low urinary albumin excretion *(UAE)*. High and low UAE are defined by either the UAE measurement from the baseline screening *(orange and violet lines)* of approximately 4.2 years before follow-up screening or the repeated UAE measurement at time of the follow-up screening *(blue and green lines)*. To allow comparison, the survival curves for the 6800 individuals with either the baseline or follow-up measurement of UAE are plotted in the same graph. A high UAE *(dashed lines)* is defined as a UAE ≥ 16.2 mg/24 h, being the 75th percentile of UAE with use of the UAE measurement of the baseline screening. *(From reference 57.)*

Podocytes are involved early in the course of DN in type 1 and type 2 diabetes mellitus (Fig. 30-17), and an increase in foot process width is already observed in microalbuminuric type 1 diabetics.[61,62] Longitudinal studies in DN demonstrated a reduction in podocyte number that closely correlated with proteinuria.[61] Renal biopsy specimens from Pima Indians with type 2 diabetes showed a broadening in podocyte foot processes and a concomitant reduction in the number of podocytes per glomerulus.[63]

Arteriolar lesions are prominent in diabetes. Hyaline material progressively replaces the entire wall structure and involves both the afferent and efferent vessels, which is highly specific for diabetes.

A new classification of DN was introduced in 2007. This classification considers not only glomerular changes (Fig. 30-18), but also pathologic alterations of the tubulointerstitium and the vasculature.[64] Immunohistology is usually negative, but linear IgG can be seen occasionally because of passive trapping in the GBM (Fig. 30-19).

Tubulointerstitial leukocyte infiltration is often found in DN. Tubulointerstitial fibrosis and tubular atrophy may be the best pathologic correlates for the progressive decline in GFR. Tubulointerstitial fibrosis and renal arteriosclerosis are more prevalent in type 2 than type 1 diabetes. In fact, renal structure is heterogeneous in type 2 diabetic patients; only a subset of type 2 patients have typical diabetic glomerulopathy, whereas a substantial proportion have more advanced tubulointerstitial and vascular rather than glomerular lesions, or they have normal or near-normal renal structure.[64] Some patients with type 2 diabetes have a kidney appearance more suggestive of glomerular ischemia or tubulointerstitial disease.

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

The diagnosis of DN is based on the detection of proteinuria. In addition, most patients also have hypertension and retinopathy. The

main diagnostic procedures in the patient with suspected DN include the following:

- Measurement of urinary albumin or protein
- Measurement of serum creatinine concentration and estimation of GFR
- Measurement of blood pressure
- Ophthalmologic examination

Measurement of Albuminuria or Proteinuria

Microalbuminuria is arbitrarily defined as the excretion of 30 to 300 mg/24 h of albumin in at least two of three consecutive nonketotic sterile urine samples (Table 30-1). There is substantial

Urinary Albumin Excretion Rate

	UAER	
Condition	***24 hr (mg/day)***	***Overnight (µg/min)***
Normoalbuminuria	<30	<20
Microalbuminuria	30-300	20-200
Overt nephropathy	>300	>200

Table 30-1 Urinary albumin excretion rate (UAER). Levels of 24 hour and overnight UAE are diagnostic for microalbuminuria and overt diabetic nephropathy.

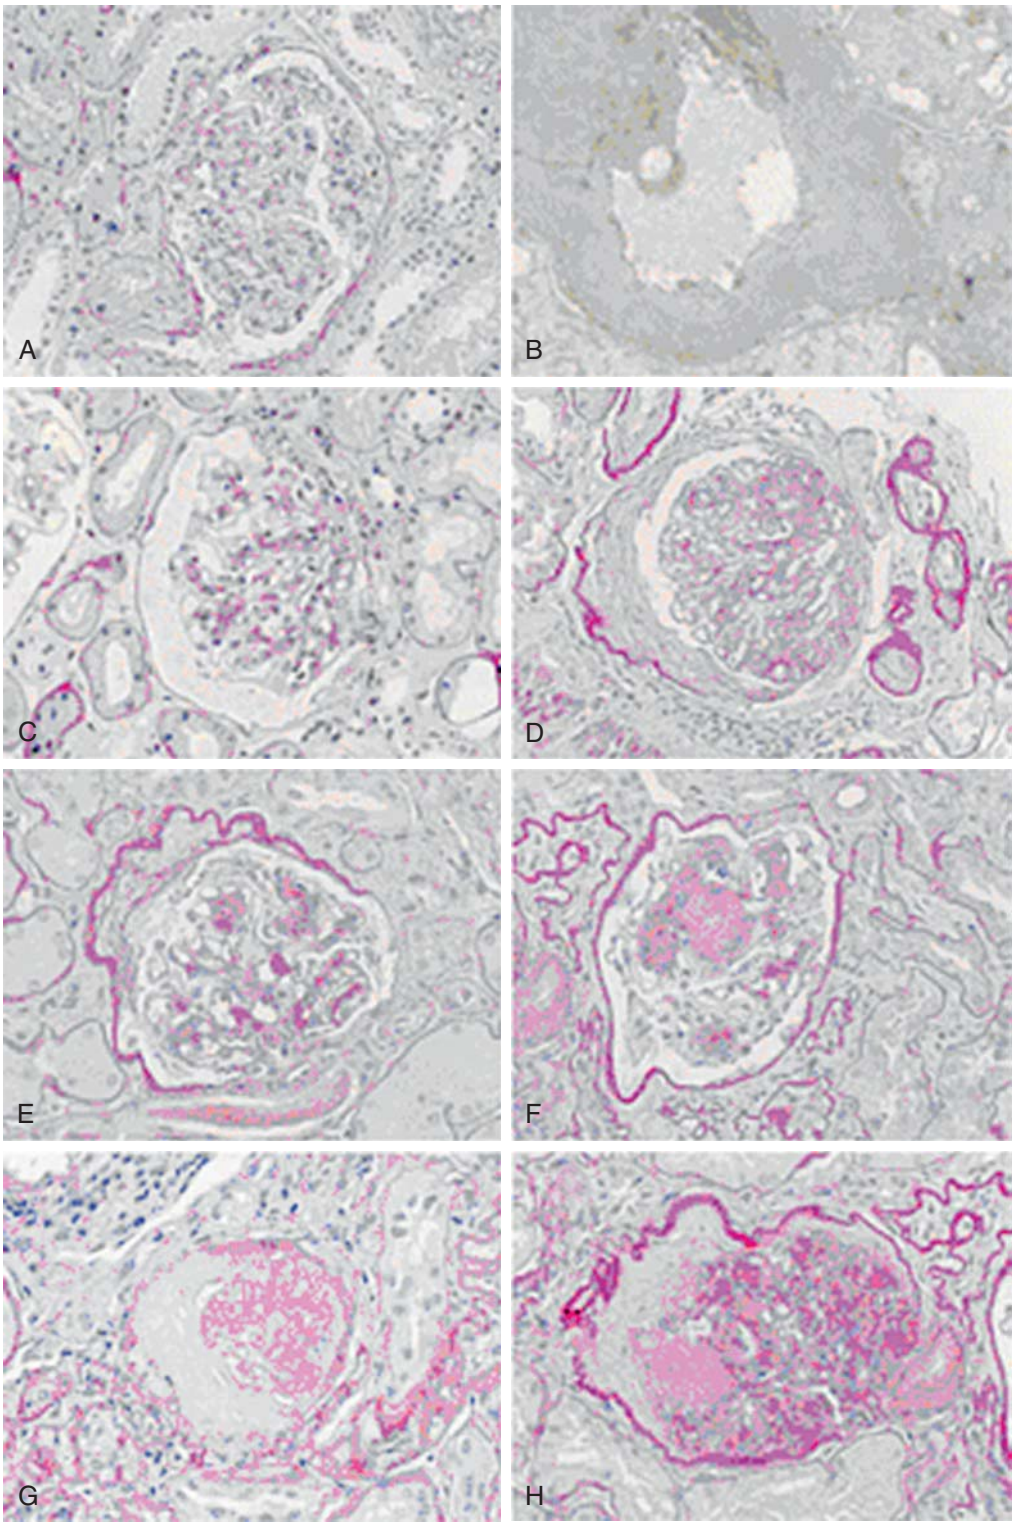

Figure 30-18 Pathologic classification of diabetic nephropathy (DN; according to Tervaert et al). Representative examples of the morphologic lesions in DN. **A,** Glomerulus showing only mild ischemic changes, with splitting of Bowman capsule. No clear mesangial alteration. **B,** Electron micrograph of this glomerulus: the mean width of the GBM was 671 nm (mean taken over 55 random measurements). Electron microscopy provides the evidence for classifying the biopsy with only mild light microscopy changes into class I**. C** and **D,** Class II glomeruli with mild and moderate mesangial expansion, respectively. In **C**, the mesangial expansion does not exceed the mean area of a capillary lumen (IIa), whereas in **D,** it does (IIb). **E** and **F,** A class III Kimmelstiel-Wilson lesion is seen in **F.** The lesion in **E** is not a convincing Kimmelstiel-Wilson lesion; therefore, on the basis of the findings in this glomerulus, the finding is consistent with class IIb. For the purpose of the classification, at least one convincing Kimmelstiel-Wilson (as in **F**) needs to be present. **H,** Signs of class IV DN consist of hyalinosis of the glomerular vascular pole and a remnant of a Kimmelstiel-Wilson lesion on the opposite site of the pole. **G,** Example of glomerulosclerosis that does not reveal its cause (glomerulus from same biopsy as **H**). For the purpose of the classification, signs of DN should be histopathologically or clinically present to classify a biopsy with global glomerulosclerosis in more than 50% of glomeruli as class IV. *(From reference 64.)*

individual day-to-day variation in albumin excretion (coefficient of variation, 30% to 50%) and also between day and night collections (Fig. 30-20). Even in the upper quantiles of so-called normoalbuminuria, however, the risk of progression and of CV events is definitely elevated. At concentration of 30 to 300 mg/24 h, albumin is normally not detected by nonspecific tests for protein (e.g., Biuret reaction). Albumin can be detected, however, by use of specific techniques such as dipstick, enzyme-linked immunosorbent assay, nephelometry, and radioimmunoassay. Instead of difficult-to-obtain 24-hour urine collections, the albumin concentration can be determined in spot urine or, better, first-void morning urine samples. The normal range is <20 mcg/min or <20 mcg/ml.

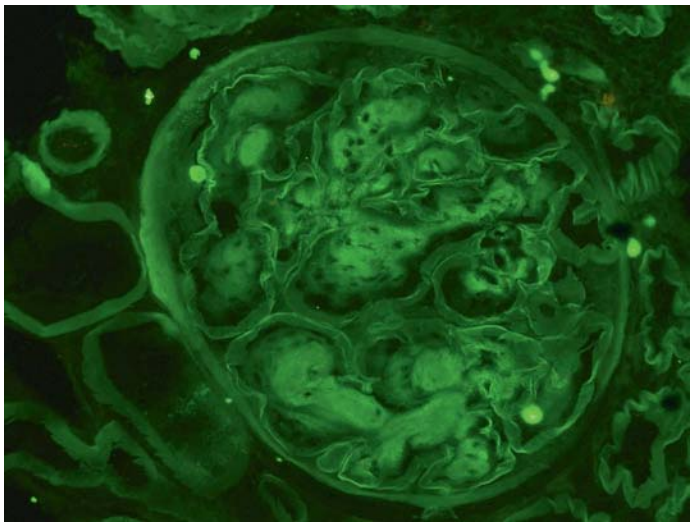

Figure 30-19 Immunofluorescence for glomerular IgG in diabetic nephropathy. Faint staining of the glomerular basement membrane for IgG results from passive trapping of IgG in the expanded GBM. *(Courtesy Prof. Peter Furness, Leicester, UK.)*

The detection of urinary albumin is a specific indicator of DN only if confounding factors such as fever, physical exercise, urinary tract infection, nondiabetic renal disease, hematuria from other causes, heart failure, uncontrolled hypertension, and uncontrolled hyperglycemia have been excluded.[65,66]

The main advantage of searching for microalbuminuria early in the course of diabetes is that it predicts a high renal and CV risk and thus allows targeted intervention. The American Diabetes Association (www.diabetes.org) and other societies recommend annual screening of all diabetic patients.

By definition, there is clinically overt DN (macroalbuminuria) if the rate of albumin excretion exceeds 300 mg/day. At this point, serum proteins other than albumin are usually excreted in the urine as well (nonselective proteinuria).

Although there are few guidelines regarding repeated measures of albuminuria or proteinuria after a diagnosis of diabetic kidney disease has been established, it is likely useful to repeat measures of albumin-creatinine ratio or protein-creatinine ratio annually to determine if there is progression of disease.[66]

Measurement of Blood Pressure

When measuring the BP in a diabetic patient, the following issues should be taken into account:

- In overweight patients with type 2 diabetes, the size of the cuff has to be adapted to the upper arm circumference. When this exceeds 32 cm, cuffs of 18-cm width are indicated.
- Patients with severe autonomic neuropathy tend to develop orthostatic hypotension, defined as a decrease of systolic BP by more than 20 mm Hg in the upright position. It is therefore advisable to measure BP after being in the upright position for a defined period (e.g., 30 minutes). However, such an approach may not always be feasible in a primary care setting.
- The circadian BP profile tends to be abnormal in early stages, and even a paradoxical increase in the nighttime BP is not rare.

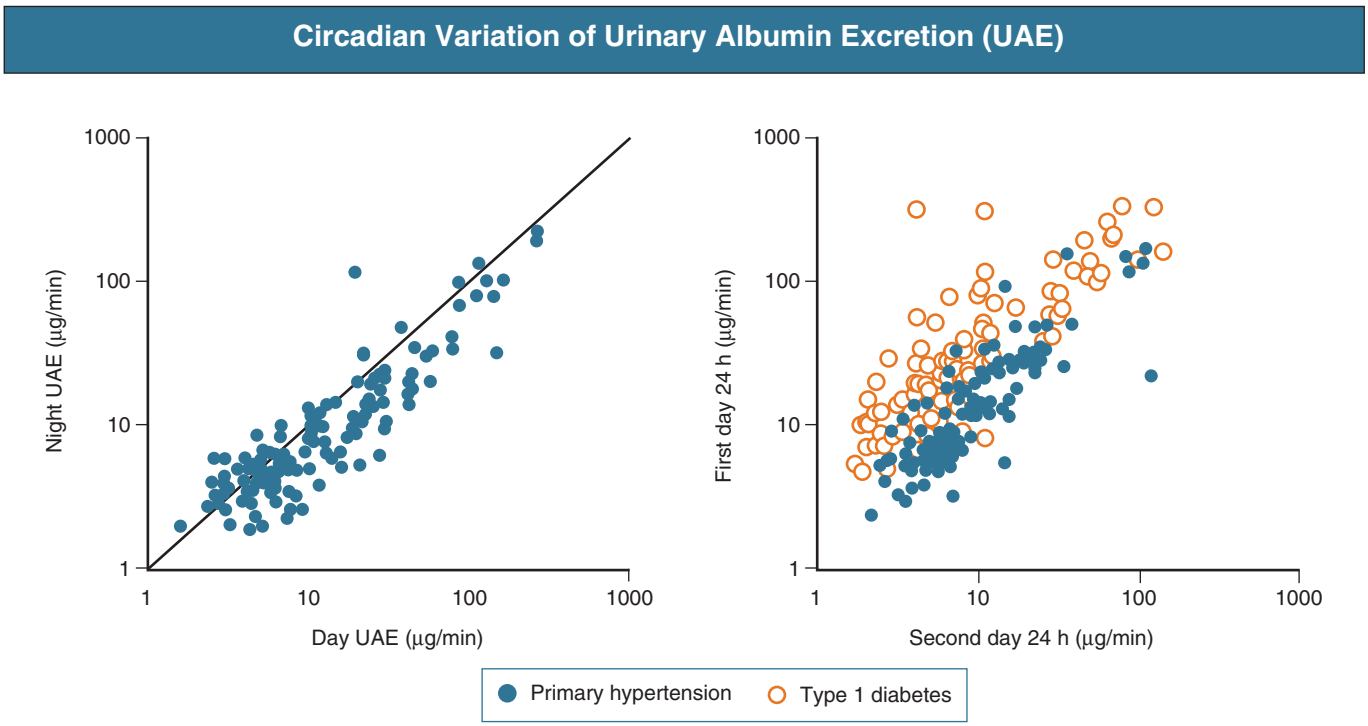

Figure 30-20 Circadian variation of urinary albumin excretion (UAE). UAE is lower in resting conditions at night than during daytime activity. Relationship between UAE assessed on two different days 1 week apart in patients with type 1 diabetes *(open circles)* and primary hypertension *(closed circles)*. There is substantial individual day-to-day variation of albumin excretion and also between day and night collections. *(From reference 66.)*

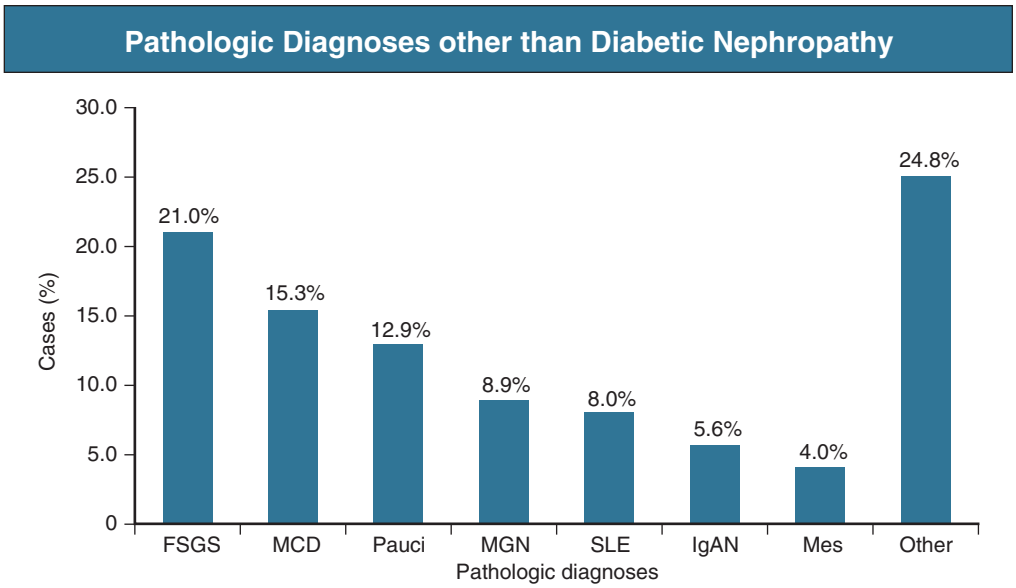

Figure 30-21 Pathologic diagnoses other than diabetic nephropathy are found in more than half of patients with type 2 diabetes with proteinuria. A total of 233 patients were studied; 53.2% (124 patients) had a diagnosis of nondiabetic renal disease; *FSGS,* focal segmental glomerulosclerosis; *IgAN,* IgA nephropathy; *MCD,* minimal change disease; *Mes,* mesangial immune complex glomerulonephritis; *MGN,* membranous nephropathy; *Pauci,* ANCA-positive pauci-immune glomerulonephritis; *SLE,* systemic lupus erythematosus. *(From reference 68.)*

In the diabetic patient with nephropathy, it has been shown that a nighttime increase in BP is independently associated with a 20-fold higher mortality and a higher risk of renal failure. Occasional measurements of ambulatory BP are particularly useful to assess the efficacy of antihypertensive treatment.

- In diabetic patients with sclerosis or calcification of the radial and brachial arteries, pseudohypertension, or "white-coat hypertension," may occasionally occur, that is, spuriously reduced BP values despite normotension established by intra-arterial BP measurements. This condition should be suspected if a discrepancy is found between modest target organ damage (e.g., left ventricular hypertrophy) and very high measured BP values. Such patients tend to develop marked hypotension even with relatively modest antihypertensive therapy.

Measurement of Serum Creatinine and Estimation of Glomerular Filtration Rate

In clinical practice, the serum creatinine concentration is most frequently used to assess renal function, but it may be grossly misleading in wasted patients when muscle mass is low. This problem is particularly frequent in elderly female patients with type 2 diabetes. Therefore, the Kidney Disease Outcome Quality Initiative (KDOQI) guidelines recommend that the GFR be estimated according to the Modification of Diet in Renal Disease (MDRD) study equation (see Chapter 3).

Differential Diagnosis

Although hematuria has been considered one of the atypical features indicating the presence of nondiabetic renal disease in patients with diabetes, the clinical significance of hematuria in the overall course of DN suggests that hematuria could be a sign of DN. Moreover, a study identified hematuric patients with pathologically defined DN, who had significantly lower renal function than nonhematuric patients with DN.[67] The prevalence of nephrotic syndrome and retinopathy was significantly higher in hematuric patients than in nonhematuric patients with diabetic glomerulosclerosis.

On the other hand, non-DN disease may be found in type 2 diabetic patients. Younger patients with diabetes, shorter duration of diabetes, and proteinuria in the absence of retinopathy strongly suggest nondiabetic renal disease.[68] Membranous nephropathy, FSGS, acute interstitial nephritis, postinfectious GN, and IgA nephropathy have all been described in type 2 diabetic patients in whom DN was clinically suspected (Fig. 30-21).

Indications for Renal Biopsy

Further investigation, including renal biopsy, should be considered in the following patient situations (Fig. 30-22):

- If retinopathy is not present in type 1 diabetes with proteinuria or moderately impaired renal function (absence of retinopathy does not exclude DN in type 2 diabetes).
- If the onset of proteinuria has been sudden and rapid, particularly in type 1 diabetes, and if the duration of type 1 diabetes has been less than 5 years. Alternatively, if the evolution has been atypical, for example, without transition through the usual stages, particularly the development of nephrotic syndrome without previous microalbuminuria.
- If macroscopic hematuria is present or active nephritic urinary sediment is found that suggests GN, such as acanthocytes and red blood cell casts; the sediment in DN typically is unremarkable apart from some occasional erythrocytes.
- If the decline in renal function is exceptionally rapid, or if renal dysfunction is found without significant proteinuria (first, renovascular disease must be excluded) (Fig. 30-23).

If renal ultrasound reveals small kidneys or a size difference, it is prudent not to perform a renal biopsy. Overall, renal biopsy is indicated only in a small minority of diabetic patients.

Approach to the Diabetic Patient with Impaired Renal Function

When seeing a diabetic patient with CKD, the nephrologist should do the following:

- Assess the cause of CKD (acute vs. chronic renal impairment; DN vs. alternative causes of renal damage).
- Assess the magnitude of proteinuria and the rate of progression.
- Search for evidence of the typical extrarenal microvascular and macrovascular complications of diabetes.

The majority of diabetic patients with heavy proteinuria or renal failure have DN. Renal ischemia (atherosclerotic renal artery stenosis

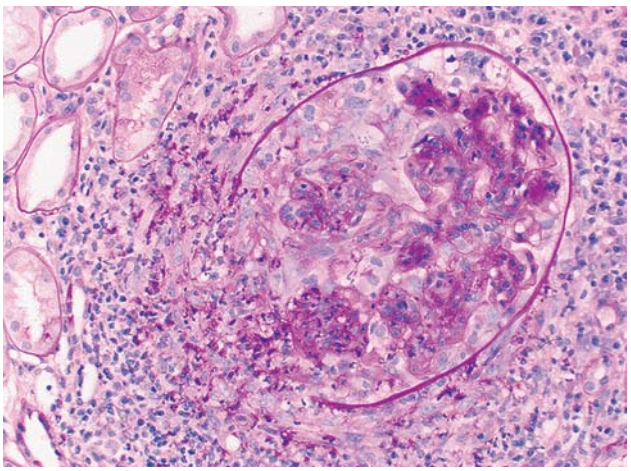

Figure 30-23 Glomerulonephritis superimposed on diabetic nephropathy (DN). A glomerulus showing a cellular crescent with rupture of Bowman capsule superimposed on nodular DN. The patient, known to have DN, presented with rapidly deteriorating renal function and red cell casts in the urine.

or cholesterol embolism) is common in diabetic patients, and a substantial proportion of type 2 diabetic patients have small kidneys and low GFR without albuminuria, possibly the result of macrovascular disease.

If urinary tract infection occurs, it is more severe in the diabetic than the nondiabetic patient. Purulent papillary necrosis and intrarenal abscess formation, however, have now become rare.

Diabetic patients with nephropathy are particularly prone to development of AKI after administration of nonsteroidal anti-inflammatory drugs (NSAIDs) or radiocontrast media, or after CV events or septicemia. Preventive measures for AKI are discussed in Chapter 73. AKI superimposed on preexisting DN carries a very poor renal prognosis.

CHAPTER 31

Prevention and Treatment of Diabetic Nephropathy

Li-Li Tong and Sharon Adler

In diabetic patients, the development of diabetic nephropathy (DN) signifies the presence of a generalized microvascular syndrome that is frequently accompanied by macrovascular disease (see Chapter 30). Classically, DN evolves through several clinical stages based on urine albumin excretion (UAE) values: normoalbuminuria, microalbuminuria, and macroalbuminuria, or overt nephropathy. Regression of microalbuminuria to normoalbuminuria occurs spontaneously in a substantial proportion of patients with type 1 and type 2 diabetes. Without treatment, however, patients with persistent microalbuminuria are at high risk of progressing to overt nephropathy.

There is consensus that the level of UAE has predictive importance for both renal outcome and cardiovascular (CV) morbidity and mortality and affects the choice of therapeutic intervention. In patients with established DN, regression to normoalbuminuria and preservation of renal function, although difficult, is the ideal treatment goal. Strict blood pressure (BP) and glycemic control early in the disease course is vital. Aggressive lipid-lowering and lifestyle modifications, including adherence to low-protein and low-sodium diet, exercise, weight loss, and smoking cessation all are beneficial and likely to improve renal and CV outcome. Most patients with advanced-stage diabetic kidney disease, however, are likely to progress relentlessly to end-stage renal disease (ESRD), even though treatment may slow this progression.

This chapter reviews the current preventive and therapeutic strategies that promote renoprotection and cardioprotection in diabetic patients (Fig. 31-1). In general, the treatment principles for established DN are similar to those adopted for the prevention of DN, although multiple and more intensive strategies may be required for treatment. Special considerations are indicated in the management of the diabetic patient with advanced chronic kidney disease (CKD) (see Chapter 32). Many therapeutic issues discussed here are not specific for DN and thus are also relevant for CKD in general (see Chapter 80).

PREVENTION OF DIABETIC NEPHROPATHY

Prevention and early detection of DN improve patient outcome. General measures for prevention of DN include glycemic control and rigorous BP control. Because diabetes is associated with increased risk for CV morbidity and mortality, treatment of dyslipidemia as well as diet and lifestyle modifications, including physical activity and weight reduction as appropriate and smoking cessation, can significantly lower the CV risks.

Glycemic Control

In type 1 diabetic patients, strict glycemic control decreases the risk for microalbuminuria and impaired glomerular filtration rate (GFR). The Diabetes Control and Complications Trial (DCCT) compared the effects of intensive glucose control with conventional treatment on the development and progression of the long-term complications of type 1 diabetes (Fig. 31-2). During a 9-year period, patients receiving intensive therapy (mean hemoglobin A_{1c} 7%) had a 35% to 45% lower risk for development of microalbuminuria compared with the control group (mean HbA_{1c} 9%).[1] More recently, DCCT and Epidemiology of Diabetes Interventions and Complications (EDIC) trial data indicated that the long-term risk of an impaired GFR was lower by 50% in patients treated for an average of 6½ years with DCCT intensive glucose control than among those treated with conventional therapy. This effect was not evident until more than 10 years after randomization, beyond the period of the DCCT treatment intervention.[2] Moreover, the restoration of euglycemia with pancreas transplantation prevents recurrent DN in renal allograft of type 1 diabetic patients.[3]

For type 2 diabetic patients, several major studies have demonstrated a lower risk of nephropathy with stricter glycemic control. In a study design similar to the DCCT, the Kumamoto study found a 60% reduction in microalbuminuria in relatively young, nonobese type 2 diabetic patients receiving intensive glycemic treatment (HbA_{1c} 7.1%) compared with conventional treatment (HbA_{1c} 9.4%).[4] In the United Kingdom Prospective Diabetes Study (UKPDS) trial, newly diagnosed patients with type 2 diabetes were randomly assigned to intensive management (HbA_{1c} 7.0%) with a sulfonylurea or insulin or to conventional management (HbA_{1c} 7.9%) with diet alone. After 9 years of intensive therapy, relative risk reduction for the development of microalbuminuria was 24%.[5] After termination of the study, patients were observed for a further 10 years. The differences in HbA_{1c} were lost within 1 year, but a 24% lower risk of microvascular disease and myocardial infarction (−15%) persisted. All-cause mortality (−13%) was also reduced. This phenomenon of ongoing beneficial effects on diabetic complications after a period of improved glycemic control even if followed by a return to less intensive metabolic control has been described as representing "metabolic memory" by the DCCT/EDIC investigators and as a "legacy effect" by the UKPDS investigators. This observation underlines the importance of early glycemic control before complications develop.

Three recent major trials testing whether glycemic control reduced cardiovascular disease (CVD) risk in type 2 diabetic patients have refined our approach to establishing glycemic goals. The Action in Diabetes and Vascular Disease, Perindopril and Indapamide Controlled Evaluation (ADVANCE) study showed that intensive blood glucose control (HbA_{1c} 6.5% vs. 7.3%) yielded a 10% relative reduction in the combined outcome of major macrovascular and microvascular events, primarily because of a 21% relative reduction in nephropathy.[6] However, in the Action to Control Cardiovascular Risk in Diabetes (ACCORD) trial, very tight glycemic control (lowering of HbA_{1c} to median of 6.4% vs. 7.5% with conventional control)

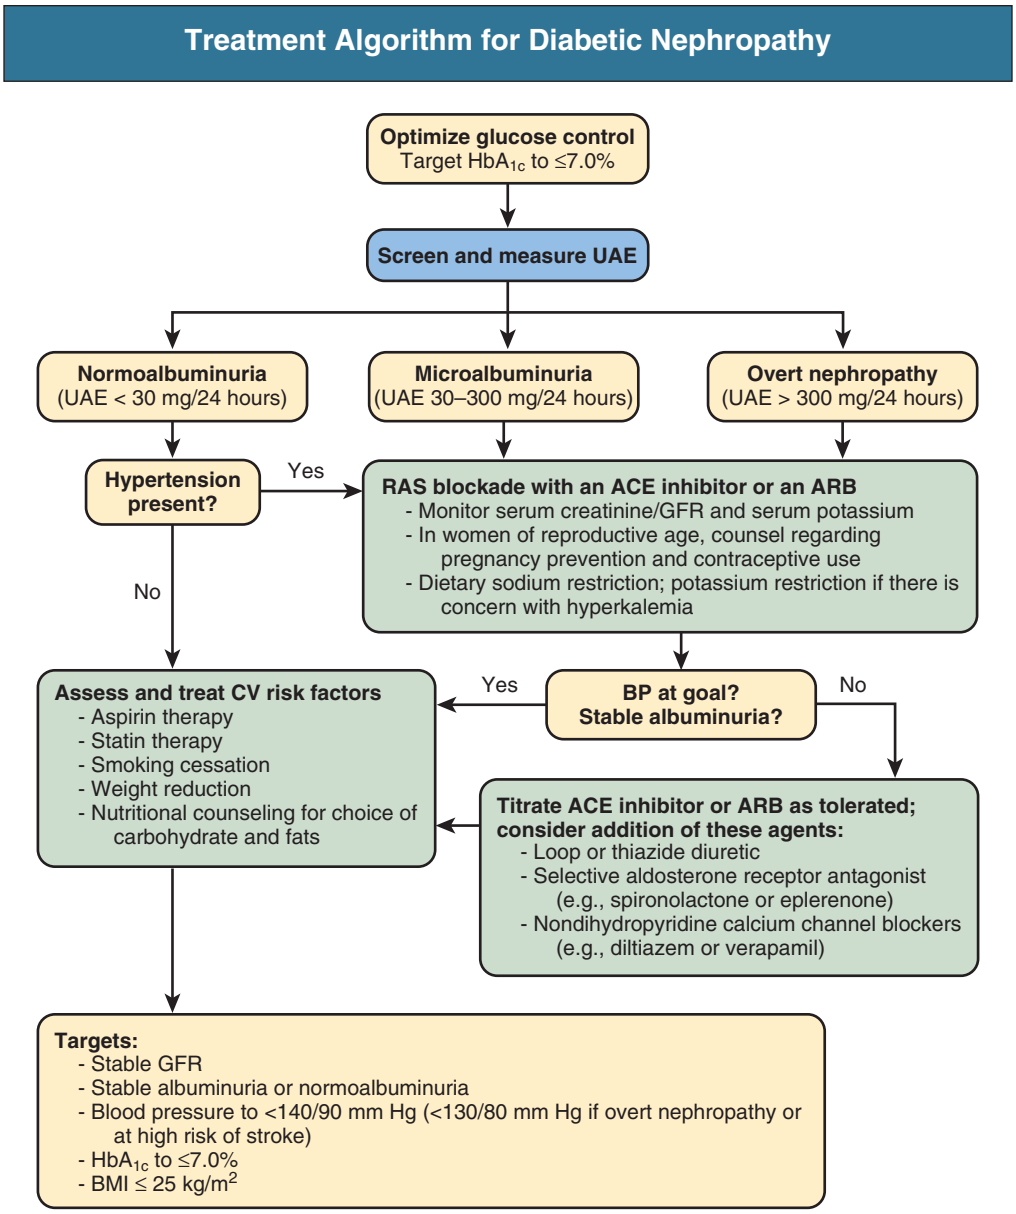

Figure 31-1 Treatment algorithm for diabetic nephropathy. In considering the management of patients with diabetes and chronic kidney disease (CKD), a global perspective is required, which includes therapy that retards progression of kidney disease as well as therapy that minimizes cardiovascular risk and addresses other major diabetic complications, including coronary artery disease, peripheral vascular disease, retinopathy, neuropathy, gastroparesis, and dyslipidemia. *Hb,* Hemoglobin; *UAE,* urine albumin excretion; *HTN,* hypertension; *RAS,* renin-angiotensin system; *ACE,* angiotensin-converting enzyme; *ARB,* angiotensin receptor blocker; *BP,* blood pressure; *GFR,* glomerular filtration rate; *CV,* cardiovascular; *LDL,* low-density lipoprotein; *CVD,* cardiovascular disease; *BMI,* body mass index.

was associated with 22% increase in mortality from any cause and did not significantly reduce major CV events.[7] A third major study of tight glucose control in type 2 diabetics, the Veterans Affairs Diabetes Trial (VADT), found no significant reduction in CV deaths or events during 7.5 years in high-risk patients treated aggressively for glycemic control (median HbA_{1c} 6.9%) compared with standard therapy (median HbA_{1c} 8.4%).[8]

It is apparent that glycemic control in type 2 diabetic patients must be individualized and take into account the patient's age, duration of diabetes, presence of CVD, presence of CKD, and microvascular risks and complications, as well as previous glycemic control and susceptibility to and awareness of hypoglycemia. In younger patients with recently diagnosed diabetes and no prior CVD events, strict glycemic control can reduce the risk of nephropathy and other microvascular complications. In patients with longstanding diabetes and known CVD, data do not support glycemic control to HbA_{1c} of less than 7% in reducing the risk of further CVD events or mortality. The National Kidney Foundation's Kidney Disease Outcomes Quality Initiative (KDOQI) guideline recommends lowering of HbA_{1c} levels to 7.0% for both type 1 and type 2 diabetic patients.[9] At even lower glycemic targets, any potential renoprotective effects of tight glucose control must be counterbalanced by the possibility of more frequent hypoglycemic episodes.

Blood Pressure Control

In patients with type 1 diabetes, microalbuminuria typically precedes hypertension. In patients with type 2 diabetes, however, as

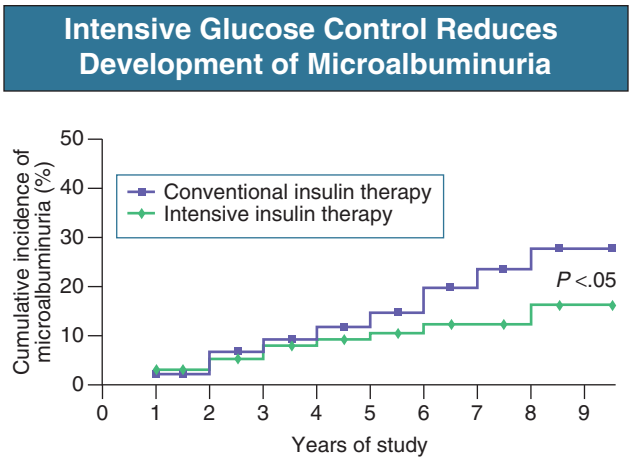

Figure 31-2 Microalbuminuria risk reduction with intensive versus conventional insulin therapy. Intensive glucose control was associated with a decreased risk for the subsequent development of microalbuminuria in patients with type 1 diabetes. *(Modified from reference 1.)*

many as 40% are hypertensive before the diagnosis.[10] In both type 1 and type 2 diabetic patients, higher BP is associated with increasing albuminuria and with more rapid progression and increased risk of kidney failure.[11] Early treatment of hypertension is critical for prevention of DN, retinopathy, and CVD. Major guidelines published before the Action to Control Cardiovascular Risk in Diabetes Blood Pressure (ACCORD BP) trial have suggested that the target blood pressure in diabetic patients should be less than 130/80 mm Hg.[12] However, this BP target was challenged by findings of the ACCORD BP trial. Among diabetic patients with high CV risk randomized to goal systolic BP of less than 120 mm Hg or standard therapy aiming for under 140 mm Hg, there was no difference in the risks of composite major CV events.[13] A cross-sectional analysis of patients in the Swedish National Diabetes Registry also failed to show a reduction in mortality in patients with systolic BP below 130 vs. 130 to 139 mm Hg.[14] The recent Kidney Disease: Improving Global Outcomes (KDIGO) guideline for diabetic patients with CKD recommends a target BP of 140/90 mm Hg or less for all diabetic patients, and 130/80 mm Hg or less for patients with urine albumin excretion of greater than 30 mg per 24 hours.[15] For diabetic patients at highest risk for cerebrovascular accident (CVA, stroke), even lower systolic BP goals may provide greater protection against stroke, but the potential risks and burdens of serious adverse events attributable to antihypertensive therapy must be considered with such treatment goals.

Renin-Angiotensin System Blockade in Prevention

The role of blockade of the renin-angiotensin system (RAS) in normotensive, normoalbuminuric diabetic patients for the primary prevention of DN is unproved and cannot be recommended at this time. Most patients with diabetes do not develop DN, even after long periods of uncontrolled hyperglycemia, and there are hazards with the use of RAS-blocking drugs, including their potential teratogenicity in pregnancy. In a *post hoc* analysis of three randomized controlled trials (RCTs) conducted as part of the multicenter Diabetic Retinopathy Candesartan Trials (DIRECT) program, which included normotensive and normoalbuminuric type 1 diabetics and normoalbuminuric type 2 diabetics with or without hypertension, the ARB candesartan was found to have no effect on the development of microalbuminuria.[16] A recent study investigating whether olmesartan would prevent microalbuminuria in type 2 diabetic patients showed that the incidence of microalbuminuria was slightly reduced from 9.8% to 8.2% in the olmesartan arm, but this difference disappeared after adjusting for the lower BP in that arm. Of potential concern, was a higher rate of fatal CV events with this ARB among patients known to have preexisting coronary heart disease, especially those with lower BP.[17]

In hypertensive diabetic patients, an angiotensin-converting enzyme (ACE) inhibitor or an angiotensin receptor blocker (ARB) is effective as a first-line antihypertensive agent. The Bergamo Nephrologic Diabetes Complications Trial (BENEDICT), which randomized hypertensive normoalbuminuric type 2 diabetic patients to placebo, verapamil, trandolapril, or a combination of verapamil plus trandolapril, showed less progression to microalbuminuria in patients receiving trandolapril either alone or with verapamil.[18] Verapamil alone was no different from placebo. There were similar findings in smaller studies with other RAS inhibitors, implicating a class effect.[19] Longer-term studies would be required to demonstrate the effects of RAS blockade on the clinically important outcomes of death, dialysis, and doubling of serum creatinine level in normoalbuminuric patients. Therapy for the prevention of DN likely will be guided exclusively by studies using albuminuria as a surrogate.

Treatment of Dyslipidemia

Few clinical data are available on the effects of lipid lowering alone in preventing DN. In the Diabetes Atherosclerosis Intervention Study (DAIS), type 2 diabetic patients taking fenofibrate had a significantly lower rate of progression from normoalbuminuria to microalbuminuria at 3 years compared with the placebo group.[20] Earlier clinical practice guidelines had emphasized specific treatment targets for low-density lipoprotein (LDL) cholesterol of below 100 mg/dl (2.6 mmol/l) for diabetic patients in general and below 70 mg/dl (1.8 mmol/l) for diabetic patients with CVD. These targets, however, have not been proven beneficial in any clinical trial. Newer guidelines from the American College of Cardiology and the American Heart Association are shifting away from specific LDL cholesterol treatment targets.[21] Emphasis is now placed on assessing a patient's global risk for CVD and using maximum tolerated statin intensity for primary and secondary prevention of CVD.

Nonpharmacologic Interventions

For all diabetic patients, emphasis should be placed on lifestyle modification to lower the risk of diabetic kidney disease and CV events, including dietary restriction of salt and saturated fat, weight reduction and exercise as appropriate, and smoking cessation. Smoking in particular is an independent risk factor for the development of nephropathy in type 2 diabetes and is associated with an accelerated loss of renal function.[22]

TREATMENT OF DIABETIC PATIENTS WITH MICROALBUMINURIA OR OVERT NEPHROPATHY

For diabetic patients with incipient or established DN, the optimal therapeutic approach to reduce the rate of progression of nephropathy and to minimize the risk for CV events involves aggressive management of hypertension with emphasis on a RAS blocker, combined with management of dyslipidemia, hyperglycemia, and albuminuria, as well as diet modification, exercise, and smoking cessation. Such multifactorial therapy in the Steno type 2 trial in type 2 diabetics

included management of hyperglycemia and of hypertension, ACE inhibition, statins, aspirin, reduction of fat intake, light to moderate exercise, and cessation of smoking.[23,24] Impressive lowering of the risk of CVD, nephropathy, retinopathy, and autonomic polyneuropathy was noted after 7.7 years, and even a delayed reduction of mortality was seen.

In general, patients with DN require multiple antihypertensive agents (including RAS-blocking agents) to achieve BP goal, intensive insulin therapy in type 1 diabetes, two or more drugs for glucose control in type 2 diabetes, at least one lipid-lowering agent, and an aspirin or other antiplatelet agent for CV protection. One obstacle to achieving adherence is the number of medicines and the complexity of these regimens. Therefore, treatment of patients with DN needs to be individualized and requires considerations of the cost, side effects, and convenience of the drug regimen. Regular monitoring of UAE and serum creatinine concentration to assess response to therapy and progression of disease is required.

Antihypertensive Treatment

In type 1 and type 2 diabetic patients with overt nephropathy, hypertension is an almost universal finding and is associated with volume expansion and salt sensitivity. The absence of hypertension in an untreated patient with overt nephropathy should raise suspicion for underlying cardiac problems. Uncontrolled hypertension is associated with more rapid progression of DN[25] and increased risk of fatal and nonfatal CV events.[26] Thus, effective treatment of systemic hypertension is arguably the single most important strategy in the treatment of established DN (Fig. 31-3). Some have suggested that the overall effect of BP lowering may be more important than the type of antihypertensive used.[27] Antihypertensive therapies, regardless of agent used, reduce UAE, delay progression of nephropathy, postpone renal impairment, and improve survival in both type 1 and type 2 diabetic patients with DN.[28]

The optimal lower limit for BP control in DN though remains unclear. In a secondary analysis of the Irbesartan Diabetic Nephropathy Trial (IDNT), progressive lowering of systolic BP to 120 mm Hg was associated with improved renal and patient survival, an effect independent of baseline renal function.[29] However, mortality increased with systolic BP below 120 mm Hg, although a cause-and-effect relationship cannot be inferred from the data. From a safety perspective, diastolic pressure is also important. Low diastolic BP is poorly tolerated, and the incidence of myocardial infarction and mortality increases at values below 70 mm Hg, at least in patients with coronary heart disease, presumably because coronary perfusion occurs only during diastole. Indeed, in the IDNT study, CV mortality increased not only with higher systolic pressure but also with low diastolic pressure. The recent ACCORD BP trial failed to show reduced CV events, but found increased rates of hyperkalemia and renal dysfunction, when targeting a systolic BP less than 120 mm Hg compared with less than 140 mm Hg.[13] Thus, given the lack of strong evidence of benefit from reducing systolic BP to below 130 versus below 140 mm Hg, it is reasonable to strive for a BP target of 140/90 mm Hg or less for all diabetic patients. These recommendations are consistent with the KDIGO guideline and the Eighth Joint National Committee (JNC VIII) on BP management in diabetic patients.[15]

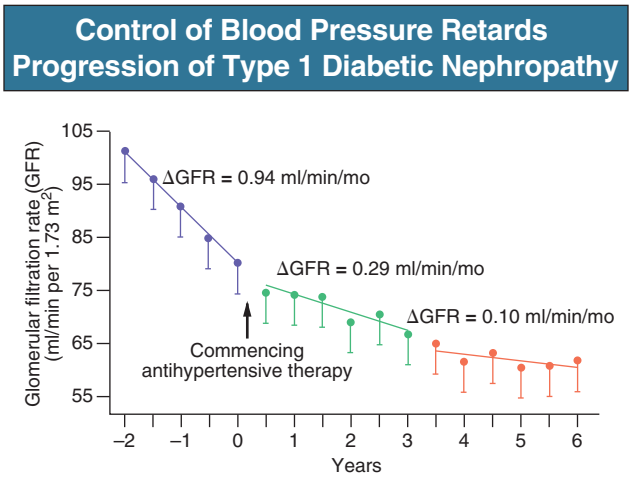

Figure 31-3 Control of blood pressure reduces the risk for progression in type 1 diabetic nephropathy. *(Modified from reference 25.)*

Renin-Angiotensin System Blockade in Treatment

In diabetic patients with established DN, RAS blockade with ACE inhibitors or ARBs confers preferential renoprotection that is independent of BP reduction. Intraglomerular hemodynamic and nonhemodynamic renal effects of angiotensin II (Ang II) best explain the observed renoprotection. Supporting this hypothesis, evidence-based *in vitro* models of DN show cellular effects of RAS inhibition that are consistent with benefit independent of BP effects (see Chapter 30).

Although many demonstrated a beneficial effect of ACE inhibitors and ARBs in retarding progressive renal disease, these studies did not differentiate between the relative contributions of the RAS blockade versus aldosterone system blockade. The renin-angiotensin-aldosterone system (RAAS) represents a hormonal cascade that functions in the homeostatic control of arterial pressure, tissue perfusion, and extracellular fluid homeostasis (see Chapter 7). In fact, plasma aldosterone levels are elevated in a subset of patients despite ACE inhibitor and ARB therapy (also known as aldosterone breakthrough; see Chapter 82). In studies that defined aldosterone breakthrough as any increase from an individual's baseline serum aldosterone level (i.e., before ACE inhibitor or ARB therapy), the incidence ranged from 40% during 10 months to 53% during 12 months.[30] In addition to its classic effects of promoting sodium retention and enhancing potassium and magnesium excretion, aldosterone promotes tissue inflammation and fibrosis.[31] Small studies have demonstrated considerably faster decline in glomerular filtration rate (GFR) in patients who experienced aldosterone breakthrough (median 5.0 ml/min/yr) than in those who did not (median 2.4 ml/min/yr). Aldosterone blockade, independent of RAS blockade, reduces proteinuria and retards progression of nephropathy. Current evidence is not strong enough to support widespread screening for aldosterone breakthrough. However, in select patients, additional aldosterone blockade with close monitoring of serum potassium levels may represent optimal therapy for patients who show aldosterone breakthrough during treatment with an ACE inhibitor or an ARB and who no longer show maximal antiproteinuric effects with these agents.

Type 1 Diabetic Patients

In type 1 diabetic patients with microalbuminuria, ACE inhibitors reduce the risk of progression to overt nephropathy.[32,33] In a meta-analysis of 12 placebo-controlled trials in 698 normotensive patients with type 1 diabetes and microalbuminuria treated with ACE inhibitors, the majority for more than 2 years, treatment was associated with a 60% reduction in progression to macroalbuminuria and a threefold increase in regression to normoalbuminuria.[34] Changes

in BP cannot entirely explain the antiproteinuric effect of ACE inhibitors.

In patients with macroalbuminuria or overt nephropathy, the Collaborative Study Group trial demonstrated that captopril reduced albuminuria, slowed the decrement in GFR, and delayed the onset of kidney failure compared with placebo.[35] The beneficial effect of captopril was greater in patients with reduced GFR at baseline largely because the end point, a doubling of baseline serum creatinine level, was achieved more quickly in these patients.

There are insufficient data and no large long-term clinical trials to demonstrate the efficacy of ARBs in type 1 DN. Nevertheless, based on the shared properties of ACE inhibitors and ARBs in inhibiting the RAS, there is reason to believe that both are effective in the treatment of type 1 DN.

Type 2 Diabetic Patients

In patients with type 2 diabetes, more data are available on the renoprotective effect of ARBs compared with ACE inhibitors. In the stage of microalbuminuria, the IRMA 2 study showed that the ARB irbesartan reduces progression to overt nephropathy by 70% in hypertensive type 2 diabetic patients during a 2-year follow-up period.[36] In the MARVAL trial, the ARB valsartan (80 mg/day) produced a greater reduction in UAE than did amlodipine (44% vs. 8%) with the same degree of BP reduction, suggesting that the antiproteinuric effect of ARBs is blood pressure independent.[37]

In type 2 diabetic patients with macroalbuminuria and decreased GFR, large RCTs (IDNT and RENAAL) have demonstrated that ARBs are effective in lowering proteinuria and decrease the relative risk of reaching the composite end point of death, dialysis, and doubling of serum creatinine level.[38,39] However, the risk reduction for reaching the composite end point was only 18% to 20% in these studies in patients with type 2 diabetes and nephropathy, compared with the more robust risk reduction of about 50% in patients with type 1 diabetes receiving captopril. ARBs did not decrease CV death in these trials but did decrease the incidence of heart failure.

Compared with ARBs, data on the efficacy of ACE inhibitors in type 2 DN are less strong, largely because the studies were underpowered by small sample size or short follow-up. Nevertheless, some studies did show that ACE inhibitor use results in greater reduction in albuminuria and slower decrease in GFR compared with other antihypertensive agents. Whereas both ACE inhibitors and ARBs are probably effective for treatment of DN in patients with type 2 diabetes, few studies have directly compared their efficacy. In a small RCT of type 2 diabetes and early nephropathy with 5 years' follow-up, the ARB telmisartan was not inferior to the ACE inhibitor enalapril in providing long-term renoprotection.[40] Some pharmaceutical companies marketing both ACE inhibitors and ARBs have attempted to make the argument that particular characteristics of individual agents within these classes, such as differences in tissue levels or differential effects on the metabolic syndrome, confer some with special beneficial properties. However, no high-quality prospective RCT has proved such superiority for any particular agent for DN.

Combination Therapy with Renin-Angiotensin System Antagonists
